FIGURE 50-4 Landmarks for the location of the temporal branches and main trunk of the facial nerve: (1) the distance between the anterior margin concavity of the meatus to the zygomatic arch (3.5 ± 0.8 cm); (2) the distance between the inferior margin of the meatus to the trunk (2.3 ± 0.28 cm); (3) the distance between the postglenoid tubercle to the main trunk (3.0 ± 0.31 cm); (4) the distance from the tragus to the facial nerve trunk is variable.

into a preauricular crease immediately anterior to the auricle. The exact length and decision to incorporate an anterior temporal extension are governed largely by the nature of the surgical procedure. For some surgeons, the approach for diskectomy requires a smaller incision than that for diskoplasty.

The incision is approximately 3 to 4 cm in length and consists of two limbs: a small superior curved limb (1–2 cm) and an inferior vertical limb anterior to the tragus (variable distance approximately 1–2 cm) (Figure 50-5). The junction of these limbs is the site of attachment of the superior aspect of the helix to the temporal tissue. The extent of the superior limb of the preauricular incision is dictated by the amount of access required, which may not be determined until the dissection has reached the lateral TMJ ligament and capsule. The incision is usually not extended as inferiorly as the lobule of the ear.

The incision should be placed posteriorly to the superficial temporal vessels

and auriculotemporal nerve and within a preauricular crease. The skin and subcutaneous tissues are incised the length of the entire incision. The deeper dissection is begun in the temporal region by sharply dissecting progressively through the auricularis anterior and superficial

FIGURE 50-5 Preauricular incision.

fascial layers to the stark white temporalis fascia (Figure 50-6). A retractor is placed on the anterior flap, and tension is applied in a forward direction. The dissection over the zygomatic arch is addressed. The anatomic layers in this region are usually not clearly defined. There is a condensation of tissues consisting variably of the auricularis interior, superficial fascia, temporalis fascia, periosteum, and occasionally cartilage. This tissue is incised to the level of fibrous connective tissue. A retractor is placed in the incision opposite the tragus, and forward traction is applied to the flap. This results in the definition of a cleft between the perichondrium and cartilage of the external auditory canal and the parotidomasseteric fascia. The perichondrium is followed medially with sharp dissection (Figure 50-7). Care should be exercised not to proceed perpendicularly to the skin surface, as the external auditory canal inclines anteromedially at approximately 45° to the surface. The dissection is continued along the outer surface of the external auditory

FIGURE 50-6 The preauricular incision has been carried sharply through the skin, subcutaneous tissue, superficial temporal fascia, auricularis anterior and superior, and outer layers of the temporal fascia. The flap is reflected anteroinferiorly, revealing the inner layer of the temporal fascia.

canal until the lateral TMJ ligament is reached.

When the condyle and its overlying temporomandibular ligament are palpated, the flap is reflected inferiorly and anteriorly forward with a combination of sharp

FIGURE 50-8 Retraction is accomplished by using a self-retaining retractor positioned between the external auditory canal and flap and a right-angle retractor at the inferior portion of the flap. The condyle (dotted line) is noted under the lateral TMJ ligament and/or simply the lateral capsule depending on the depth of the reflection.

and blunt dissections. Scissors may be used to cut some fascial attachments to the lateral TMJ ligament. The blades of the scissors are held parallel to the ligament to ensure that the joint is not violated. The flap is reflected as far forward as the midportion of the anterior tubercle. The surgeon can now see the bulging of the lateral pole of the condyle under cover of the lateral ligament and capsule. Gentle manipulation of the jaw to cause movement of the condyle helps to orient the surgeon. The deep surface of the flap and the tissues overlying the zygomatic arch may be touched with a nerve stimulator to ascertain the location of the facial nerve. Retraction is accomplished using a self-retaining retractor (eg, cerebellar Weitlaner or a Dolwick-Reich) placed between the flap and the perichondrium. A small right-angled retractor may be placed at the inferior portion of the flap (Figure 50-8).

Endaural Approach

Rongetti described a modification of Lempert's endaural approach to the mastoid process for surgical improvement of otosclerosis, for approaching the TMJ.^{5,6} The endaural incisions employed today either incorporate the anterior wall of the external auditory canal, or the tragus, or simply the skin overlying the mental aspect of the tragus (Figure 50-9).

The incision begins well within the external auditory meatus at the superior mental wall. At this level the incision is made down to the bone and extended in a curvilinear fashion upward hugging the anterior helix (see Figure 50-9). It becomes less penetrating as it approaches the superior surface, ending at about the level of the inferior tragus. The incision is deepened to the level of the temporalis fascia. The incision is now continued inferiorly, with the knife in continuous contact with the tympanic plate, to make a semi-circular incision to the inferior point of the meatus. The incision is then continued

FIGURE 50-9 A–C, Endaural approach according to J. R. Rongetti. Adapted from Rongetti JR.⁵

anteroinferiorly to fall into the incisura intertragica, ending just before it approaches the surface. The application of forward traction on the inner aspect of the tragus assists the surgeon in completing the incision. Sharp dissection is carried deeply for some distance along the perichondrium. The flap is then reflected en masse anteroinferiorly off the lateral capsule and ligament.

The advantages of this incision lie in its excellent access to the lateral and posterior aspects of the joint, good exposure of the anterior aspect, and its esthetic value. The access afforded through this approach is equal to that obtained through the preauricular approach. Disadvantages lie in the potential for perichondritis and an esthetic compromise if tragal projection is lost.

Postauricular Approach

In the postauricular approach the incision is made posterior to the ear and involves the sectioning of the external auditory meatus.⁷ Excellent posterolateral exposure is afforded with this technique. The flap, once reflected, contains the entire auricle and superficial lobe of the parotid gland. A perimeatal approach combining the preauricular and postauricular incisions has also been described.^{8,9}

The incision in the postauricular approach begins near the superior aspect of the external pinna and is extended to the tip of the mastoid process. The superior portion may be extended obliquely into the hairline for additional exposure. The incision is made 3 to 5 mm parallel and posterior to the postauricular flexure (Figure 50-10). The dissection is performed through the posterior auricular muscle to the level of the mastoid fascia, which is contiguous with the temporalis fascia. A combination of blunt and sharp dissections is used to isolate the cartilaginous portion of the external auditory canal. A blunt instrument is placed in the external auditory canal to assist in the

FIGURE 50-10 *Postauricular approach.* The incision is placed 3 to 5 mm parallel and posterior to the postauricular flexure.

transection of the external auditory canal. The transection may be partial or complete, depending on the need for exposure. The incision should leave 3 to 4 mm of cartilage on the medial aspect to permit adequate reapproximation of the canal (Figure 50-11). This technique helps to prevent meatal stenosis. The incision is carried through the outer layer of the temporalis fascia, continuing inferiorly, reflecting the parotidomasseteric fascia off the zygomatic arch and lateral TMJ ligament (Figure 50-12). A self-retaining retractor is used to maintain exposure. The advantages of the postauricular approach lie in the predictability of the anatomic exposure. Dissection to the joint is rapid with minimal bleeding. The approach offers an alternative for a patient who has had previous procedures in this region. This approach may not be desirable in the patient susceptible to keloid formation, owing to the potential for a keloid to develop in the meatus. Meatal atresia has been reported with this technique.¹⁰ The risk of facial nerve injury is not eliminated. Paresthesia in the area of the posterior aspect of the auricle usually occurs and lasts 3 to 4 months.

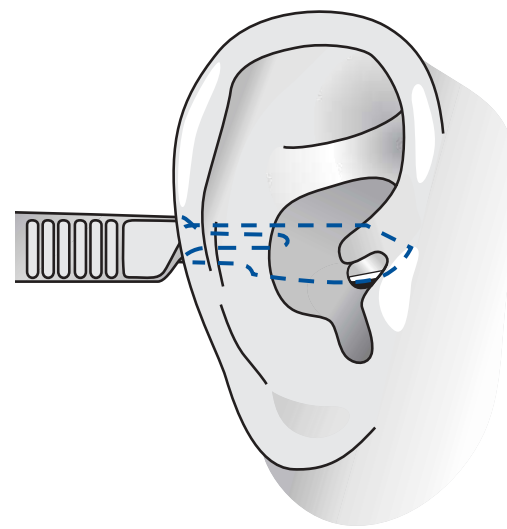

FIGURE 50-11 *The external auditory canal is sectioned, leaving 3 to 4 mm of cartilage on the medial aspect to assist reapproximation of the canal.*

Capsular Incisions

Horizontal Incision Over the Lateral Rim of the Glenoid Fossa The lateral ligament, capsule, and periosteum are reflected inferiorly en masse. Diskal or posterior attachment connections, or both, to the lateral capsule are dissected sharply with scissors to the level of the condylar neck (Figure 50-13A). Posterior dissection is performed diligently to avoid severing the retrodiskal tissue. This portion of the dissection exposes the superior joint space (Figure 50-13B). A Freer septum elevator

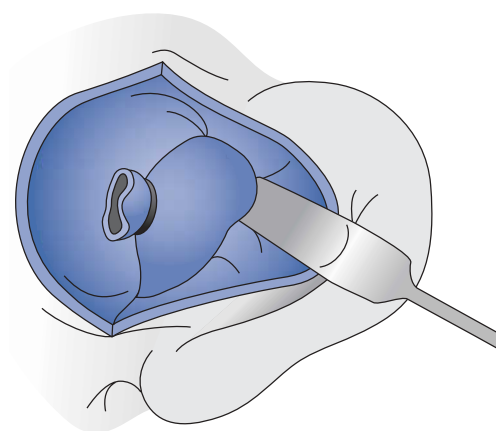

FIGURE 50-12 *The external auditory canal has been sectioned and the flap retracted forward.*

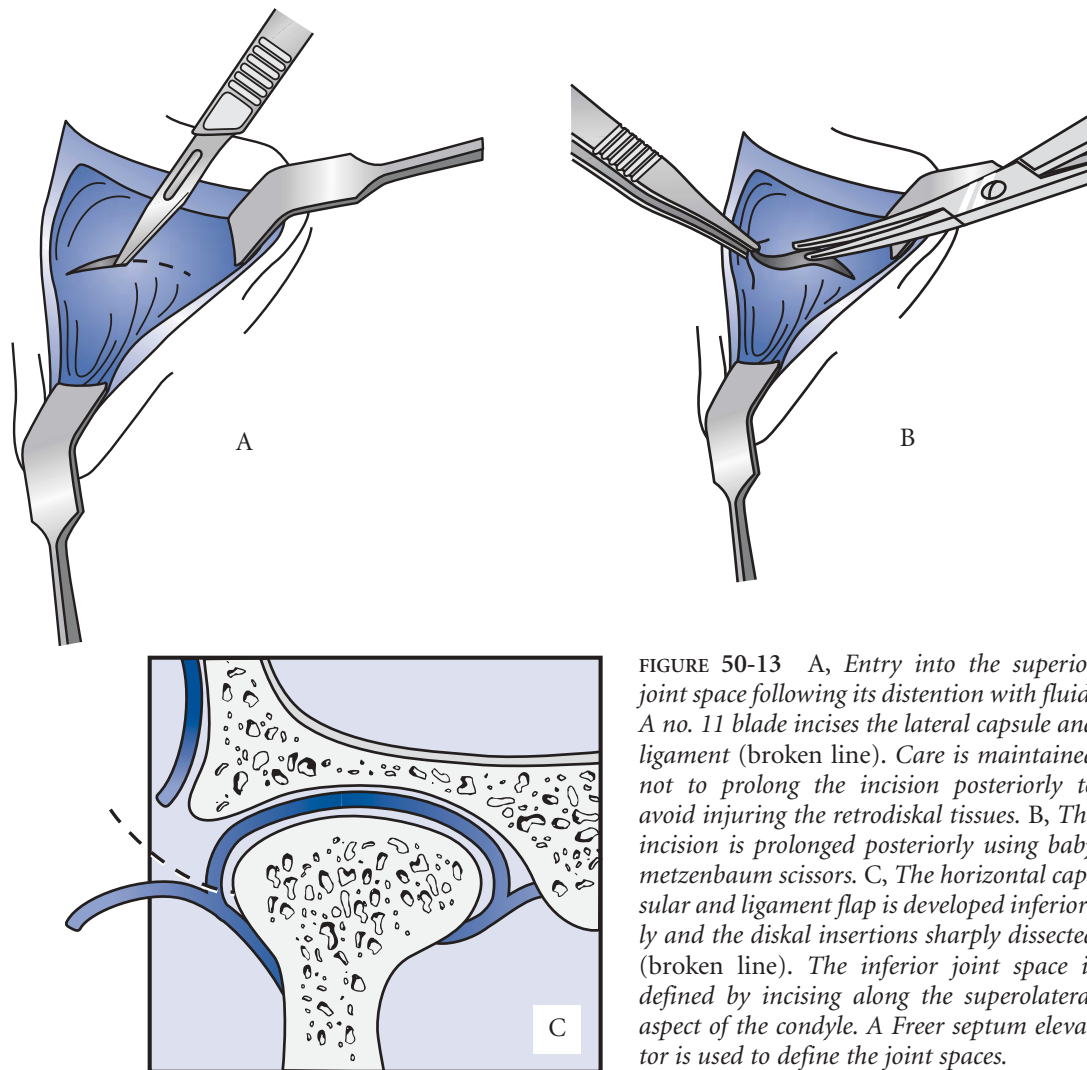

FIGURE 50-13 A, Entry into the superior joint space following its distention with fluid. A no. 11 blade incises the lateral capsule and ligament (broken line). Care is maintained not to prolong the incision posteriorly to avoid injuring the retrodiskal tissues. B, The incision is prolonged posteriorly using baby metzenbaum scissors. C, The horizontal capsular and ligament flap is developed inferiorly and the diskal insertions sharply dissected (broken line). The inferior joint space is defined by incising along the superolateral aspect of the condyle. A Freer septum elevator is used to define the joint spaces.

may be used to define and explore the space. The posterior attachment and disk attachments are then severed sharply at the lateral pole of the condyle from within the developed flap. The Freer septum elevator is used to reflect the posterior attachment and disk superiorly off the head of the condyle to expose the inferior joint space. A periosteal elevator may be used to stretch the capsule and lateral ligament flap outward to form a pocket (Figure 50-13C).

There is a risk of reflecting the fibrous connective tissue that lines the glenoid fossa when this approach is used (Figure 50-14A). The surgeon may form the incorrect assumption that he or she is stripping adhesions from the temporal bone while defining the space. The result may be a

partial or total synovectomy of the superior joint space. Prearthrotomy arthroscopic examinations have alerted clinicians to this error. The ability of the pathologic joint to regenerate this synovium and fibrous connective tissue layer has not been determined.

Horizontal Incision Below the Lateral Rim of the Glenoid Fossa A no. 11 blade may be used to puncture into the superior joint space at the level of the lateral diskocapsular sulcus (Figure 50-14B). The opening is then lengthened anteriorly and posteriorly using sharp-pointed scissors. A dissection technique, similar to that described in the foregoing approach, is used to define the superior joint space. A

dissection is then carried inferiorly removing the attachment of the capsule to the disk and exposing the inferior joint space. There is less risk of injury to the retrodiskal tissue with this approach; the risk to the fibrocartilage is also reduced. This is the approach I favor.

Horizontal Incisions Above and Below the Disk The horizontal approach above and below the disk (Figure 50-14C) leaves some of the capsule and ligament attached to the disk or remodeled retrodiskal tissue.

L-Shaped Incision A horizontal incision is made at or below the lateral rim of the glenoid fossa. The horizontal incision is then joined by either an anterior (Figure 50-14D) or posterior (Figure 50-14E) vertical extension. The posterior vertical incision carries the risk of severing the retrodiskal tissue. The anterior vertical incision should not be placed farther anteriorly than the tubercle to avoid injury to the facial nerve. The capsule and ligament are then reflected either anteroinferiorly or posteroinferiorly.

T-Shaped Incision A horizontal incision is joined by a vertical incision to create a T-shaped incision over the midportion of the glenoid fossa (Figure 50-14F).

Cross-Hair Incision Dissection of the posterior attachment of the lateral ligament and capsule may be tedious with the cross-hair incision (Figure 50-14G).

Open-Sky Incision In the open-sky incision two horizontal incisions are joined by a central vertical incision (Figure 50-14H).

Vertical Incision After a vertical incision is made, the capsular flaps are reflected anteriorly and posteriorly to expose the posterior attachment and disk (Figure 50-14I). Closure of the capsule is often difficult to attain following open surgical procedures. When diagnostic arthroscopy precedes the

FIGURE 50-14 Capsular incision designs: A, horizontal incision over the lateral rim of the glenoid fossa; B, horizontal incision below the lateral rim of the glenoid fossa; C, horizontal incisions above and below the disk; D and E, L-shaped incision; F, T-shaped incision; G, cross-hair incision; H, open-sky incision; I, vertical incision. The lateral pole of the condyle and lateral aspect of the remodeled posterior attachment (broken lines) are illustrated.

arthrotomy, the inflow and outflow ports violate the capsule, making watertight closure extremely difficult. Support for the lateral ligament can be obtained by raising a temporalis muscle and fascia flap, about 2 cm in length, pedicled inferiorly, and rotated inferiorly over the lateral rim of the glenoid fossa and sutured to the lateral capsular tissue. The pedicle stabilizes the flap but has not been shown to contain nutrient vessels. Closure of the capsule may not be critical to the success of the

discectomy procedure, and in some cases the closure may restrict mandibular motion.^{11,12} However, closure of the capsule and ligament after disk repositioning lends stability to the diskorrhaphy.

Operative Procedures

A concerted comparative evaluation of different surgical techniques is difficult because for many years there was no uniform set of criteria for selection of patients or compilation and evaluation of results.

Criteria and guidelines for disk surgery were initially developed in 1984 by the American Association of Oral and Maxillofacial Surgeons (AAOMS).¹³ The criteria were established through a literature review and consensus. In 1990 a standards and criteria document was published by the AAOMS.¹⁴ The document established indications for surgery, identified markers for favorable and unfavorable results, and outlined risk factors. These publications have laid the groundwork for peer review.

Disk-Repositioning Procedures

The goal of disk-repositioning procedures is to relocate the disk so that its posterior band can be returned to the normal condyle-disk-fossa relationship. Essentially, the repositioning places the posterior band over the superior or superoanterior surface of the condyle. This repositioning is accomplished by one of three procedures: plication in which the remodeled posterior attachment is folded on itself and the lateral tissues are approximated (Figure 50-15); full-thickness excision in which a wedge-shaped portion of the posterior attachment is removed and the lateroposterior tissues are approximated (Figure 50-16); or partial-thickness excision in which the superior lamina of the retrodiskal tissue and posterior attachment are removed, without violation of the inferior joint space, and the lateroposterior tissues are approximated (Figure 50-17).

When the disk displaces, the pathologic changes are not seen uniformly throughout the entire lateromedial extent of the joint. Typically, the medially displaced disk must be rotated posterolaterally to achieve a correct condyle-disk-fossa relation; therefore, a greater amount of tissue is pliated or excised laterally rather than medially. Rarely, the disk may be displaced in the lateral direction, in which event the reverse would be true.

The technical improvements in TMJ arthrography in the 1970s stimulated interest in correcting disturbances in the condyle-disk-fossa relations,¹⁵ and the

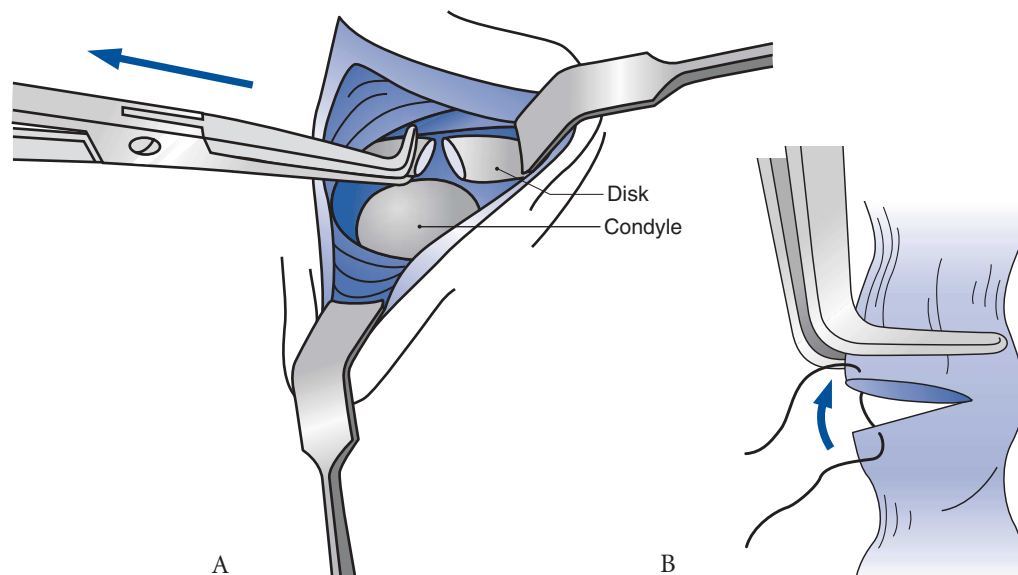

FIGURE 50-16 Disk repositioning achieved through a full-thickness excision of the posterior attachment. Retention of disk position is through sutures placed on posterior and lateral margins. A, A clamp has been placed over the posterior attachment. The arrow represents the direction of pull of the clamp to complete the incision and reveal the condylar surface. B, View from above demonstrating the wedge-shaped resection (arrow indicates the direction of closure).

concept that disk repair procedures were a viable answer to many cases of TMJ dysfunction was re-introduced.¹⁶ Reports on the outcome of disk repair procedures have indicated an 80% or greater success rate.¹⁷⁻¹⁹ The latter assumes an accurate diagnosis has been made. Surgeon diagnostic acumen has evolved with time. Although the results of the procedures may have been good in the 1980s, readers must be cautious as the indications for performing the procedure have changed and hence the outcomes may be misleading given the new subset of surgical candidates.

The histologic basis for performing surgery within vascular retrodiskal tissue was described in animals by Wallace and Laskin and by Zeitler and colleagues.^{20,21} Synoviocytes play an important role in the healing process. Stimulated by inflammation, synoviocytes proliferate and migrate to fill the surgically created gap in the tissues.²²⁻²⁴ The synoviocytes produce ground substance and collagen fibers and phagocytose the debris. The degree of tissue vascularity and the distance from capsular and synovial vasculature have also been described as important factors in the healing process.^{25,26}

Extrapolations to the clinical situation must be made from these results as an animal model for TMJ pathology is lacking. In the human, variable decreases in the vascularity of the remodeled posterior attachment are believed to occur with an increasing duration of displacement and load. The disk-repositioning techniques thus involve a repair in the pathologic remodeled retrodiskal tissue with a variable degree of vascularity. The primary source of nourishment to the repositioned

FIGURE 50-15 Disk repositioning achieved through plication of the posterior attachment. Retention of disk position is through sutures to the lateral capsule ligament. A, Preoperative location. B, Postoperative location.

disk appears to be through the synovium on the medial aspect of the disk and posterior recesses of the joint spaces. Thus, a critical aspect of the successful surgical repair in the retrodiskal tissue appears to be the rapid migration of synoviocytes to the area of the surgical repair. Smith and Walters followed up 12 patients for 1 year and reported success suturing tears in the avascular portion of the disk.²⁷ Others, however, have reported that suturing anything but vascularized tissue results in failure of the repair.^{20,28}

With an increasing displacement of the disk, the retrodiskal tissue comes into contact with the condyle and sustains increasing loading. The loading results in decreased vascularity of the retrodiskal tissue. With the reduction in retrodiskal tissue vascularity, this tissue becomes transformed into a pseudodisk. MRI of chronically displaced retrodiskal tissues demonstrates a signal intensity of the tis-

sue that resembles the disk. In fact, radiologists may inaccurately describe a disk fragmentation because only a portion of the displaced disk may display its original signal intensity. The remainder, owing to alterations in the glycoprotein distribution and hence the attraction of water, demonstrate a moderate signal intensity. With increasing displacement of the disk, the superior joint space does not accommodate for the increase in length of the retrodiskal tissue. Rather, the disk undergoes atrophy, deformation (buckling), and absorption into the anterior capsule. These changes can make anatomic repositioning of the disk impossible.

Disk repositioning without diskoplasty is indicated in the following instances:

- There is minimal disk displacement
- The disk is of near-normal length
- The disk structure is near normal (bow-tie)

The rationale behind repositioning is founded on the belief that the disease process is reversible or can be halted by normalizing the position of the disk. In addition, removal of the posterior attachment overlying the condyle is intended to remove a source of localized inflammation. The repositioned disk facilitates movement of the condyle previously blocked by the displaced disk, provides joint stabilization, and improves articular cartilage nutrition and lubrication. Moreover, the rationale is that the workload of the masticatory muscles is reduced when the obstructing disk is repositioned.

Before performing disk-repositioning procedures in patients with satisfactory disk morphology, adequate trials of nonsurgical therapy should be undertaken to determine whether the patient can be made symptom free despite disk displacement. In 1989, reports were published demonstrating, by postarthroscopic MRI, persistent disk displacement despite the resolution of pain and increase in mandibular mobility.^{29,30} These reports,

and the appearance of anterior disk displacement in patients without any history of TMJ symptoms, support the execution of nonsurgical therapy prior to deciding whether it is necessary to perform disk-repositioning surgery.

Deformation of the disk in all planes is an important feature to recognize when planning a repositioning procedure. When a bulge-shaped disk is of appropriate length and can be repositioned, a diskoplasty may be performed to minimize the change in the occlusion.³¹ It has been reported that during function, the fiber arrangement and proteoglycan distribution of the repositioned disk change to those of a normal disk and that diskoplasty therefore would be unnecessary.³² More evidence is still required to substantiate these changes.

In general, the limiting factor to disk repositioning is the degree of lateral disk atrophy or resorption. Despite severe lateral atrophy, the most medial aspect of the disk may have a normal length and shape (Figure 50-18). Disk shortening may preclude disk repositioning without an extensive release of the anterolateral disk attachments, calling into question the procedure of repositioning.

Disk Repositioning and Diskoplasty A rosette-shaped disposable orthopedic meniscus knife, typically used for orthopedic arthroscopic procedures, is used to effect a release of the disk from its most anterior and lateral attachments (Figure 50-19). This is accomplished by gently prodding the knife along the inside perimeter of the capsule (Figure 50-20). As the dissection is performed under cover of the capsule, there is no danger of injuring the facial nerve. Disk mobility is evaluated by applying posterolateral traction with a forceps (Figure 50-21). A DeBakey bulldog vascular clamp is inserted to the medial limit of the posterior attachment and guided posteriorly as far as possible in the glenoid fossa (see Figure 50-20B). The

FIGURE 50-17 Disk repositioning achieved through a partial-thickness excision of the superior lamina of the retrodiskal tissue. The inferior joint space is not violated. A, Outline of a partial-thickness excision of the superior lamina. B, Excision is closed, resulting in posterior repositioning of the disk.

FIGURE 50-18 A series of sagittal histologic sections through a joint, demonstrating partial disk displacement. Note the change in disk length and morphology as one moves from lateral (A) to medial (C) (hematoxylin eosin stain; macroscopic section).

clamp greatly assists in the control of hemorrhage from the retrodiskal tissue, stabilization of the posterior attachment during tissue excision, and stabilization of the posterior attachment during suturing.³³ The design of the instrument minimizes tissue damage. A wedge of remodeled posterior attachment is excised, leaving a 1 mm margin anterior to the beaks of the clamp. This permits suturing of the disk to the retrodiskal tissue without removal of the clamp. Range of motion is then verified. Tissue forceps are used to stabilize and slightly evert the disk so that the infe-

rior surface may be sculpted with meniscus knives (Figure 50-22). The tissue is closed with nonresorbable suture on an S-2 spatula needle (Figure 50-23). Once the disk has been sutured into its new position, its lateral rim is sutured to the lateral capsule ligament.

Operative difficulties with the repositioning techniques include control of hemorrhage from the retrodiskal tissue and access to the medial aspect of the fossa. Bleeding may be controlled by using the DeBakey clamp before sectioning the posterior attachment. Access to the medial aspect of the joint is greatly improved when the anterior attachment is released, permitting the surgeon to draw the disk outward posterolaterally while it remains pedicled to the medial attachment. Interestingly, the problem of access was one of the impetuses for combining disk repositioning with a condylar and/or eminential arthroplasty.

Disk Repositioning and Arthroplasty

Several operators have advocated combining an arthroplasty of the condyle or eminence with disk repositioning.^{16,32,34-36} Arthroplasty reduces the amount of posterolateral repositioning required and therefore permits repositioning of an atrophic disk (Figure 50-24). The current trend, however, is to avoid removal of any normal articular bone since the postoperative healing phase already involves some loss of bone substance, which may be additive and result in occlusal disturbances. In addition, postoperative bleeding from cut bone surfaces into the joint can result in fibrous adhesions of the disk or fibrous/bony ankylosis of the joint.

A 2 to 4 mm condylar-eminence arthroplasty procedure can be performed with rotary or hand instruments. Hand instruments such as fine chisels are preferable to avoid heat generation (Figure 50-25). Bone files should be used judiciously because, once the compact bony layer is interrupted, the trabeculae of bone can be

FIGURE 50-19 Orthopedic arthroscopic knives (blade handles are not illustrated): A, rosette mini-meniscus curved; B, curved (right or left available); C, sickle; D, retrograde.

easily and rapidly removed. A periosteal elevator may be used to burnish sharp edges. Care should be exercised not to exaggerate the arthroplasty in the lateral condylar regions while accessing the medial condylar region. In some cases an arthroplasty of the eminence is essentially a lateral tuberculectomy for access and decompression of the anterior recess of the superior joint space (Figure 50-26).^{36,37} Disk repositioning is then performed through the plication or excision technique. The capsule is closed in the customary fashion. Intermaxillary fixation or training elastics are used for 1 to 3 weeks to allow muscular adaptation and dental compensations to occur.

Repair of Perforated Posterior Attachment

Perforations rarely occur within the disk proper but rather within the lateral third of the remodeled posterior attachment.^{38,39}

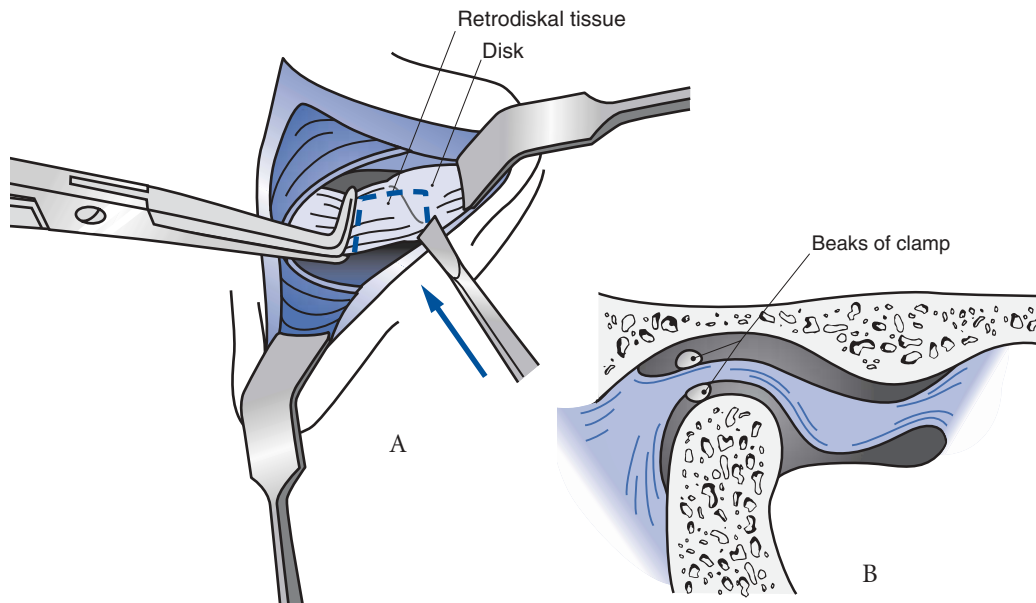

FIGURE 50-20 A, View of partially reducing disk displacement from above and slightly posterior. Note that when the medial portion of the disk is in the normal position, that portion of the disk may be preserved. Note the path of incision of the crescent-shaped mini-meniscus knife (broken line). B, Positioning of the beaks of the DeBakey clamp on retrodiskal tissue.

When the disk is perforated, it may be secondary to a developmental rather than a pathologic process. Condylar overgrowth often occurs in the areas of the perforations; therefore, an arthroplasty is frequently performed in conjunction with the pro-

cedure. The repaired remodeled retrodiskal tissue is intended to maintain the shape of the articular surface and to prevent ankylosis. Repair of a perforation without repositioning the disk is successful only if the disk is atrophied and is not an obstruction to

condylar movement. This procedure is performed rarely and only in those patients refractory to intra-articular steroid injection, arthrocentesis, or arthroscopy.

Management of Small Perforations When primary closure of a small perforation (1–3 mm) is planned, the atrophic displaced disk is repositioned posteriorly to only a minor degree. If the disk is to be fully repositioned, the margins of the perforation should be excised and the posterior attachment on the posterior edge of the disk approximated to the tympanic portion of the retrodiskal tissue. Anterolateral release of the diskal attachments is usually necessary to mobilize the disk posteriorly. The margins of the perforation are oversewn in a straight-line fashion with a nonresorbable material. The repair procedure is often performed in conjunction with an arthroplasty to reduce sharp bony spurs that may be present.

Management of Large Perforations Large perforations are usually grafted after excision of the edges. The disk is not repositioned. In many cases this procedure is a partial diskectomy (Figures 50-27 and 50-

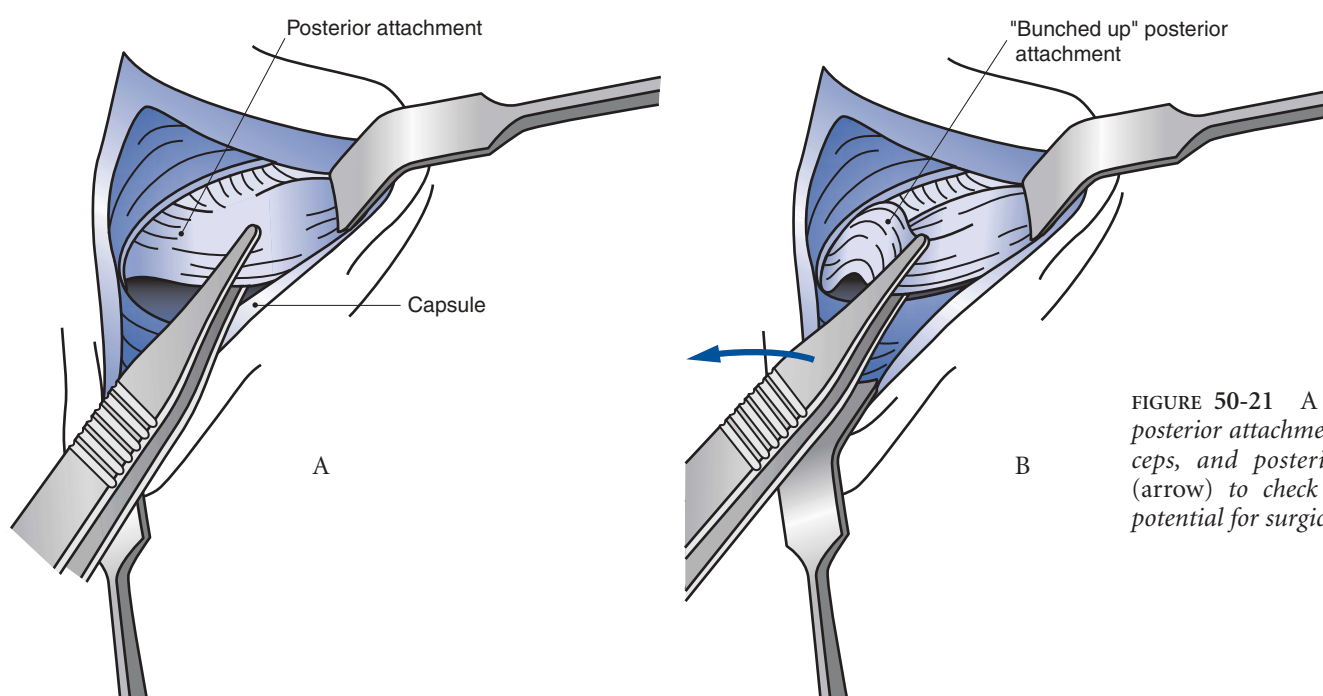

FIGURE 50-21 A and B, The pathologic posterior attachment is grasped with a forceps, and posterior traction is applied (arrow) to check disk mobility and the potential for surgical repositioning.

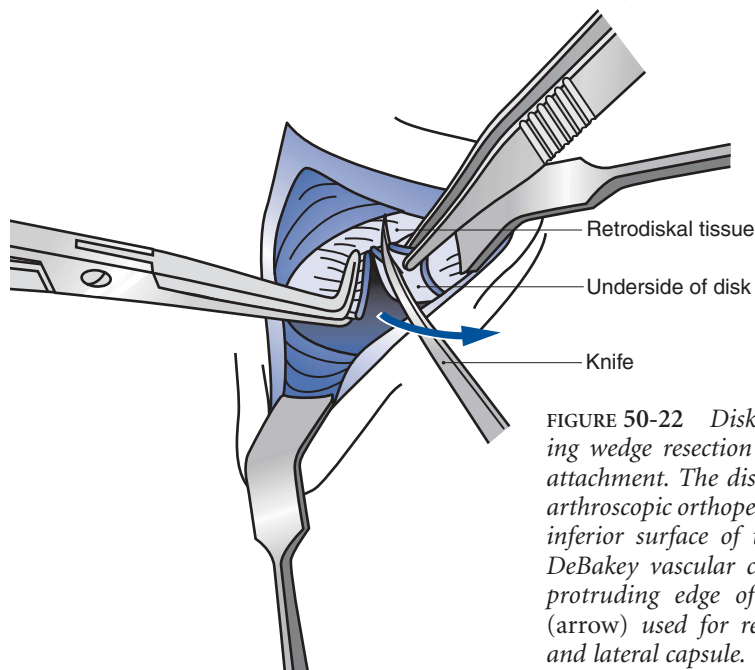

FIGURE 50-22 Diskoplasty is performed following wedge resection of the pathologic posterior attachment. The disk is slightly evened, and an arthroscopic orthopedic knife is used to sculpt the inferior surface of the bulge-shaped disk. The DeBakey vascular clamp is in place. Note the protruding edge of the posterior attachment (arrow) used for reapproximation to the disk and lateral capsule.

28). The graft material is laid over the perforation and posterior attachment. Autografts (dermal) and homografts have been used (Figure 50-29). The free edges of the graft are sutured to the underlying posterior attachment and disk. Typically, medial sutures are difficult to place. A suturing technique using an S-2 spatula or RD-1 needle is recommended.

Disk-Removal Procedures

Partial Diskectomy The partial diskectomy procedure is used to correct partial reducing disk displacement.^{12,40} The goal of the procedure is to excise the pathologic posterior attachment and that portion of the displaced atrophic/resorbed disk that represents an obstruction or is presumed to be responsible for terminal jolting. The portion of the disk that is properly positioned, usually the medial aspect of the disk, is left in place. This procedure was recently re-described under the term *disk reshaping*.⁴¹ Kondoh and colleagues reported a favorable 5-year outcome in their patients.⁴¹ The absence of portions of the TMJ disk may predispose the joint to areas of fibrous or bony ankylosis. The

postoperative import of ankylosis largely depends on the efficacy of physical therapy, the surface area affected, and ability of synovium to regenerate.

The rationale for electing to perform a partial diskectomy rather than a disk repositioning is based on the belief that those factors responsible for the initial disk displacement are often not adequately controlled or identified and thus eventually cause redisplacement of the disk. Usually osseous remodeling changes have occurred to accommodate the change in disk position. Sprinz described the histologic basis for the partial diskectomy procedure.⁴² Surgically created defects within the rabbit meniscus healed uneventfully if the defects

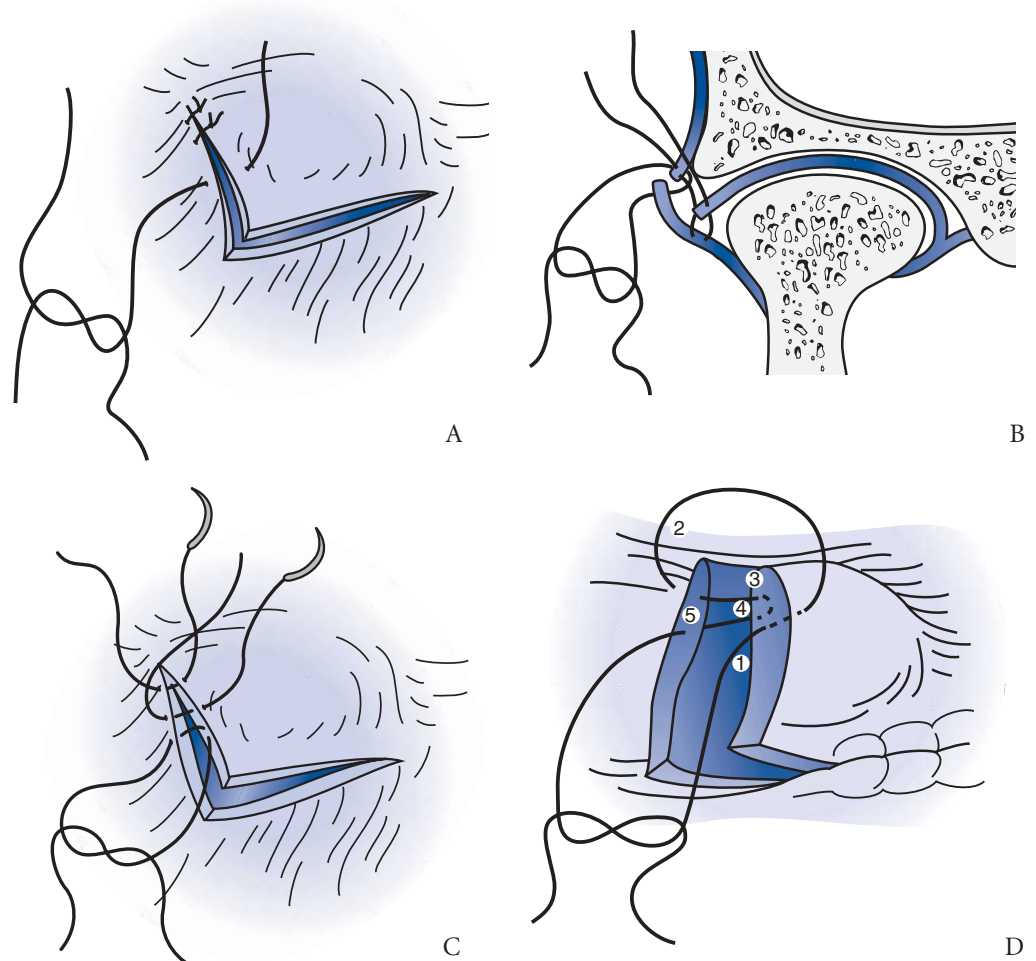

FIGURE 50-23 Disk reapproximation: A, simple posterior and lateral sutures; B, layered closure of the superior and inferior lamina; C, figure-of-8 closure; D, the order of passage of the figure-of-8 suture labeled 1 to 5.

were close to the vascular periphery. In the rabbit knee meniscus subjected to partial meniscectomy, the replacement tissue appeared to be derived from the synovium of the articular capsule.⁴³

Preoperative confirmation of a partial reducing disk using MRI or arthrotomographic images is imperative in deciding whether to perform this procedure. After exposure of the joint spaces, the DeBakey

clamp is inserted to the medial limit of the posterior glenoid fossa. Retrodiskal tissue and displaced portions of the disk are then

FIGURE 50-25 Condylar arthroplasty using an osteotome. An osteophyte has already been excised. The direction of the osteotome (arrow) is indicated in order to skim the condylar surface. Self-retaining and right-angle retractors are in place.

FIGURE 50-26 Lateral tuberclelectomy may be performed to acquire access to the anterior glenoid and eminence regions (broken line indicates bone to be excised and arrow indicates direction of osteotome).

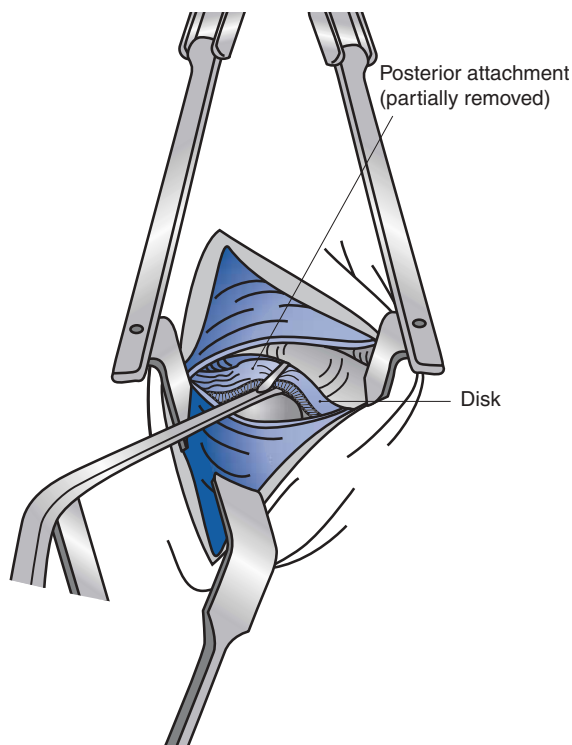

FIGURE 50-27 Partial diskectomy. Midcondylar region is illustrated. Bulge portions of the disk are excised in a piecemeal fashion using otologic basket forceps. Portions of the excised disk partially excised are hatched exposing the remodeled disk in cross-section.

removed in a piecemeal fashion using otologic basket forceps (see Figure 50-27). The tissues are removed until the properly positioned disk is noted. The surgeon may then graft the surgical site with an autologous dermal graft. The graft is sutured to a cuff of tissue left at the circumference of the surgically created perforation (see Figures 50-28 and 50-29). In some cases the surgeon may elect not to graft the artificially created perforation. Capsular and skin closures are accomplished in the customary fashion. Following extirpation of the disk portion in question, joint movement is simulated to ensure that there is smooth condylar movement in lateral and anterior planes. The procedure can produce excellent immediate gratification to the patient and improve joint function. However, complete smooth excision of the inferior aspect of the disk is required to prevent recurrence. A perforation is sometimes intentionally created to

remove the obstacle. The displaced disk is essentially changed to a displaced meniscus. The perforation is rarely problematic for the patient as it is created anterior to the condyle. The perforation repair described earlier is performed over the head of the condyle; such perforations can lead to chronic pain refractory to steroid injection.

Total Diskectomy Total diskectomy is the procedure in which the remodeled posterior attachment and entire disk are excised. It is the most extensively used and reported surgical procedure, having been applied from as early as the 1900s. Total diskectomy has been used to treat the full gamut of internal derangements, without consideration for the degree of displacement of disk morphology, with generally good to excellent results.⁴⁴⁻⁵⁰

Despite the reported successes with diskectomy,⁵¹⁻⁵³ the more sophisticated diskoplasty techniques supplanted the diskectomy during the 1970s to mid-1980s.⁵¹⁻⁵³ In the 1980s diskectomy became popular once again following the introduction of implantable biomaterials that were used as disk replacements.

Diskectomy is indicated in those situations for which disk repositioning is not feasible because of disk atrophy, deformation, or severe degeneration. A joint with an atrophied, deformed, or degenerated disk cannot be rejuvenated because some of the associated pathologic changes—collagen fiber reorientation, increased ground substance, presence of elastic fibers in all disk zones, cartilaginous deposits, and increased vascularity—are irreversible. The goal of surgery is to assist the host to adapt to the pathology at hand by removing the physical impediment to movement and the pathologic posterior attachment.

Bowman studied the results of total diskectomy in 52 patients followed over 3 months to 22 years.¹² Thirty of his patients were studied for 4 years or more. Subsequently, in 1986, Eriksson and West-

FIGURE 50-28 For repair of a large perforation, a partial diskectomy is performed first. A portion of the disk and the retrodiskal tissue may be retained.

esson reported a follow-up (mean 29 yr) on 15 of Bowman's patients.⁴⁰ Bowman's observations, which have been corroborated by others,^{10,54,55} form the basis of much of the discussion that follows.

Total diskectomy deprives the joint of the posterior attachment and posterior aspect of the remodeled disk. In the diseased state these tissues serve as the shock absorbers for the bony surfaces. The residual "normal" synovium is responsible for the lubrication and nutrition of the articular surfaces. The absence of retrodiskal tissue may interfere with the normal flow and diffusion of synovial fluid.⁵⁶ With diskectomy, the surgeon probably transforms a joint into what more appropriately would be described as two bones in close apposition. As a result, several adaptive changes

FIGURE 50-29 A dermal graft covers the surgically created perforation. The edges of the graft overlay the disk, retrodiskal tissue, and lateral capsule to assist in suturing.

rapidly occur. These changes are reflected in the manner in which the joint functions and how it appears radiographically. Many clinical examples of such a bony arrangement providing the patient with adequate pain-free function may be drawn from the reconstructive literature.

Clinicians often observe the loss or reduction of gliding motion in the joint with nonreducing disk displacement. In this situation the joint behaves principally as a ginglymoid joint. Initially there is limited translational capability. As healing progresses and osseous remodeling occurs, the rotational (hinge) movement becomes minimal and the gliding motion predominates. The patient must rapidly regain mobility through prescribed physical therapy to prevent the development of ankylosis.

Adult cartilage derives its nutrients solely from synovial fluid. The prolonged contact of bony surfaces following meniscectomy may interfere with diffusion of nutrients from the synovial fluid. The decreased diffusion of nutrients to cartilage may result in the eventual resorption of noncalcified cartilage.

After a diskectomy some masticatory muscle and joint tenderness can be expected for a variable period, extending from several weeks to months. The patient at first favors mastication on the operated side. Later, when healing is advanced, mastication is performed on the nonoperated side. An opening deviation of as much as 8 to 9 mm may occur toward the operated side. The deviation appears to be a normal compensatory function secondary to the loss of posterior attachment and synovium, the change in the joint architecture, and areas of fibrous ankylosis. Counteracting the lateral deviation actively or passively causes pain in the operated joint.

Hypermobility of the nonoperated joint may develop or increase after diskectomy. Limitation of mandibular movement on the operated side appears to be responsible for the hypermobility. The

hypermobility may be responsible for awakening symptoms of a quiescent internal derangement. Capsular tightening procedures have been performed in conjunction with diskectomy to reduce condylar hypermobility (Figure 50-30).⁵⁷⁻⁵⁹ Physical therapy greatly assists the control of the ipsilateral deviation and hence contralateral hypermobility.

Joint crepitations or “snappings” often occur postoperatively. The snappings have been attributed to the condyle rubbing on residual nonextirpated portions of the disk and usually cease after several months. Patients often report an alteration in their bite, although rarely as a major complaint. The thicker the retrodiskal tissue removed, the greater is the anticipated change in occlusion. The sensation of an altered bite usually resolves within a week to several months, with resolution of intra-articular edema, clot retraction, and dental compensations. Occlusal equilibration is rarely indicated.

There is considerable variation in the ability of each patient and joint to adapt to the postdiskectomy state. Individual factors, such as inclination of the eminence, state of preoperative symptoms, loss of molar support, and amount of postoperative remodeling, do not seem to play a substantial role.

Clinicians are often alarmed by the degree of osseous remodeling observed

after a diskectomy. The morphologic and radiologic changes observed in the TMJ concur with those observed in experimental diskectomy.^{41,60} After approximately 1 year the morphologic appearance of the condyle and temporal bone appear similar to those observed in a typical arthroal joint, that is, there are planar (flat) articular surfaces. This is reflected by the manner in which the joint is observed to function. Agerberg and Lundberg described erosion of the articular surfaces and interruptions of the cortical outline on transcranial radiographs.⁶¹ The osseous changes appeared primarily in the lateral and anterior aspects of the joint. The posterior aspects were least affected. Remodeling changes have even been identified in the lateral third of the contralateral (nonoperated) joint.^{62,63} However, this was not confirmed by Bowman.¹² Agerberg and Lundberg concluded that the remodeling process stabilized after 2 years.⁶¹ They used the term *remodeling* and not *osteoarthritis* to describe the radiographic changes because the osseous changes occurred in the absence of symptoms. The bony changes appear similar to those that are observed longitudinally with chronic disk displacement, suggestive of the same mechanism. The rate of remodeling, however, is accelerated in the postdiskectomy state. A similar observation has been made in the postmeniscectomy human knee joint.⁶⁴

FIGURE 50-30 Capsular tightening procedure as per Martin and colleagues. The lateral ligament is reflected from the zygomatic arch (arrow) (A) and then sutured posterior to its anatomic origin (B). Adapted from Martin BC et al.⁵⁹

Diskectomy without Replacement Disk extirpation is facilitated when the atrophic disk is severed from its anterior and lateral attachments and then retracted laterally and posteriorly to complete the incisions. This approach permits the surgeon to verify the ability of the disk to be repositioned posteriorly before excision. With severe atrophy of the disk, substantial resistance to posterolateral traction is noted. A hemostatic clamp is positioned across the anterior attachment to serve as a guide plane for the knife, which is used to sever the attachment lateromedially (Figure 50-31). As the posterior attachment demonstrates a variable degree of vascularity changes, the DeBakey bulldog vascular clamp or straight mosquito clamp may be applied here before severing the posterior attachment. Next, a hemostat is used to apply outward traction to the tissue to be extir-

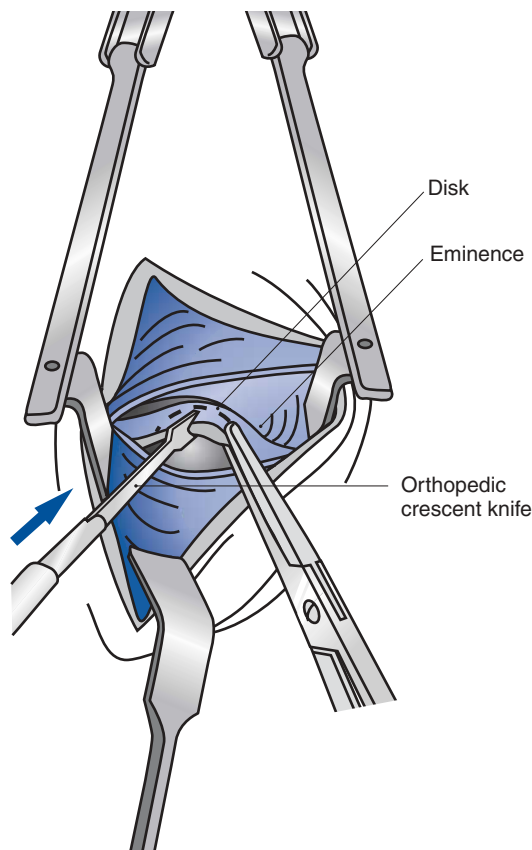

FIGURE 50-31 Total diskectomy. A straight clamp is inserted onto the anterior attachment. A meniscus knife separates the anterior attachment guided by the clamp. The arrow represents the direction of the incision.

pated (Figure 50-32). A meniscus knife is used to sever the medial attachments. When the remodeled posterior attachment and disk are extirpated, the retrodiskal tissue is electrocauterized to control bleeding. Care is taken not to disrupt the fibrous connective tissue lining of the fossa and condyle. The morphology of the condyle and glenoid fossa often prevent excision in one piece. Incomplete excision of the posterior attachment over the lateral pole of the condyle may account for some cases of failure with diskectomy. After the disk and posterior attachment are excised, the surgeon should verify that there is not a significant diaphragm of irregular posterior attachment tissue that remains laterally around the head of the condyle.

With the disk and posterior attachment removed, mandibular range of motion is simulated by manipulating the mandible in lateral and protrusive excursions. Joint noises, characterized as snapping, may indicate a disk remnant. Disk remnants are usually located on the medial aspect of the joint cavity. The surgeon should remove all disk remnants that appear to impede movement.

Disk Replacements

Autogenous, homologous, and alloplastic replacements for the disk have been used following diskectomy to prevent or reduce intra-articular adhesions, osseous remodeling, and recurrent pain. In addition, the interpositional material was believed to decrease joint noises by dissipating loading forces on the osseous surfaces. The effectiveness of interpositional grafts in reducing adhesions, protecting the articular surfaces, and diminishing pain and postdiskectomy joint noise has not been substantiated. The use of these materials is sporadic and according to operator preference.

The dermal graft may be harvested from the buttock, upper lateral thigh, groin, or the inner aspect of the upper extremity. When the thigh is selected as the donor site, a dermatome may be used to

FIGURE 50-32 An arthroscopic knife severs the posterior attachment (broken line), guided by the clamp. The clamp retracts the disk anterolaterally for visibility.

raise the skin (0.30–0.38 mm) and then the dermis (0.46–0.51 mm). The dermatome width should be set to take the dermal graft 20 to 30% larger than is required to compensate for immediate contraction of the graft. Bleeding in the donor site should then be thoroughly controlled to prevent hematoma formation under the skin, which is replaced over the donor site. Adhesive strips may be applied, or the skin edges may be sutured with 5-0 nylon. The surgical site is then dressed with an occlusive dressing. Postoperatively the donor site should be checked for seroma formation during the first 48 hours.

Alternatively, when size requirements are minimal, the graft may be harvested freehand. An elliptic wedge of epidermis and underlying dermis is harvested. The underlying surface of the dermis must be defatted before being implanted. The defatted graft is trimmed and sutured to the retrodiskal tissue and the anterior and lateral capsular attachments.

The dermal graft is believed to function as a framework for the new disk. Vascularization of the graft is probably derived from the joint periphery.^{20,21,28,42} The vascular retrodiskal tissue provides pluripotential cells and synoviocytes to participate in the healing process. Dermal grafts implanted in the primate TMJ were

reported to be viable at postoperative week 36.⁶⁵ The collagen and elastic elements of the dermal graft were reported to persist, whereas the dermal appendages atrophied.^{66,67} Chao and colleagues reported, however, that the dermal grafts were completely repaired by fibrous tissue.⁶⁸

The temporalis muscle has been used as an interpositional material. The flap may be pedicled in a variety of ways, some of which risk the blood supply owing to torsion of the pedicle. Advantages of this technique over a free graft include its stability, owing to its connection at the base (Figure 50-33), its availability at the same surgical site, and its lack of morbidity.

Feinberg and Larsen described a technique that pedicled the posterior temporalis

FIGURE 50-33 Disk replacement using temporalis muscle/fascial graft (broken line) pedicled from above the glenoid fossa and rotated inward (arrow). Lateral, anterior, and posterior sutures hold the graft in place.

muscle fibers anteriorly.⁶⁹ A 1 cm-wide paddle is developed above the posterior root of the zygomatic arch. The paddle is elevated and rotated anteriorly and inferiorly around the posterior root of the zygomatic arch. The muscle is then sutured to the retrodiskal tissues (Figure 50-34).

Sanders and Buoncristiani described a technique for using the temporalis myofascial flap for interpositional tissue in TMJ reconstruction.⁷⁰ The shape and size of the flap is outlined by incising posteriorly near the postglenoid spine of the joint through temporalis fascia muscle and periosteum. This incision is extended superiorly near the temporal line. Subperiosteal dissection elevates the amount of flap needed from the temporal bone. A transverse incision is made at the superior portion anteriorly to create a 3 cm-wide flap. The width should be greater than the anteroposterior coverage desired in the joint to allow flap contraction. An anterior incision is made parallel to the posterior incision. The superior aspect of the anterior incision is carried to bone in this thin area of the temporalis. Inferiorly, as the arch is approached, the muscle thickens; therefore, the dissections are not carried completely through muscle to bone. Blunt dissection is carried inferiorly to a point just medial to the arch to permit adequate mobility of the flap. Branches of the temporal artery found in this area are preserved if possible. The length of the flap is usually 5 cm.

The flap is fully reflected off the bone, and resorbable interrupted sutures are placed in several areas on the edge of the flap through fascia, muscle, and the periosteum to keep the layers from separating. Holes are drilled in the bone of the lateral lip of the glenoid fossa posteriorly and anteriorly before placement of the flap into the joint. One suture is placed through bone anteriorly near the eminence, and a second posterior suture is placed near the postglenoid spine. Two additional sutures hold the medial edge to

FIGURE 50-34 A and B, Disk replacement using temporalis muscle/fascial graft pedicled anteriorly and rotated anteriorly and inferiorly around (beneath) the posterior root of the zygomatic arch (arrow). The graft is sutured to the retrodiskal tissues.

anterior and posterior medial tissues. These medial sutures are sometimes difficult or impossible to secure, and the sutures through lateral bone are usually adequate to hold the flap in place. A cosmetic temporal defect may result depending on the thickness of tissue harvested.

Autogenous fascia interpositional grafts were described in 1911 for use as interpositional material in gap arthroplasties for ankylosis.^{71,72} The attractiveness of this material lies in its resistance to resorption, response to mechanical stress, and biocompatibility.⁷³⁻⁷⁵

Autogenous conchal cartilage was first used as a disk replacement by Perko, according to Witsenburg and Freihofer.⁷⁶ Cartilage harvested from the cavum conchae results in minimal esthetic compromise. The graft can be tailored to fit the condyle or glenoid fossa. Notably, the quality and thickness of the aural cartilage is variable. In some cases an iatrogenic tear in the cartilage may occur during the harvesting process.

The procedure to obtain chondral cartilage as interpositional material for TMJ reconstruction has been described by Hall and Link.⁷⁷ A 3 to 4 cm postauricular incision is made on the ear a few millimeters lateral to the auriculocephalic sulcus and is carried through to the perichondrium. The middle division of the posterior auricular artery may be encountered and ligated or cauterized. A careful supraperichondral dissection with a fine dissecting scissors exposes the surface of the cartilage. A scalpel is used to cut through the cartilage in the shape of the desired amount of graft, usually 1.5 by 2.5 cm. It is important not to extend to the rim of the antihelix to avoid permanent deformity of the ear. Subperichondral dissection between the skin of the bowl and cartilage permits the cartilage to be removed without tearing it or perforating the skin. The ear is packed with gauze or other material to maintain the shape of the bowl and to apply pressure to the skin. The pressure pack is maintained for 48 hours.

Timmel and Grundschober and Boyne and Stringer reported the use of lyophilized dura in both the porcine and human TMJ.^{78,79} Foreign body reactions were always associated with the material. There was gradual replacement of the material with fibrous connective tissue, although they noted this was not complete by 120 to 130 days. There is increasing resistance among surgeons toward using fresh homologous materials owing to the possibility of transmitting communicable diseases. Relatively recently Creutzfeldt-

Jakob disease has been transmitted to a patient who received lyophilized dura.⁸⁰

In the future surgeons may be able to use tissue explants or biocompatible allogeneic collagen sheets as disk replacements.⁸¹

Alloplastic Materials The requirements for an ideal alloplastic implant are that it be biocompatible, easily secured, adaptable to the variable morphology of the recipient site, and resistant to the compressive and shear forces of the joint. Currently there is no alloplastic material or technique that fulfills all of these requirements. Computer-aided design using three-dimensional computed tomography images of the TMJ may bring us closer to defining the ideal characteristics and design of the various components of the TMJ.

Silicone elastomer is a rarely used implantable material. It is exclusively and rarely used in the TMJ for temporary use, but even in this application it is not free of problems. Its sole reputed advantage is that the material does not incorporate into the surrounding tissues. In the past when it was used as a permanent implant, the material's properties were responsible for its migration through stabilizing wires. Gallagher and Wolford suggested that this lack of stability resulted in the loss of as many as one-third of all implants placed following condylectomy.⁸² Continued loading of silicone elastomer interpositional implants by the condyle has led to fragmentation and foreign body reactions because of its high coefficient of friction and poor wear characteristics under direct function.⁸³ Recognition of the limitation of this material led to the abandonment of the permanent silicone implant elastomer and its subsequent rare use as only a temporary implant replacement.

Implants laminated with a composite of polytetrafluoroethylene (PTFE) and aluminum oxide were used extensively in the early and mid-1980s.^{84,85} The PTFE material's ultraporosity and watability permitted rapid ingrowth of fibrous con-

nective tissue to facilitate anchorage of the prosthesis. The polytef surface on which the condyle interfaced was chosen to provide a smooth surface resistant to shear and compressive forces.

In the mid-1980s reports of problems with the PTFE implant began to surface.⁸⁴ Patients reported pain, swelling, joint crepitus, and limitation of range of motion resistant to conservative management. In such TMJ reconstructions the PTFE implants that were removed demonstrated perforations, shredding, and displacement. Severe osseous remodeling changes, particularly of the condyle, were reported.⁸⁶ Previous reports indicated that the PTFE-carbon implants elicited a severe histiocytic foreign body reaction,⁸⁷ similar to what was being reported as happening in the human TMJ. Because of the growing number of failures with PTFE, in 1990 the Food and Drug Administration formally withdrew the PTFE implant from the market and cautioned that patients should be closely followed up for progressive bony changes using radiographic studies at 6-month intervals.

Temporary Implant Insertion To date only the high-performance polymeric silicone implant has been considered for temporary (retrievable) implant insertion. The paddle-shaped implant is inserted with the neck of the paddle rolled over the zygomatic arch (Figure 50-35). Several tacking sutures are placed to the temporalis fascia. Retrieval is planned for 2 to 6 months postoperatively. As the polymeric silicone material is never incorporated into the host, the implant is easily removed at a second operation under local anesthesia. The fibrous connective tissue that encapsulates the implant is left in place to act theoretically as the permanent layer between the condyle and the fossa. However, at the time of retrieval of the temporary implant, the fibrous connective tissue encapsulation may be incomplete. As a result, this procedure has dropped out of favor.

FIGURE 50-35 Temporary (retrievable) polymeric silicone implant inserted. The paddle extension is sutured to the temporalis fascia. A Freer elevator holds the implant in place (arrow) while the sutures are secured.

Condylectomy

Low condylectomy or simply condylectomy is the procedure that is defined as the removal of the entire condylar process. The procedure used to be performed to increase the joint space to alleviate pressure on nerve endings,⁴⁸ but it has largely been abandoned in the surgical repertoire for treatment of internal derangements because of problems of reduced condylar mobility, mandibular deviations, and open bite.

High condylectomy is the removal of only the articular surface of the condyle. The disk is left intact to prevent ankylosis and to promote healing. This contrasted with the radical condylectomy in which the tendon of the lateral pterygoid muscle was released. Only slight mandibular deviation was reported in patients after high condylectomy.⁸⁸⁻⁹⁴

When the condylar or eminence articular surfaces appear intact, most clinicians are reluctant to shave the osseous surfaces. Arthroplasty is performed when the rate

and distribution of bone remodeling have resulted in mechanical interferences.

Condylotomy

The condylotomy procedure is an osteotomy performed through the condylar neck. Campbell, one of the originators of the technique, made the observation that symptoms of TM dysfunction disappeared after condylar fractures.⁹⁵ This led to his application of the closed condylotomy to patients with TMJ symptoms refractory to nonsurgical therapy. The rationale behind its use in treatment of internal derangements was to produce anteromedial displacement of the condyle to change the condyle-disk-fossa relation, increase joint space, shorten the lateral pterygoid muscle, and alter load forces.^{88,96-100}

Originators of the technique performed a closed osteotomy with a Gigli wire saw with the intent of creating an anteromedial fracture dislocation. Intermaxillary fixation was sometimes applied in the immediate postoperative period. Today, when the procedure is performed, the intraoral route used for the vertical mandibular ramus osteotomy is employed.

Postoperative Management

Surgery should reduce painful symptoms to a level that represents little or no concern to the patient. It is important to weigh the contribution of masticatory muscle myalgia to the patient's chief complaint. Although joint surgery can relieve the joint pain, in many cases it may be ineffectual in controlling muscle discomfort. Nonsurgical management of the muscle disorders must continue in many patients after surgery for internal derangements. Joint surgery does not restore the joint to its prepathologic state. The patient should understand that biting force may be reduced and jaw fatigue may become apparent with heavy meals or long conversations. After primary surgery (ie, no previous TMJ surgery), one should strive for the following passive range-of-motion

parameters: maximum interincisal opening of 35 to 40 mm, lateral excursive movements of 4 to 6 mm, and protrusive excursive movements of 4 to 6 mm. However, success should not be measured by the attainment of a finite measurement. A patient's overall success should be measured by the eradication or diminution of the preoperative complaints. Surgery is rarely performed to correct purely functional complaints. Elimination of pain during function is usually the predominant concern for the patient, who is willing to accept some compromise in degree of opening and lateral excursions.

Bite appliances should be used to maintain a stable occlusal relation in the immediate postoperative phase. This is particularly important after disk repositioning. The appliance is frequently adjusted as the edema resolves and disk tissues heal. The patient should be able to return to a normal mechanical diet with minimal dietary restrictions. Restricted foods include such items as French bread, toffee apples, and popcorn. A stable acceptable occlusion should be maintained. Joint sounds may develop or persist, but the asymptomatic sounds should be of minimal concern to the patient.

Postoperative outcomes may be influenced by several factors, including concomitant facial pain from other sources, degenerative bony changes, advanced morphologic changes in the disk, perforation of the posterior attachment, poorly controlled parafunctional habits, malocclusion, psychological overlay, previous TMJ surgery, history of facial nerve paralysis or orofacial numbness, history of infection, or systemic diseases affecting the muscles, ligaments, or bone.¹⁴

Historically, clinicians emphasized restricted joint function after joint surgery. The clinician must balance his desire to rapidly and actively restore a normal range of motion with the capacity of the joint and facial muscles to adapt. Some latitude must be maintained on the part of

the clinician in dealing with a patient's rehabilitation schedule. Care should be exercised in the rehabilitative process of the patient with bilateral joint disease whose operation was unilateral. Diet restrictions are important. Excessive lateral excursive movements to the ipsilateral side may contribute to the exacerbation of contralateral symptoms. There is no cookbook recipe to postoperative management of these patients. Some patients, regardless of the procedure, achieve an acceptable range of motion within 7 to 14 days, with minimal effort on their part. Others need to follow a strict physical therapy regimen. The help of a physical therapist may sometimes be enlisted to regain joint mobility, especially when patient cooperation with a home exercise program is questionable. In general, some light passive opening and protrusion stretching exercises are prescribed four times a day beginning 5 days postoperatively. With disk repair procedures the physical therapy exercises should be more gradual.

Patients should be maintained on a full-liquid to soft diet for the first 2 postoperative weeks. Heat may be applied before and after exercises to improve comfort. Splint therapy is routinely used when a large parafunctional component is present. Some authors advocate using anterior repositioning devices to permit healing of suture sites following disk repositioning. Patients should be encouraged to chew gum after 4 weeks to improve lateral excursive movements.

Complications

Complications may arise immediately (intraoperatively or within 24 hr) or be delayed (> 24 hr).

Transient neuropraxia of the temporal branches of the facial nerve occurs in as many as 20 to 30% of cases. Typically, the injury is of little significance to the patient and resolves within 3 to 6 months. The incidence increases when a separate skin flap is raised.¹⁰¹ Rarely, the zygomatic

branches and, even more rarely, the entire temporofacial division may be injured. Injury to the chorda tympani from aggressive condylar retraction in the medial aspect of the fossa may occur rarely as well. Neuropraxia of the inferior alveolar and, less commonly, the lingual nerves may result from clamp placement for joint manipulation. Auriculotemporal syndrome (gustatory sweating, Frey's syndrome) has been reported as a result of the dissection of the joint.

Hemorrhage from the retrodiskal tissue may interfere with performance of the disk repair. Temporary control may be obtained with seating of the condyle in the glenoid fossa. Electrocautery, injection of epinephrine, or application of hemostatic agents while maintaining the mandible in the closed position may be necessary.

Infections rarely occur. Microorganisms cultured may originate from the skin or external auditory meatus flora. Auriculitis and external otitis are more likely to occur with the postauricular and endaural approaches. To avoid contamination an ear packing is avoided as it frequently becomes dislodged during surgery. In addition, the ear is not suctioned during surgery. When the wound is closed the external auditory canal is irrigated gently with saline via an 18-gauge angiocatheter.

Postoperatively, joint sounds are a frequent occurrence, regardless of the surgery. The sounds following diskectomy may be the loudest. In some patients the sounds may be obtrusive enough to disturb them. The surgeon should delay re-intervention until the patient is reevaluated at 6 to 12 months, as some sounds may become inconsequential to the patient.

Summary

Remarkably good success has been reported with several surgical procedures, which differ in their fundamental approach to the problem and their aggressiveness. Most of these techniques share common denominators: first, a lateral approach to the capsule

and ligament; second, a severing of the posterior attachment-disk attachments to the capsule once the superior joint space is accessed; and, third, a blunt delineation of the joint spaces. Although the capsule and ligament tissues are approximated at the conclusion of the procedure, the patient is encouraged to function on the operated joint. Long before arthroscopic surgery, Toller recognized the importance of mobilizing the condyle-disk-fossa relations to achieve a successful result.¹⁰² He devised the lateral capsular arrangement procedure. It remains to be determined whether disk repositioning, posterior attachment repair, diskectomy, high condylectomy, and even condylotomy derive some or all of their therapeutic benefits through a lateral capsule and ligament release and mobilization of the disk complex. Arthrocentesis and arthroscopic surgical procedures for treatment of the closed lock condition appear to be therapeutic through the same mechanism.¹⁰³

Open surgical approaches to TMJ internal derangements are now relegated to a tertiary line of care following nonsurgical therapy and arthrocentesis/arthroscopy for most conditions. They do, however, have a clear indication for certain mechanical conditions directly attributed to a disk obstruction.

Much of what was written in the previous edition of this chapter has stood the test of time. As we increase our understanding of the pathology, open surgical procedures are being performed for specific well-defined conditions. However, the new TMJ surgeon will never quite appreciate the experience that comes with performance of arthrotomy procedures. Arthroscopy developed as a consequence of this experience. Now, as we regress with progress, arthrocentesis with and without steroid injection, a procedure performed by many surgeons years before the pathology of the joint was even elucidated, has become a mainstay for treatment. This treatment alone has significantly reduced the need to intervene via arthrotomy.

Management of the Patient with End-Stage Temporomandibular Joint Disease

Stephen B. Milam, DDS, PhD

The patient with end-stage temporomandibular joint (TMJ) disease is typically characterized by a protracted history of multiple therapeutic interventions, often including multiple TMJ surgeries. The patient with end-stage TMJ disease commonly suffers from unrelenting pain and severe limitation of jaw movement. In addition, some patients with end-stage TMJ disease may also endure facial deformities, sensory or motor abnormalities, dysfunctional malocclusions, and upper airway compromise. The suffering of these unfortunate individuals is often compounded by their compromised position in managed health care systems and mounting personal debt. Understandably, virtually all patients with end-stage TMJ disease exhibit signs and symptoms of depression, often straining relationships with significant others.

Several factors likely contribute to the evolution of end-stage TMJ disease. The progression of some TMJ disorders may be influenced by variables such as sex (ie, mediated by sex hormones such as estrogen and prolactin), genetic backdrop (eg, predisposition to rheumatoid arthritis is associated with some estrogen receptor polymorphisms), nutritional status, age, and psychological stress (eg, plasma levels of nerve growth factor, an endogenous

peptide implicated in the genesis of some muscular and neurogenic pains, are elevated in humans following psychological stress). In addition, it is clear that many patients with end-stage TMJ disease also suffer from iatrogenic injury.

Currently the prognosis for recovery of the patient with end-stage TMJ disease is extremely poor. Clearly, the best strategy is prevention. How can risks for developing end-stage TMJ disease be reduced?

Basic Elements of Care

Effective management of any TMJ disorder is primarily dependent on three elements of care: an accurate diagnosis, careful patient selection, and effective perioperative patient management (Table 51-1).

An accurate assessment of a patient's condition(s) is an absolute requirement for the selection of an effective treatment. The experienced clinician recognizes that many painful conditions of the head and neck region can mimic a TMJ disorder. For example, it is well known that some masticatory myalgias can produce pain of various qualities (ie, ranging from aching sensations to “stabbing” or “throbbing” pains) that may be felt in the area of one or both TMJs.¹ Furthermore, some of these painful conditions, such as the masticatory myalgias, may also be associated with

restricted jaw movement and may be exacerbated by such movement. Similarities between many painful head and neck disorders with respect to clinical presentation can pose a significant challenge for the clinician to derive an accurate diagnosis. Failure to do so can lead to the initiation of an ineffective and perhaps damaging treatment that may ultimately contribute to clinical anomalies that characterize end-stage TMJ disease.

Proper patient selection is important since, although appropriate surgical objectives and proper technique are obviously significant determinants of treatment outcome, a patient's commitment and ability to perform critical perioperative tasks (eg, regular exercises, nutritional maintenance, abstinence from unhealthy habits) may be the single most important determinant of the outcome of surgical treatment of a TMJ disorder. Therefore, the clinician must accurately assess the patient's willingness

Table 51-1 Basic Elements of Surgical Care

Accurate diagnosis
Careful patient selection
Effective perioperative management
Pain management
Restoration of jaw movement

and ability to comply with an often-difficult perioperative regimen. Depending on the condition, patients who are unwilling or unable to comply with a demanding but essential perioperative regimen may not be viable candidates for the indicated surgery. Failure to recognize this limitation preoperatively often leads to a significantly compromised surgical outcome.

It is also important to delineate realistic objectives of therapy, including surgery, and to recognize the limitations of each approach. Experienced surgeons often reliably achieve TMJ surgical objectives, including excision of neoplastic or diseased tissues, relief of physical obstructions to joint movement, and restoration of important anatomic relationships. However, even the most experienced surgeon may not reliably achieve some treatment objectives such as relief of pain. Clinicians may sometimes recommend treatment by default (eg, other approaches have failed to provide adequate pain relief) without clearly delineated and reliably achieved treatment objectives. Such an approach has significant potential for worsening the patient's overall condition by iatrogenic injury. All recommended treatments should be based on an accurate diagnosis, and a plan based on well-delineated achievable treatment objectives.

Perioperative Management

Patients with end-stage TMJ disease suffer primarily from persistent pain and restricted jaw function. Recent evidence suggests that some persistent pain may result from neuroplastic changes evoked in nociceptive pathways of the central nervous system (CNS) by intense stimulation or nerve injury. There is also strong evidence that these changes may be prevented or significantly obtunded by preemptive techniques that reduce or block CNS responses to surgical stimulation (ie, preemptive analgesia). Two primary goals of perioperative management of the operated TMJ patient are pain control (ie, using

preemptive analgesia techniques) and establishment and maintenance of acceptable joint movements (ie, mandibular range of motion). These goals are not exclusive. Patients who suffer from temporomandibular pain are often noncompliant with recommended jaw exercises that must be performed to achieve and maintain physiologic joint movements.

Pain-Control Strategies

With few exceptions, pain is the primary chief complaint of patients with TMJ disease and is often the principal limiting factor in the patient's willingness to comply with physical therapy designed to restore jaw movements. In addition, patients suffering from persistent pain often exhibit clinical signs of depression. They are often socially withdrawn, and interpersonal relationships with significant others may become compromised. Therefore, effective pain control strategies must be identified, preferably in the preoperative period, and implemented aggressively to ensure an optimum surgical outcome and to sustain an acceptable quality of life for the patient (Table 51-2).

Preemptive Analgesia

Effective postsurgical pain control begins in the operating room. It is now recognized that methods that limit CNS neuronal activation by surgical stimulation may significantly reduce pain in the postsurgical period and may also reduce the liability for the development of some persistent pains. The term *preemptive analgesia* is used to describe methods that apparently reduce postsurgical pain by protecting the CNS from surgical stimulation. The concept is based on recent observations that collectively indicate that nociceptive processing is highly dynamic. Nociception and subsequent pathway sensitization likely involves de novo protein synthesis and even establishment of novel connections by neurons in the affected pathway.²⁻⁴ The old view that nociceptive

pathways are merely static conductors of neural signals generated by noxious stimuli appears to be invalid. We now know that gene transcription is induced in stimulated neuronal populations.^{5,6} Some neuropeptides that are translated from these genes may facilitate future neural activities by receptive field expansion or by facilitation of specific interneuronal interactions. The term *neuroplasticity* is often used to refer to the dynamic state of stimulated neural pathways. These, and perhaps other more ominous changes (ie, neuronal death from excessive stimulation), may be fundamental to the development of some chronic pain states. Fortunately, these CNS responses may be significantly attenuated by preemptive analgesic techniques.^{3,7}

Techniques From animal and clinical studies there is evidence that protracted neural responses to painful stimuli can be modified or prevented by the following: (1) neural blockade with local anesthetics,⁸⁻¹⁰ (2) administration of opioids,¹¹⁻¹⁵ (3) administration of *N*-methyl-D-aspartate receptor antagonists (eg, MK801, ketamine, dextrophan),¹⁶⁻¹⁸ or (4) administration of ketorolac, a peripherally and centrally acting nonopioid analgesic.¹⁹⁻²¹ These agents must be administered *prior* to noxious stimulation to prevent CNS changes that may be related to the development of postsurgical pain, and perhaps persistent pain. It is interesting to note that a general anesthetic state does not prevent neuroplastic changes induced by surgical stimulation, unless the general anesthetic technique employs high-dose opioids or ketamine. Neural impulses from surgical stimulation apparently reach the CNS evoking sensitization despite the fact that overt signs of surgical stimulation (ie, patient movement, heart rate, systemic blood pressure) are blocked by general anesthesia. This stimulus-dependent neural sensitization, characterized by receptive field expansion and the “wind-up” phenomenon,^{2,3} has been attributed to postsurgical hyperesthesia and pain.

When regional anesthesia is employed as an adjunct to general anesthesia, there is strong evidence that postoperative pain is significantly reduced, consistent with current models of central sensitization and neuroplasticity. However, to ensure that neural activities induced by surgical stimulation are fully blocked, the surgeon must administer regional anesthesia *prior* to surgical stimulation. If necessary during long procedures, the surgeon should reanesthetize the operative field and not rely solely on a general anesthetic state for CNS protection.

Jebeles and colleagues studied the effects of preemptive regional anesthesia on postsurgical discomfort associated

with tonsillectomy and adenoidectomy performed under general anesthesia.²² Twenty-two children were given either bupivacaine or saline infiltrations in the peritonsillar regions prior to surgical stimulation. For this study postsurgical analgesics were standardized for all subjects and postsurgical pain was assessed over a 10-day period by three dependent measures (ie, constant pain, pain evoked by swallowing a standard volume of water, and the time required to drink 100 mL of water based on the assumption that the rate-limiting factor for this activity is throat pain). All three dependent measures confirmed that subjects given bupivacaine regional anesthesia with general anesthesia experienced significantly less pain over a 10-day postsurgical period compared with the saline-injected group.²² Other studies have provided similar evidence that regional anesthesia, provided prior to surgical stimulation, can significantly reduce pain following craniotomy and bone harvesting from the iliac crest.^{23,24} To date no published papers have documented the efficacy of preemptive regional anesthesia on postoperative pain, or on the subsequent development of chronic pain, in the operated patient with TMJ disease. Nevertheless, existing evidence strongly suggests that the use of regional anesthesia as an adjunct to general anesthesia will significantly reduce postsurgical pain in such a patient.

Opioids administered *prior* to surgical stimulation may also reduce postsurgical hyperesthesia believed to be due to central sensitization. For example, isoflurane or isoflurane and nitrous oxide, administered in a concentration sufficient to suppress cardiovascular responses to surgical stimuli (ie, minimum alveolar concentration that blocks adrenergic responses [MACBAR]), do not inhibit formalin-induced hyperesthesia.²⁵ Formalin injected intradermally provides a potent noxious stimulus that results initially in a volley of neural activity that

sensitizes central nociceptive neurons in the pathway. This observation reinforces previous studies indicating that general anesthesia alone does not offer protection against central sensitization. However, morphine administered *prior* to formalin injection significantly reduces postinjection hyperesthesia in this model.²⁵ In fact, a significant reduction in formalin-induced hyperesthesia was also observed even if morphine was reversed by naloxone shortly after the formalin injection was administered, indicating that even a brief exposure to an opioid prior to noxious stimulation is sufficient to prevent or significantly reduce stimulation-induced hyperesthesia.²⁵ Likewise, alfentanil reduces capsaicin-induced hyperalgesia in human subjects, but only if this agent is administered prior to capsaicin administration.²⁶ Capsaicin is a vanilloid extracted from peppers that is known to selectively stimulate C-fiber neurons expressing the vanilloid receptor (VR-1). Stimulation of C-fiber neurons by capsaicin administration produces receptive field expansion and hyperesthesia by mechanisms that involve central sensitization.³ Notably, alfentanil did not effectively reduce pain scores, flare response, or secondary hyperalgesia when administered *after* an intradermal injection of capsaicin in these human studies.²⁶ These studies highlight the fact that, as is apparent for regional anesthesia, opioids are only optimally effective as modulators of central sensitization and subsequent hyperalgesia if they are administered prior to surgical stimulation.

Ketorolac is a peripherally and centrally acting nonopioid analgesic that is also an effective preemptive analgesic.¹⁹⁻²¹ In a randomized double-blind trial involving 48 patients undergoing ankle fracture surgery, ketorolac 30 mg administered prior to surgical stimulation significantly reduced postsurgical pain relative to the same amount of ketorolac administered after stimulation.²⁰

Preemptive Analgesia and Persistent Pain

Some preemptive analgesia techniques significantly reduce postsurgical pain. There is also evidence that preemptive analgesia may provide some protection against the development of some chronic pain states. Bach and colleagues reported one of the few investigations designed to assess the impact of preemptive analgesia on the evolution of a chronic pain state.²⁷ In this clinical study 25 elderly patients scheduled for a below-the-knee amputation received either treatment with epidural bupivacaine and/or morphine to produce a pain-free state for 3 days prior to surgery, or no pretreatment (control group). All patients subsequently underwent amputation under spinal anesthesia. After 6 months, none of the patients assigned to the presurgery analgesia group experienced phantom limb pain.²⁷ However, 38% of the subjects who did not receive the presurgical pain treatment had phantom limb pain at the 6-month post-amputation period. Furthermore, 27% of these subjects experienced persistent phantom limb pain at the 1-year follow-up period.²⁷

Recommendations It is recommended that, when feasible, an opioid-based or opioid-supplemented general anesthetic technique be employed for TMJ surgery. Also, regional anesthetic should be administered to cover the entire surgical field *prior* to surgical stimulation. During long procedures, the surgical field should be reanesthetized periodically. If there are no contraindications (eg, bleeding concerns), some consideration can also be given to ketorolac administration (ie, 0.5 mg/kg or 30 mg IV) *prior* to surgical stimulation. Finally, postoperative pain should also be well controlled with a combination of regional anesthesia and opioid or ketorolac analgesia. These regimens may significantly reduce postsurgical pain facilitating a shortened convalescence, and may also protect the patient from

CNS responses to surgical stimulation that may be involved in the genesis of some chronic pain states.

Postsurgical Pain Management and Pharmacologic Approaches

Effective pain management permits immediate postsurgery physical therapy by improving patient compliance, which is crucial to the establishment and maintenance of an acceptable mandibular range of motion. Based on the studies cited above, it is reasonable to assume that a continuation of effective pain control beyond the intraoperative period may offer some additional benefits in the prevention of some protracted (ie, chronic) pain states, although this remains a subject for future studies. The most common methods of postsurgical pain management incorporate a combination of opioid and nonopioid analgesics. In some instances other medications (eg, tricyclic antidepressants [TCAs], γ -aminobutyric acid [GABA]-ergics) may also offer significant pain relief for the patient with end-stage TMJ disease. Finally, some patients may benefit from nonpharmacologic approaches (eg, walking 30 min/d for 6d/wk, acupuncture, cold or hot pack applications, hypnosis, meditation, progressive relaxation, biofeedback).that can be used as a substitute for (eg, the medication-intolerant patient) or in tandem with pharmacologic approaches.

Nonopioid Analgesics Nonopioid analgesics, including salicylates (eg, acetylsalicylic acid), *p*-aminophenols (eg, acetaminophen), arylacetic acids (eg, indomethacin), arylpropionic acids (eg, ibuprofen), and keto-enolic acids (eg, piroxicam), are commonly used to manage pain that is associated with inflammation. Nonopioid analgesics block the synthesis of prostaglandins (PGs) from arachidonic acid by the action of cyclooxygenases (COXs) (Figure 51-1). Some PGs (eg, PGE₂) are known to sensitize peripheral nociceptors contributing to the development of hyperalgesia.

Two isoforms of COX are known (COX-1 and COX-2). COX-1 is constantly expressed in most tissues to provide a steady production of PGs that are required for many normal cellular functions.²⁸⁻³⁰ On the other hand, COX-2 is an inducible COX. It is not typically expressed under normal conditions, but, rather, it is synthesized in response to injury accounting for the increased production of PGs associated with inflammation.^{28,31,32} Studies indicate that some PGs (eg, PGE₂) sensitize sensory neurons to stimulation by other biochemicals, including bradykinin and histamine.³³ It is generally felt that PGs play an important role in the genesis of inflammatory pain via this mechanism. PGs, specifically PGE₂, have been detected in lavage fluid or synovial fluid samples obtained from symptomatic human TMJs in concentrations ranging from 0.1 to 3.5 ng/mL.^{34,35} These concentrations are above the dissociation constants for prostanoid receptors (ie, the concentration required for receptor binding) and are therefore physiologic. Nonopioid analgesics are believed to exert their primary effects by inhibiting the synthesis of PGs in peripheral tissues, including the TMJ.

Some nonopioid analgesics may produce analgesia by central mechanisms, perhaps by suppressing COX activity in CNS neurons or adjacent glial cells. An intrathecal administration of acetylsalicylate produced analgesia in humans suffering from late-stage cancer pain.³⁶ Furthermore, central injections of nonopioid analgesics produce antinociception in several animal models of pain.^{37,38} Therefore, it appears that some nonopioid analgesics may relieve some types of pain by both central and peripheral mechanisms.

Side Effects As noted above, it is currently believed that basal levels of PGs are generated under normal circumstances in tissues by the action of COX-1.³⁰ PGs regulate important physiologic processes in several tissues, including gastric

FIGURE 51-1 Proinflammatory molecules derived from arachidonic acid. Proinflammatory prostanoids and leukotrienes (LTs) are derived from arachidonic acid liberated from cell membrane phospholipids by phospholipases. Prostanoids are generated by the actions of cyclooxygenases (COX-1 and COX-2). COX-2 is an inducible form that is synthesized by cells stimulated by molecules produced after injury (eg, interleukin-1 β [IL-1 β], tumor necrosis factor [TNF], IL-6). Leukotrienes are generated by the actions of lipoxygenases. 12-hydroxyeicosatetraenoic acid (12-HETE) and 12-hydroperoxyeicosatetraenoic acid (12-HPETE) may be capable of stimulating nociceptors by direct action (ie, by binding vanilloid receptor 1; see text). Selective COX-2 inhibitors (eg, rofecoxib, celecoxib, meloxicam, and valdecoxib) block the activity of COX-2, thereby reducing prostanoid synthesis under inflammatory conditions. Nonselective COX inhibitors (eg, indomethacin, piroxicam, and ibuprofen) inhibit both COX-1 and COX-2 activities. At higher doses these drugs may also inhibit lipoxygenases.

mucosa, kidney, bone, and cartilage.^{39–44} For example, in the stomach nonopioid analgesic suppression of PG synthesis results in an increase in gastric acid secretion since PGs inhibit this process.³⁹ Also, the secretion of gastric mucus that provides a protective coating of the stomach lining is inhibited by some nonopioid analgesics. These combined effects, in susceptible individuals, can produce gastrointestinal irritation and bleeding. In fact, chronic users of nonopioid analgesics have a threefold greater risk of serious gastrointestinal complications compared with the risk in nonusers.⁴⁵

Selective COX-2 Inhibitors Relatively selective COX-2 inhibitors have been introduced for clinical use in an attempt to reduce systemic side effects associated with chronic nonopioid analgesic consumption. Four relatively selective COX-2 inhibitors are available in the United States at the present time: celecoxib, meloxicam, rofecoxib, and valdecoxib. There has been a general misperception that these agents provide superior analgesia relative to the

traditional nonselective COX inhibitors. However, clinical trials have generally not supported this notion. For example, ibuprofen provides superior analgesia to celecoxib following third molar extraction with a similar side-effect profile.⁴⁶ Therefore, the primary indication for the use of relatively selective COX-2 inhibitors appears to be the control of inflammatory pain in patients with gastrointestinal or renal disorders. However, it should be noted that these agents do not prevent serious gastrointestinal or renal side effects, although the incidence of their occurrence may be relatively low.

Leukotrienes: a Target for Future Therapies Leukotrienes are generated from arachidonic acid by the action of lipoxygenases. Leukotrienes (LTs), particularly LTB₄, are proinflammatory molecules that promote leukocyte chemotaxis, sensitize nociceptors, stimulate free radical production, and promote bone and cartilage destruction. LTB₄ has been detected in lavage fluids obtained from symptomatic human TMJs.³⁴

In addition to well-documented effects on bone and cartilage catabolism, some lipoxygenase products may also play an important role in nociception; they appear to be endogenous analogs of capsaicin.^{47,48} As noted above, the pepper extract capsaicin selectively stimulates nociceptors. The tertiary structures of 12-hydroxyeicosatetraenoic acid and 12-hydroperoxyeicosatetraenoic acid are very similar to that of capsaicin.⁴⁷ Furthermore, these lipoxygenase products are capable of stimulating nociceptors in a concentration-dependent fashion. This evoked activity can be inhibited by antagonists for the primary capsaicin receptor VR-1.⁴⁷ These findings indicate that some lipoxygenase products are capable of directly stimulating nociceptors. By this mechanism, these arachidonic acid products could contribute to inflammatory pain. Therefore, lipoxygenase inhibitors may have significant analgesic properties, in addition to potential inhibitory effects on LT-mediated bone and cartilage catabolism.

Recommendations At the present time the efficacies of nonopioid analgesics employed to manage pain in the patient with end-stage TMJ disease have not been determined. Some nonopioid analgesics to treat arthritic pain are effective. Therefore, one may expect to see beneficial responses to nonopioid analgesics when a significant inflammatory component underlying reported TMJ pain is suspected.

Nonopioid analgesics vary considerably in relative potency. All clinically available nonopioid analgesics suppress PG synthesis to a variable extent (ie, they differ in relative potencies for COX-1 and COX-2 inhibition) in either peripheral or CNS tissues. Some nonopioid analgesics also block LT synthesis in the recommended dose range. LTs, as noted in the previous discussion, can promote potentially detrimental effects in inflamed tissues, and some lipoxygenase products

may be endogenous analgesics. At the present time specific LT inhibitors are not available for clinical use, although compounds have been identified that hold future promise.⁴⁹ Therefore, nonopioid analgesics that inhibit both PG and LT pathways may be preferred.

All nonopioid analgesics achieve synovial fluid concentrations that are above their median effective dose (ED₅₀) following the administration of their recommended oral dose. Therefore, it is difficult to favor one nonopioid analgesic over another in this respect.

Nonopioid analgesics may be indicated when an inflammatory component of the patient's condition is suspected (ie, joint effusion, acute localized pain, local swelling, or acute posterior open bite). Clearly, nonopioid analgesics may offer significant benefits in the postsurgical period, perhaps used in combination with opioids. Given well-documented potentially serious side effects, nonopioid analgesics should be discontinued if a brief trial fails to provide significant clinical benefit or if the patient experiences side effects. If benefits are not apparent after a reasonable trial period (ie, 7–10 d) or if side effects are observed, the drug should be withdrawn. If the nonopioid is found to be effective, it can be continued. However, patients receiving nonopioid analgesics should be monitored on a regular basis for drug side effects. Furthermore, periodic tapered withdrawal trials should be performed to reassess the need for the drug.

Opioids Opioids elicit their physiologic effects via interactions with one or more subclasses of opioid receptors located in the CNS and in peripheral tissues. Three classes of opioid receptor are known to exist, designated μ -opioid receptor (MOR), δ -opioid receptor (DOR), and κ -opioid receptor (KOR). In addition, at least two subclasses of MOR and DOR receptors and four subclasses of the KOR receptor have been identified.^{50,51} Opioids

affect neurons and some non-neural cells such as leukocytes by several mechanisms, including inhibition of cyclic adenosine monophosphate (cAMP) formation, activation of G_o or G_{i/o} proteins, or altered Ca⁺⁺ or K⁺ translocation.^{52–54} Increasing evidence suggests that analgesia may be produced by opioid effects in the CNS, spinal cord, or peripheral tissues. Some types of pain may be refractory to opioid effects. For example, it is generally believed that opioids are ineffective for the relief of neurogenic pain, although there is recent evidence to the contrary.⁵⁵

In animal models of TMJ injury, activation of neurons in multiple areas of trigeminal nuclei can be demonstrated by expression of Fos.⁵⁶ Fos is a transcription factor that regulates the expression of specific genes in all cells including neurons. In neurons Fos expression is used as a measurement of activation and is typically determined using standard immunohistochemical approaches employing monospecific antibodies directed against Fos. Systemically administered morphine significantly reduces Fos expression in the trigeminal nucleus following acute TMJ stimulation in the rat.⁵⁶

Peripheral Mechanisms of Opioid Analgesia

For many years clinicians have been aware of the analgesic effects of peripherally administered opioids. Chase reported that local application of small amounts of morphine was effective in relieving toothache.⁵⁷ Hargreaves and colleagues have recently validated this early observation.⁵⁸ In this latter study endodontic patients diagnosed with acute dental infection were administered morphine (0.4 mg), lidocaine, or saline by intraligamentous injection in a randomized double-blinded fashion. These investigators found that at one-tenth the systemic dose required to relieve dental pain, morphine administered locally (ie, by intraligamentous injection) produced significant pain relief. This supports the belief that opioids can produce

relief of some types of pain by actions in peripheral tissues.

There is additional support for the concept that opioids may provide relief of TMJ pain by peripheral action. In the rat TMJ MOR has been detected at nerve terminals supplying both anterior and posterior synovial tissues, as well as other cell types, presumed to be resident macrophages, mast cells, and endothelial cells.⁵⁹ In other articular joints local injections of opioids can suppress the release of neuropeptides from peripheral nerve terminals supplying the injected joint.⁶⁰ Some neuropeptides, such as substance P and calcitonin gene-related peptide, are proinflammatory and have been detected in nerve terminals supplying the TMJ and in synovial fluid samples recovered from symptomatic TMJs.^{61–64} Release of these neuropeptides into articular tissues can generate a variety of inflammatory responses that may underlie joint pain and disease. The term *neurogenic inflammation* is used to describe this phenomenon. It is speculated that the intra-articular administration of an opioid into the TMJ could inhibit neurogenic inflammation by blocking the release of proinflammatory neuropeptides from stimulated nerve terminals located in the TMJ. Opioids employed in this fashion could be effective “anti-inflammatory” agents if this model is correct.

Despite clinical and animal studies that suggest that peripherally administered opioids produce analgesic responses, studies examining the effects of intra-articular morphine on TMJ pain remain equivocal.^{65–67} In the largest of the three published studies to date, 53 patients diagnosed with unilateral TMJ arthralgia or osteoarthritis were assigned to one of three groups receiving a single intra-articular injection of 1 mg morphine sulfate, 0.1 mg morphine sulfate, or saline.⁶⁷ The dependent measures employed in this study included pain at rest, assessed by a standard visual analog scale, pain at maximum opening, pressure pain

threshold, and mandibular range of motion measurements (ie, maximum vertical opening, lateral and protrusive movements). Significant group differences in pain at maximum opening were not observed until 4 days after the injection in subjects given the 0.1 mg morphine dose. Subjects reported less pain at maximum opening indicating that intra-articular morphine lessened mechanical allodynia (ie, pain with non-noxious mechanical stimulation or movement). However, no dose response was observed (ie, the higher dose of morphine did not produce a similar or greater effect), and pain at rest was not affected by intra-articular morphine. The pressure pain threshold was significantly elevated (ie, more pressure required to produce pain) at the 1-week follow-up period in patients given the 0.1 mg dose of morphine.

Several factors may govern responses to locally administered opioids. Opioids do not produce measurable effects when administered into normal peripheral tissues.⁶⁸⁻⁷⁰ However, when injected into inflamed peripheral tissues, opioids may reduce pain,^{58,71} inhibit plasma extravasation and edema,^{72,73} and alter leukocyte function.^{74,75} Animal studies have demonstrated potent effects of opioids injected into inflamed tissues.⁷⁶ For example, PG-induced hyperalgesia is suppressed by nanomolar concentrations of opioids.⁷⁶ The primary mechanism(s) by which opioids exert their influence in inflamed peripheral tissues is unknown. From previous studies of opioid receptor distribution in the TMJ, it appears that a variety of cells, including neurons, leukocytes, synoviocytes, and endothelial cells, can respond to peripherally administered opioids.⁵⁹ Therefore, it is likely that opioids exert their effects on both neural and non-neural cell populations in inflamed tissue. It is also possible that some inflammatory molecules (eg, bradykinin, PGs) may “sensitize” opioid receptors to opioid stimulation.

Factors Affecting Response to Peripheral and Central Opioids Responses to peripherally administered opioids may be sex dependent. Cai and colleagues examined jaw muscle electromyographic activity in the rat following an injection of glutamate, an algescic amino acid, into the TMJ.⁷⁷ Peripherally applied morphine significantly reduced glutamate-evoked muscle activity in male Sprague-Dawley rats but not when administered to female animals. This observation is consistent with sex-based differences in neural responses following systemically administered opioids. Brainstem neural responses to intense noxious stimulation of the TMJ are obtunded by a prestimulation systemic administration of morphine in male rats to a much greater extent than is observed in female animals.⁵ Morphine is predominantly a MOR agonist. Interestingly, a KOR agonist was found to attenuate brainstem responses to TMJ stimulation in the female to a greater extent than in the male.⁵ These observations indicate that sex hormones may differentially regulate the expression of different opioid receptor types, and that males and females may therefore differ significantly in responses to different opioids (eg, MOR agonists vs KOR agonists). Further research is clearly needed in this area to confirm sex-based differences in opioid receptor expression in the CNS and in peripheral tissues such as the TMJ.

Another factor that may govern responsiveness to opioids is the genetic backdrop of the patient. Polymorphisms of opioid receptor genes could account for some of the variability observed in response to opioids. Polymorphisms are subtle gene mutations that result in the production of a protein, in this case an opioid receptor that differs from native protein with respect to structure and function. Some gene polymorphisms may perturb function of the protein, whereas others may enhance function. Studies are needed to determine whether polymor-

phisms of opioid receptors explain apparent individual differences in clinical response to either peripherally or systemically administered opioids.

Chronic Opioid Therapy Drug dependency or addiction, reinforcing drug-seeking behavior, drug-induced depression, drug tolerance, and fear of government prosecution are frequently cited reasons for avoiding opioids in management protocols for chronic pain patients. Until recently each of these concerns was considered a valid reason for avoiding opioid therapy. However, recent evidence suggests that the risk of addiction may be extremely low in chronic pain patients with no prior history of substance abuse.⁷⁸ Drug use alone does not appear to be the major determinant of addiction. Rather, other factors such as social, psychological, and economic conditions appear to contribute more to addictive behavior.⁷⁹ Psychiatric consultation may be valuable in the identification of individuals with true addictive behavior.

Despite clinical impressions to the contrary, studies have not validated concerns regarding development of opioid tolerance. These data indicate that the analgesic potency of opioids seldom declines over time, unless there is a worsening of the patient’s physical condition.⁸⁰⁻⁸² Furthermore, cross-tolerance is often incomplete in patients who do exhibit signs of opioid tolerance.^{83,84} In these instances switching to another narcotic can produce an analgesic response. Future studies are required to determine the true benefits and risks of protracted opioid therapy to manage persistent pain experienced by the patient with end-stage TMJ disease.

Indications for Opioid Therapy Opioids do not appear to be effective for all types of pain. It is often difficult to determine whether the apparent lack of efficacy observed in some patients is due to this

fact or if the dose administered is simply inadequate. However, a rational approach that can be employed to confirm the analgesic efficacy of opioid therapy for a specific patient is suggested in a study conducted by Dellemijn and Vanneste.⁵⁵ These investigators used an active placebo (diazepam) and an inactive placebo (saline) to demonstrate the analgesic efficacy of an opioid (fentanyl) in patients suffering from neuropathic pain. In this particular study diazepam was no more effective than saline as an analgesic. However, diazepam did produce a sedative effect similar to that produced by fentanyl and was therefore suitable for use as an active placebo. Using this experimental design, the investigators demonstrated the analgesic efficacy of fentanyl for control of neuropathic pain. A similar approach could be employed to determine whether opioid therapy would provide effective analgesia for a particular patient with end-stage TMJ disease. In this way, the clinician could provide a better estimate of the benefit-to-risk ratio of opioid therapy.

As-needed dosing schedules for opioids are avoided. It is preferable to dose opioids on a scheduled basis for optimum control of pain. For example, if the patient indicates that pain is worse in the late morning and afternoon hours, then an adequate loading dose of the opioid should be administered 1 to 2 hours prior to the morning peak pain period with supplemental dosings at 3- to 6-hour intervals depending on the drug. During the titration period patients may be asked to log their pain using a 0 to 10 intensity scale at hourly intervals. Dose adjustments can then be made based on patient reports of pain. Some consideration should be given to the use of long-acting opioids or alternate delivery systems (eg, transdermal, implanted infusion pumps) in those instances when severe protracted pain is controlled by opioid therapy. This approach may be more cost effective and can provide better long-term pain relief.

TCAs Imipramine was the first TCA found to possess analgesic properties.^{85,86} Since that time numerous well-controlled trials have documented pain relieving effects of TCAs.⁸⁷⁻⁹⁰

Mechanism of Antinociception TCAs produce significant analgesia independent of their antidepressant effects. For example, analgesic effects of TCAs are observed in pain patients with normal mood.^{91,92} Furthermore, TCA-induced analgesia is typically observed prior to antidepressant effects and at doses that are generally believed to be too low for any significant antidepressant effect.⁹³⁻⁹⁵

Amitriptyline and imipramine, antidepressants with antinociceptive actions, are potent inhibitors of serotonin reuptake.⁹⁶ Though these agents have no direct effect on norepinephrine reuptake, their metabolites are also potent norepinephrine reuptake inhibitors.⁹⁶ In vivo, these TCAs can be viewed as mixed monoamine reuptake inhibitors (ie, they inhibit the reuptake of both serotonin and norepinephrine).

TCAs enhance the biologic activities of serotonin and norepinephrine by reuptake blockade. Monoamine receptor occupancy is increased by reuptake inhibitors (ie, TCAs) resulting in an antinociceptive effect. There is recent evidence that monoamines may be important modulators of temporomandibular pain.⁹⁷ This is strongly suggested in studies investigating the relative sensitivities of patients who express different versions of the catechol O-methyltransferase (COMT) gene (ie, polymorphisms) to painful masseter muscle stimulation. COMT is an enzyme that regulates noradrenergic neurotransmission by catecholamine metabolism. The gene for COMT exists in a variety of forms created by subtle mutations (ie, polymorphisms). A COMT gene polymorphism exists at codon 158 (a codon is a three-nucleotide deoxyribonucleic acid sequence that encodes a specific amino acid of the encoded protein, in this

instance COMT), where a valine code is substituted by a methionine code. This substitution results in a COMT variant that is three to four times less active than the native COMT. Individuals who are homozygous for this COMT variant report significantly more pain following a hypertonic saline injection of the masseter muscle relative to those individuals who express the normal variant.⁹⁷ Interestingly, these individuals also show a reduction in endogenous opioid responses to this stimulation in discreet regions of the thalamus as assessed by functional magnetic resonance imaging studies.

Efficacy for Relief of Muscular Pain Amitriptyline significantly reduces the duration and frequency but not the intensity of chronic tension-type headaches.^{89,98} However, selective serotonin reuptake inhibitors do not appear to affect chronic tension-type headaches.⁸⁹ Appropriately controlled clinical studies have also provided evidence that amitriptyline is effective in relieving pain associated with fibromyalgia.⁹⁹⁻¹⁰³ However, sustained clinical improvement occurs in a relatively small percentage of fibromyalgia patients given this agent.

Efficacy for Relief of Neuropathic Pain As appears to be the case for relief of muscular pain, antidepressants with mixed serotonin and norepinephrine reuptake inhibition (eg, amitriptyline) are more efficacious than relatively selective reuptake blockers (eg, predominant norepinephrine reuptake inhibition by desipramine; predominant serotonin reuptake inhibition by paroxetine or citalopram) with respect to relief of neuropathic pain.^{92,104-108} The efficacy of mixed serotonin and norepinephrine reuptake inhibitors has been demonstrated for various types of neuropathic pain. For example, 53% of patients with neuropathic pain following treatment of breast cancer had a > 50% reduction in pain at a

median daily dose of 50 mg of amitriptyline.¹⁰⁵ Amitriptyline has also been shown to be more effective than placebo for relief of pain associated with diabetic neuropathy, postherpetic neuropathy, and central lesions.^{92,104–108} Some multiply operated patients with end-stage TMJ disease may suffer from neuropathic pains, typically described as “sharp” or “burning,” that likely result from traumatic injury to peripheral neurons during surgery. When this is suspected, it may be appropriate to consider a mixed serotonin and norepinephrine reuptake inhibitor (eg, amitriptyline).

Dosing Recommendations There is a tremendous intersubject variability in the pharmacokinetics of some TCAs. This is believed to be due, in part, to expressed polymorphisms of the sparteine/debrisoquin oxygenase system that governs metabolism of the TCAs.¹⁰⁹ Given the wide intersubject variability in TCA pharmacokinetics, standard-dose regimens may be poorly tolerated or ineffective for a particular individual. Therefore, these drugs should be titrated to effect. It should be also remembered that only 50 to 70% of patients are responders (ie, individuals who experience a desired effect), and often the response to the drug is modest. Although there is a general perception that the analgesic response to TCAs is delayed, studies have actually documented a relatively rapid analgesic response to these agents. In fact, as previously mentioned, measurable antinociceptive effects have been observed after a single dose.⁹⁵ Therefore, an analgesic response should be expected within 1 week of the administration of an effective TCA dose, but a maximum response may not be observed for 4 to 6 weeks.

For most patients amitriptyline is the TCA of choice for pain management in the patient with end-stage TMJ disease. Other TCAs (eg, desipramine) may be less effective for relief of pain owing to their relative

selectivities for monoamine reuptake inhibition. In most instances amitriptyline may be administered as a single dose given at bedtime. An initial dose of 10 to 25 mg is typical for this application. The dose may be increased at 2-week intervals to a range of 10 to 75 mg/d based on subjective pain reports by the patient and drug tolerance. It should be recognized that a therapeutic window has been observed for some TCAs, with maximum analgesic responses typically observed at lower doses.^{110,111} For this reason a ceiling dose of 75 mg (1 mg/kg) amitriptyline for an adult is recommended. If significant pain relief is not observed after trial dosing up to this recommended ceiling, then the agent should be withdrawn by a tapering regimen. If significant pain relief is observed, then the agent should be continued at the effective dose. Periodic tapered withdrawals of the agent are recommended to ascertain the need for continued dosing.

TCAs can usually be administered with few side effects observed at recommended doses. However, side effects including morning sluggishness, urinary retention, weight gain from enhanced appetite, sleep disturbances, and constipation are reported by some patients. Serious side effects, such as cardiac dysrhythmias/myocardial infarction, seizures, stroke, agranulocytosis, and thrombocytopenia, are very rare with low-dose regimens in patients who are not otherwise medically compromised. TCAs should be administered cautiously in patients with a history of cardiovascular disease, seizure disorders, or urinary retention or who concurrently take medications that can influence monoamine activities (eg, antidepressants/antipsychotics, tramadol).

Drug-Induced Bruxism and Jaw Clenching

Patients with end-stage TMJ disease may be subjected to drugs that can exacerbate their condition by induction of focal dystonias leading to increased bruxism or jaw clenching. For example, bilateral masticatory myalgia with TMJ symptoms was ob-

served shortly after the administration of sustained-release bupropion in a 44-year-old man for relief of depression secondary to chronic lower back pain and tension headaches.¹¹² These temporomandibular symptoms developed within 48 hours of a dose adjustment from 150 mg/d of sustained-release bupropion to 300 mg/d. Furthermore, these symptoms resolved completely with withdrawal of the medication. Dystonic reactions to some antipsychotic and antidepressant medications may result from an acute reduction in dopaminergic activity in the brain.^{113,114} Ninety percent of these reactions occur within 3 to 5 days of drug initiation or dose adjustment.¹¹² Selective serotonin reuptake inhibitors (eg, fluoxetine, citalopram, paroxetine, and sertraline) may evoke this response. Ironically, some patients with end-stage TMJ disease are placed on these agents to manage the inevitable depression that occurs in this group of patients. In some of these patients, it is conceivable that the antidepressant could worsen their condition by evoking focal dystonic reactions or bruxism affecting the masticatory and cervical musculature. Such a response could provoke additional muscle pain and may even aggravate a TMJ condition by increasing mechanical loads.

Opioid addiction may be associated with exaggerated oromotor behavior and signs and symptoms of temporomandibular dysfunction. Winocur and colleagues studied 55 individuals who were addicted to opioids and were receiving treatment at a methadone clinic.¹¹⁵ A sex-, age-, and socioeconomic class-matched nonaddict group served as the control in this study. The addicted group exhibited a higher frequency of bruxism and jaw clenching, as well as morning headache, TMJ noises, and masticatory muscle tenderness. It is unclear from this study whether the apparent effects on the stomatognathic system were a direct manifestation of chronic opioid use or a mere reflection of a personality disorder that led to an opioid addiction.

Nevertheless, many patients with end-stage TMJ disease undergo chronic opioid therapy for pain management. In some instances it is possible that induction of focal dystonias in patients with end-stage TMJ disease by opioids could exacerbate their condition, resulting in an escalation in pain that could be confused with opioid tolerance. If this phenomenon is suspected, then a tapered withdrawal of the opioid should be initiated. Contrary to the reaction expected with an opioid-tolerant patient, opioid withdrawal in this instance may provide paradoxical pain relief.

GABAergics GABA is an inhibitory neurotransmitter that has been implicated in nociception modulation.^{116–118} GABA effects are mediated via at least two different types of GABA receptors: GABA_A and GABA_B.^{119,120} A third GABA receptor, GABA_C, may also exist, but its distribution appears to be exclusively restricted to the retina of the eye.¹²¹

GABA_B receptors are inhibitory G-protein coupled receptors that attenuate neural activities.^{120,122} The classic agonist for the GABA_B receptor is baclofen. Baclofen administered either systemically or intrathecally suppresses allodynia and hyperalgesia in animal models of pain.^{123,124} In a clinical study of lower back pain, 30 to 80 mg/d baclofen was found to be superior to placebo as an analgesic.¹²⁵

Gabapentin has been used to reduce pain associated with some neuropathic states including pain that is sympathetically maintained.¹²⁶ Gabapentin appears to elicit this effect by increasing the endogenous synthesis of GABA. Gabapentin's analgesic effects appear to be pain-type specific. In acute pain animal models, gabapentin does not produce analgesia.

Based on available data, it may be reasonable to consider a trial of baclofen (30–80 mg/d) or gabapentin (300–1800 mg/d) for patients with end-stage TMJ disease who may be suffering from a neuropathic component of pain. As previ-

ously mentioned, this might result from previous injury to neurons innervating tissues of the TMJ region. However, given the limited data demonstrating efficacy for temporomandibular pain, particularly in the patient with end-stage TMJ disease, these agents should be reserved for use after other approaches have been tried.

Sympathetically Maintained Pain

Sympathetically maintained pain (SMP), reflex sympathetic dystrophy, causalgia, and most recently complex regional pain syndrome (CRPS) are terms often used by clinicians in reference to a syndrome(s) characterized by continuous burning pain believed to be associated with abnormal nociception affected by activity in the sympathetic nervous system. CRPS typically follows traumatic injury to the affected region. Some multiply operated patients with end-stage TMJ disease with localized tactile or mechanical allodynia and burning pain complaints may be suffering from sympathetically driven pain. However, the incidence of CRPS in patients with end-stage TMJ disease is unknown.

Clinical Presentation Signs or symptoms of CRPS occurring with an incidence of 75% or greater include weakness (95%), pain (93%), altered skin temperature (92%), skin color change (92%), limited range of motion (88%), and hyperesthesia (75%).¹²⁷ Less common findings include edema, altered hair growth, tremor, hyperhidrosis, muscle/skin atrophy, and bone resorption.¹²⁷

The mechanism(s) underlying the development of CRPS is unknown. However, there is emerging evidence that suggests that this condition may result from neuroplastic changes induced by peripheral sensory nerve injury. In animals the sprouting of sympathetic neurons into sensory ganglia (ie, dorsal root ganglia) has been observed after injury to peripheral sensory nerves. This sprouting may be induced by a

neurotrophic substance, known as nerve growth factor (NGF), that is released into injured tissues.^{128–132} A similar response is observed in animals in which NGF is administered intrathecally.¹³² These data are consistent with the belief that CRPS results from an abnormal sympathetic input to sensory ganglia following peripheral sensory nerve injury. This abnormal sympathetic input may be made possible by the development of physical connections between sympathetic neurons and primary afferent sensory neurons. Injury may elicit this abnormal response via molecular intermediates, specifically NGF. Clearly this phenomenon does not occur in all individuals who sustain injuries to sensory peripheral nerves. Future research is needed to confirm this model and to determine risk factors that govern an individual's susceptibility to the development of CRPS.

Treatment Over 25 treatments for CRPS have been reported in the literature.¹³³ The most common therapeutic approach has involved the interruption of sympathetic activity via a stellate ganglion block. An effective stellate ganglion block may produce protracted pain relief (ie, lasting longer than the duration of anesthetic blockade), although this effect is usually transient. Other pharmacologic interventions (eg, phentolamine, prazosin, bretylium, guanethidine, calcitonin, nifedipine, gabapentin) and surgical sympathectomy have also been employed with inconsistent results.¹³³ With new information concerning the molecular events that may underlie the development of CRPS, it is hoped that more effective therapies will be developed in the near future.

Physical Therapy

A primary goal of all therapies directed to the management of the patient with end-stage TMJ disease is to restore normal joint function (ie, joint movement). Patients with end-stage TMJ disease typically exhibit severely restricted jaw move-

ments. Pain and intra-articular fibrosis or fibro-osseous ankylosis often coexist to restrict jaw movement. For this reason, pain management must be effective for optimum patient compliance with prescribed physical therapy.

Passive jaw exercises are effective at improving joint function if they are performed regularly over an extended period of time. Two devices are currently commercially available that facilitate passive motion of the TMJ. Alternatively, passive motion exercises can be performed with simple finger crossover maneuvers or with tongue depressor blades.

A simple but effective protocol incorporating passive motion exercises to increase mandibular movements in the patient with end-stage TMJ disease involves repetitive (10–12 times daily) vertical opening exercises. For these exercises the patient is given a number of tongue depressor blades that, when inserted between the maxillary and mandibular teeth, produce an opening of the jaws that is barely tolerated by the patient. The patient is instructed to apply these tongue depressor blades hourly (8–10 times daily) for 2 to 3 minutes. On the first day of each week, the patient is instructed to increase the total number of tongue depressor blades used by addition of one blade. This approach permits tissues to gradually adapt to advancing jaw movements and is generally well tolerated by the majority of patients with end-stage TMJ disease.

Therapy for Periarticular Ectopic Bone Formation

Periarticular ectopic bone formation is viewed as a significant postsurgical complication with a negative impact on functional outcomes in some patients with end-stage TMJ disease. Ectopic bone may form in adjacent native periarticular tissues or proximate to alloplastic materials used to reconstruct the TMJ. In either instance, periarticular ectopic bone formation is viewed as pathologic since it

typically restricts normal joint movement and may contribute to ongoing pain.

The pathogenesis of periarticular ectopic bone formation is poorly understood. It has been suggested that displaced osteogenic precursor cells are stimulated to form ectopic bone by inflammatory mediators formed in response to surgical insult.¹³⁴ Alternatively, osteoinductive molecules (eg, bone morphogenetic proteins) may be dispersed into periarticular tissues during surgery, resulting in the stimulation of resident pluripotent cells and subsequent ectopic bone synthesis. In addition, there may be other factors, such as genetics, sex hormones, systemic disease (eg, ankylosing spondylitis, Paget's disease), or other local conditions, that could also contribute to the formation of ectopic bone in periarticular tissues of the TMJ.

Two strategies have been employed in an attempt to prevent or minimize periarticular ectopic bone formation in either orthopedic surgery patients or those with TMJ disease. These are low-dose radiation therapy, and nonsteroidal anti-inflammatory drug (NSAID) therapy.

Low-Dose Radiation Therapy Some clinicians have advocated the use of low-dose radiation to prevent or minimize postsurgical fibro-osseous ankylosis of the TMJ.^{135–138} This approach is based on an earlier report indicating that low-dose radiation may be effective at preventing the formation of ectopic bone following hip arthroplasty.¹³⁹ For prevention of periarticular ectopic bone formation of the TMJ, fractionated total doses of 10 to 20 Gy have been used. One study reported that 10 Gy dosing was as effective as higher-dose regimens.¹³⁶

Timing appears to be critical for optimum results from low-dose radiation therapy. It is believed that low-dose radiation therapy elicits its effect on ectopic bone formation by prohibiting the proliferation of pluripotent cells that are precursors to osteoblasts. Therefore, it is rec-

ommended that low-dose radiation therapy be initiated within 4 days of surgery to provide optimum suppression of ectopic bone formation. Although there is some concern that early postsurgical radiation may have a detrimental impact on wound healing, in a recent study of the efficacy of a single dose of 600 cGy administered between postsurgical days 2 and 4 (mean 3.2 d), radiation did not appear to significantly impact wound healing after hip arthroplasty.¹⁴⁰

Radiation therapy was used to prevent ectopic bone formation in the periarticular region of the TMJ in a 53-year-old man.¹³⁷ This individual sustained mandible fractures in an automobile accident and subsequently underwent five operations to correct a TMJ ankylosis suffered as a complication of his injury. Over an 18-year period, the patient suffered from a significant limitation of jaw movement, with reported maximum interincisal movements as low as 6 mm. Following his final TMJ arthroplasty, the patient underwent fractionated cobalt radiation therapy consisting of ten sessions beginning on the first postoperative day. The patient received a total radiation dose of 20 Gy in equal fractions. He apparently tolerated the procedure well without significant complications. At the 3-year follow-up, the patient had sustained a maximum interincisal distance of 25.5 mm.¹³⁷

Schwartz and Kagan provided a report describing a similar beneficial effect of fractionated radiation (ie, 20 Gy in 10 fractions) in a 51-year old man who experienced a zygomatico-coronoid ankylosis following a depressed fracture of the zygomatic arch.¹³⁸ This condition was surgically treated with a 5 mm gap arthroplasty with placement of an intervening sheet of silicone rubber. Postsurgical radiation was initiated 1 week after the operation. At a 19-month follow-up, the patient exhibited a 40 mm maximum interincisal distance. Although the patient initially complained

of xerostomia and had some loss of facial hair, there were no reported lasting ill effects from this treatment.

Experiences with 10 patients suffering from bony ankylosis of the TMJ were reported by Durr and colleagues.¹³⁶ Four men and six women (median age 32.5 yr, range 14–59 yr) with a previous history of TMJ ankylosis underwent TMJ arthroplasties and immediate postsurgical (ie, 1–3 d) radiation therapy consisting of 10 to 11.2 Gy in five fractions over a 5-day period. The median follow-up for this reported case series was 19 months (range 7–31 mo). Only three patients (ie, 30%) were followed up for > 2 years postoperatively. Forty percent of the patients in this series experienced some recurrence of ectopic bone formation as assessed radiographically. A parotitis was identified in 30% of the patients in this series. However, the radiation therapy did not appear to interfere with healing, and there were no other reported complications.

Reid and Cooke have reported the largest case series to date involving postoperative radiation therapy to manage ectopic bone formation of the TMJ in 14 patients with histories of multiple TMJ surgeries.¹³⁵ Each patient underwent TMJ arthroplasty with total joint reconstruction using an alloplastic prosthesis. The majority of these patients received a fractionated 10 Gy radiation dose beginning on the first postoperative day. However, some patients treated early in the series received a fractionated 20 Gy radiation dose. Patients in this series were followed up postoperatively with a mean follow-up of 4.2 years (range 1–9.6 yr). The recurrence rate for ectopic bone formation at the 1-year follow-up was 21%. However, long-term follow-up revealed ectopic bone formation in 75% of the patients seen at 5 years and 100% ($n = 2$) of patients examined at the 9-year follow-up (Figure 51-2). Consistent with earlier reports, no significant persistent side effects of radiation therapy were noted.

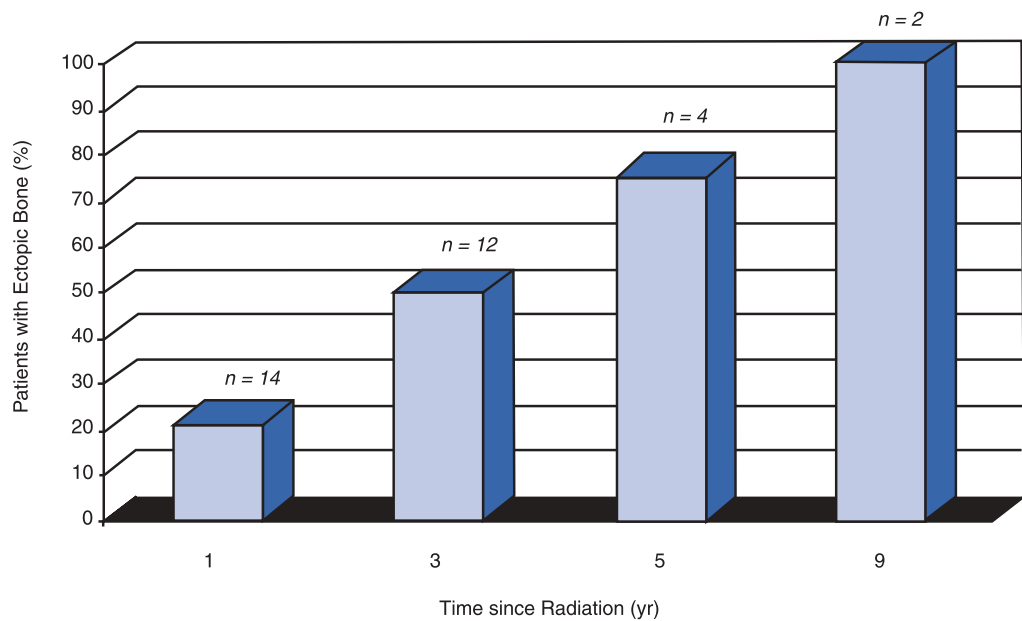

FIGURE 51-2 Recurrence of ectopic bone in patients treated with low-dose radiation. Data adapted from Reid R and Cooke H.¹³⁵

A major concern with the use of low-dose radiation for the treatment of ectopic bone formation in the TMJ area is the potential for induction of neoplasias. Despite the fact that there have been no reported cases of malignant transformation associated with low-dose radiation therapy used to manage periarticular ectopic bone formation in the TMJ area, this concern seems justified based on a report by Ron and colleagues.¹⁴¹ These investigators examined 10,834 patients who had undergone low-dose radiation therapy for the treatment of ringworm infection of the scalp (ie, tinea capitis). All irradiated subjects received treatment (mean radiation dose 1.5 Gy) before the age of 16 years. Controls included 10,834 nonirradiated age- and sex-matched individuals not related to the radiated subjects, serving as a general population control, and 5,392 nonirradiated siblings of the subjects. The subjects were monitored for up to 33 years for the development of benign and malignant neural tumors. Tumors developed in 73 individuals, 60 among irradiated subjects, 8 in the general population control group, and 5 among siblings of irradiated subjects. Overall,

there was a sevenfold increase in neoplasms of the nervous system in individuals who had undergone low-dose radiation therapy. Twenty-four malignant neoplasias were identified in this study, with 18 occurring in irradiated patients, 4 in the general population control group, and 2 in siblings of irradiated subjects. There was a 4.5-fold increase in the incidence of malignant neoplasias in patients who underwent low-dose radiation therapy relative to the control groups. The cumulative risk of developing a neural tumor over a 33-year period was significantly higher in the irradiated group ($0.84 \pm 0.16\%$) than in the controls ($0.09 \pm 0.03\%$). It should be noted that there was a prolonged latency of tumor occurrence (mean 17.6 yr after radiation exposure). From this study it appears that the risk of radiation-associated tumors was highest between 15 and 24 years postradiation. This has significance in light of the fact that the longest published follow-up for any case series reporting the effects low-dose radiation therapy for management of ectopic bone formation in the TMJ area is 9 years (only two patients).¹³⁵ It should be noted that patients receiving radiation

therapy for tinea capitis in this study were significantly younger (< 16 yr old) than the TMJ patients reported in the series cited above. It is possible that the risk of radiation-associated neoplasia may be age dependent. However, this assumption has not yet been validated in appropriately designed studies.

In summary, the evidence supporting the use of low-dose radiation therapy to prevent or minimize ectopic bone formation in periarticular regions of the TMJ is supplied by case summaries that report beneficial effects with 10 to 20 Gy exposures in fractionated doses initiated within 4 days of surgery. However, it should be recognized that definitive studies (ie, appropriately blinded and controlled) have not been reported to date. In the absence of these studies, the true efficacy of this therapy remains obscure. Furthermore, there is evidence that such therapy may pose significant long-term health risks.¹⁴¹

NSAID Therapy Several studies have provided evidence that NSAIDs may be effective retardants of ectopic bone formation.^{140,142-145} The mechanism(s) by which these drugs elicit this effect is currently unknown. However, the effect is believed to be secondary to the ability of these drugs to inhibit prostanoid, and perhaps LT, synthesis associated with normal inflammatory responses to injury.

Kienapfel and colleagues compared the effects of indomethacin, a nonselective COX inhibitor (also capable of inhibiting lipoxygenase), with those of low-dose radiation therapy employed to prevent ectopic bone formation after hip arthroplasty.¹⁴⁰ For this study 154 patients scheduled for hip arthroplasty to treat various degenerative arthritides were randomly assigned to one of three groups: (1) low-dose radiation treatment (600 cGy administered as a single dose between postoperative days 2 and 4); (2) indomethacin treatment (50 mg administered orally twice a day beginning

on postoperative day 1 and continuing until postoperative day 42); or (3) control (no postoperative radiation or NSAID). Patients assigned to the indomethacin treatment group who were either at risk for NSAID-induced gastrointestinal disease or who developed dyspepsia with the therapy were given cimetidine 200 mg (H₂ receptor antagonist) concomitantly.

All subjects enrolled in the study were assessed clinically and radiographically 18 months after surgery.¹⁴⁰ Ectopic bone formation was significantly inhibited by both treatment conditions relative to the control. Furthermore, both treatments were found to be equally effective. Surgical wound secretions were more persistent in the radiated subjects postoperatively, but neither treatment group subsequently exhibited signs of poor wound healing that were significantly different from the control. The incidence of dyspepsia was higher in the indomethacin-treated group, but gastrointestinal bleeding was not detected in this group.

Other NSAIDs have been used to prevent or minimize ectopic bone formation following hip arthroplasty, including ibuprofen, ketorolac, and diclofenac.^{142,143,145} All of these agents are nonselective COX inhibitors (ie, they block by COX-1 and COX-2). At the present time it is not known whether the selective COX-2 inhibitors are effective retardants of ectopic bone formation.

To date there have been no reported studies of NSAID use for the management of ectopic bone formation of the TMJ. Therefore, the efficacy of these agents for this specific application remains to be demonstrated. However, based on the orthopedic surgery literature, it may be prudent to consider NSAID therapy for patients who are at risk for ectopic bone formation following TMJ surgery. The potential gastrointestinal and renal complications associated with this approach should not be underestimated. Patients undergoing NSAID therapy to prevent or

minimize ectopic bone formation should be properly monitored. If indicated, misoprostol or an H₂ receptor antagonist should be administered concomitantly to reduce the potential for serious gastrointestinal complications.

Conclusions

The patient with end-stage TMJ disease is typically afflicted by severe unrelenting pain, restricted jaw function, facial deformity, depression, compromised interpersonal relationships, and financial hardships. Given the complexities involved, these patients pose a significant challenge for the most experienced clinicians. A coordinated team of specialists best provides optimum care. However, in most communities this level of care is not available. The local oral and maxillofacial surgeon is often looked on as the specialist who will manage these complicated cases. For the multiply operated patient with end-stage TMJ disease, few surgical options are viable. In these instances medical management is advised with primary treatment objectives typically being pain management and improvement in jaw movements. When surgery is contemplated, it is imperative that the surgeon complete an accurate assessment of the patient's condition. The surgeon must establish realistic surgical objectives based on this assessment. Finally, the surgeon must exercise good judgment in the selection of patients for surgery. Patients who are incapable or unwilling to comply with demanding but essential postsurgery rehabilitation programs may not be viable candidates for surgery, even when feasible surgical objectives are identified.

Hypomobility and Hypermobility Disorders of the Temporomandibular Joint

Meredith August, DMD, MD

Maria J. Troulis, DDS, MSc

Leonard B. Kaban, DMD, MD

Hypomobility

Etiology

The etiology of mandibular hypomobility is varied, and successful treatment requires an understanding of the underlying disorder. Trauma is the most commonly identified cause, followed by infection (odontogenic, otitis media, and mastoiditis). Various systemic disease states have been associated with hypomobility, including ankylosing spondylitis, rheumatoid arthritis, and other collagen vascular diseases such as scleroderma. Iatrogenic causes have also been identified and include the sequelae of high-dose radiation involving the muscles of mastication, craniotomy procedures, and, uncommonly, orthognathic surgery. Internal temporomandibular joint (TMJ) derangements may also lead to chronic hypomobility problems. Traumatic perinatal events and neuromuscular conditions can result in hypomobility in infancy. In general terms, congenital ankylosis is defined as limited interincisal opening noted at birth with no

known causative factor. Table 52-1 lists the etiologic factors associated with mandibular hypomobility.

Classification

Various classification schemes have been proposed to describe hypomobility.¹⁻³

Trismus is most commonly found in conjunction with spasm of the muscles of mastication. It can be secondary to myofascial pain dysfunction, infection, trauma, tumors, and various medications as well as psychiatric and neurologic factors. Ankylosis may be classified according to location (intra-articular vs extra-articular), type of tissue involved (bony, fibrous, or mixed), and the extent of fusion (complete vs incomplete). True ankylosis is caused by either fibrous or bony fusion of the structures contained within the TMJ capsule and, in its most severe state, is characterized by a bony union of the condyle to the glenoid fossa. True ankylosis has been further classified into subtypes depending on the anatomic positioning of the condyle and the extent of bridging bone. Topazian proposed a

three-stage classification to grade complete ankylosis as follows: stage I, ankylotic bone limited to the condylar process; stage II, ankylotic bone extending to the sigmoid notch; and stage III, ankylotic bone extending to the coronoid process.⁴ Other classification schemes have also been proposed.⁵ However, the utility of these designations in terms of treatment planning is questionable. So-called false ankylosis (pseudoankylosis), in contrast, describes limited mobility based on extra-articular factors such as fibrosis, mechanical obstruction (eg, zygomatic arch fracture), muscle spasm, or other pathologies.

Clinical Presentation

Patients with fibrous or bony ankylosis present with restricted mandibular motion and, depending on the patient's age and the condition's etiology, may have an abnormality in mandibular size and shape. Unilateral pathology in children may result in significant problems with lower facial symmetry. A shortened ramus on the affected side is usually accompanied by a prominent antegonial notch

Table 52-1 Etiologic Factors Associated with Hypomobility of the Mandible

Trismus

- Odontogenic: myofascial pain, malocclusion, erupting teeth
- Infection: pterygomandibular, lateral pharyngeal, temporal
- Trauma: fracture of the mandible, muscle contusion
- Tumors: nasopharyngeal tumors, tumors that invade jaw muscles
- Psychologic: hysteric trismus
- Pharmacologic: phenothiazines
- Neurologic: tetanus

Pseudoankylosis

- Depressed zygomatic arch fracture
- Fracture dislocation of the condyle
- Adhesions of the coronoid process
- Hypertrophy of the coronoid process
- Fibrosis of the temporalis muscle
- Myositis ossificans
- Scar contracture following thermal injury
- Tumor of the condyle or coronoid process

True ankylosis

- Trauma: intracapsular fracture (child), medial displaced condylar fracture (adult), obstetric trauma, intracapsular fibrosis
- Infection: otitis media, suppurative arthritis
- Inflammation: rheumatoid arthritis, Still's disease, ankylosing spondylitis, Marie-Strümpell disease, psoriatic arthritis
- Surgical: postoperative complications of temporomandibular joint or orthognathic surgery

noted on radiographs. Such unilateral mandibular growth disturbances have secondary effects on the maxillary occlusal plane and midfacial structures (pyriform rims and bony orbits).

Ankylosis in adults is characterized by limited jaw opening and decreased translation, but the morphologic characteristics found in the growing patient are frequently absent. Loss of condylar structure and mandibular angle prominence is seen in cases caused by rheumatologic disease, specifically scleroderma. An associated anterior open bite is frequently noted with the loss of ramus/condyle height (Figure 52-1). Unilateral cases with a traumatic etiology may result in malocclusion and ipsilateral dental prematurities. A physical examination is helpful in identifying whether the process is bilateral or unilateral and may be suggestive of the etiology.

Imaging Assessment

In addition to the clinical examination, radiographic assessment is critical in evaluating and treating patients with hypomobility disorders. Plain radiographs are limited in delineating the true extent of the deformity. What can be identified with these studies are the presence or absence of a TMJ space, obvious bony abnormalities in the region of the joint, and coronoid hyperplasia. Sanders and colleagues have reported that conventional radiographs underestimate the extent of bony ankylosis and give little information about the anatomy medial to the condyle.⁶ The use of computed tomography (CT) scans (including axial, coronal, and sagittal views with three-dimensional reconstruction) is helpful in fully defining the extent of ankylosis as well as the relationship of the ankylotic mass to important anatomic

structures, especially at the skull base (pterygoid plates, carotid canal, jugular foramen, and foramen spinosum) (Figure 52-2).^{7,8} Often in post-traumatic cases the distance between the maxillary artery and the medial pole of the condyle is reduced—a contrast CT helps to determine this distance. Fusion of the ankylotic mass to the base of the skull can also be appreciated on CT scans. Since adequate treatment requires the removal of the mass in toto, knowledge of this anatomy preoperatively is critical to surgical planning and long-term success.

Magnetic resonance imaging (MRI) has had a great impact on TMJ evaluation, especially regarding the delineation of meniscal position. Diagnosis of fibrous ankylosis is possible with the use of MRI, but the CT scan is superior in demonstrating bony pathology.⁹

Post-traumatic Hypomobility

Trauma is the most common cause of bony and fibrous ankylosis as reported by multiple authors.¹⁰⁻¹² It is hypothesized that the formation of an intra-articular hematoma with subsequent scarring and new bone formation is the common precipitant. Most often, a medially displaced fracture dislocation of the condyle is found. Subsequent hypomobility is of particular concern in growing children in whom the development of hypomobility can have significant impact on facial

FIGURE 52-1 Patient with systemic sclerosis (scleroderma) demonstrating a limitation in jaw opening and skin changes characterized by perioral furrows and telangiectasia.

FIGURE 52-2 Three-dimensional (A, B) and axial (C, D) computed tomography scans of a patient with extensive bony ankylosis of the left temporomandibular joint. Note the comparison with the unaffected right side (A, C). Coronoid hyperplasia is also seen on the affected left side (B, D).

growth (Figure 52-3). In addition, resultant hypomobility can lead to speech impairment, difficulty with chewing, poor oral hygiene, limited access to dental care, and possible airway compromise. In large reviews of pediatric facial fractures, the condylar and subcondylar regions were

FIGURE 52-3 A and B, Evident mandibular growth disturbance is noted in this child who has had bilateral condylar fractures. Note the submental scar secondary to a laceration sustained at the time of the bony injury.

involved in > 40% of cases.^{13,14} In many cases a direct blow to the chin with transmission of the impact force to the condyles resulted in the fracture. Prolonged immobilization, secondary to treatment with maxillomandibular fixation, splinting, or mechanical obstruction can lead to subsequent ankylosis.

Extra-articular ankylosis can also occur with coronoid fractures and fractures of the zygomatic arch. In both cases the resultant hematoma may calcify, resulting in a fusion of the coronoid process to the zygomatic arch.

Myositis ossificans traumatica (MOT), or fibrodysplasia ossificans circumscripta, is generally associated with a traumatic event or repeated episodes of minor trauma and can result in mandibular hypomobility.^{15,16} The precise mechanism remains to be elucidated but appears to involve fibrous metaplasia and subsequent ossification of both soft tissues and muscle after bleeding and myonecrosis. Histologically, both mature and woven bone can be noted (sometimes in distinct zones), and both

FIGURE 52-4 Computed tomography scan of patient with myositis ossificans traumatica demonstrating a focus of calcification within the medial pterygoid muscle on the left side.

osteoblasts and osteocytes are abundant. MOT is characterized by soft tissue ectopic ossifications and is relatively uncommon in the head and neck regions. Of all reported cases involving the muscles of mastication, the masseter is most commonly affected. MOT involving the medial pterygoid muscle and secondary to local anesthesia injections has also been reported.¹⁷ Diagnosis is confirmed by identification of calcifications within the muscles of mastication on CT scans (Figure 52-4). Minimal response is found with physical therapy and stretching exercises; consequently, surgical treatment is often undertaken to remove the ectopic bone. Other treatment modalities include acetic acid iontophoresis, magnesium therapy, and the use of etidronate sodium.^{18,19} Since repeated relapses and refractory cases are common, the use of multiple treatment modalities may be associated with the best outcome.

Postinfectious Hypomobility

A TMJ infection resulting in hypomobility is most commonly the result of contiguous spread from an odontogenic infection, otitis media, or mastoiditis.^{20, 21} In the era of aggressive antibiotic treatment of infection,

such reported cases are now relatively uncommon. Hematogenous spread of infection has also been reported in association with disease states such as tuberculosis, gonorrhea, and scarlet fever.

Various case series describe deep facial space infections manifesting themselves as hypomobility and often being misdiagnosed at initial presentation.^{22,23} Odontogenic infection is commonly associated with trismus. In such cases associated symptoms (fever, dysphagia) are likely present, and CT scanning is invaluable in determining a diagnosis and in treatment planning. Medial pterygoid abscess formation or fibrosis secondary to hematoma organization can be precipitated by an inferior alveolar nerve block or posterior superior alveolar block. A history of recent dental treatment should suggest this possibility; the use of CT imaging can help delineate the anatomy of the masticator and pharyngeal spaces.

Mass lesions (both benign and malignant) can also result in mandibular hypomobility. Squamous cell carcinoma of the tongue base or tonsillar pillar is often accompanied by trismus. Masses involving the mandibular condyle invariably affect range of motion and need to be included in the differential diagnosis of hypomobility.

Hypomobility following Radiation Therapy

Mandibular hypomobility is a common sequela of the treatment of head and neck malignancies (Figure 52-5). The resultant fibromyositis caused by radiation therapy may exacerbate the postsurgical problems caused by large ablative procedures.²⁴ Goldstein and colleagues reviewed the effects of tumoricidal radiation therapy on restricted mandibular opening and found a linear dose-related effect.²⁵ Mandibular dysfunction increased as the dose to the pterygoid muscles increased. The authors reported diminution in opening with doses as low as 15 Gy. Pow and colleagues reported that 30% of patients treated for

nasopharyngeal carcinoma with high-dose radiation therapy had significant trismus compared with age-matched nonradiated control subjects.²⁶ Radiation therapy for primary tumors of the retromolar trigone was associated with a 12% incidence of long-term trismus. This association, compounded by resultant xerostomia, severely compromises the ability of these patients to maintain oral health.

The efficacy of early interventional physical therapy has been described. Buchbinder and colleagues compared the outcome of unassisted exercise, mechanically assisted exercise with the use of tongue blades, and use of the Therabite System in radiated patients.²⁷ All patients presented with an interincisal opening of < 30 mm. The response to each therapy was recorded every 2 weeks over a 10-week period. All groups showed improvement over the first 4 weeks, but the group using a mechanical exercising device (ie, Therabite System) continued to demonstrate an improvement of maximal interincisal opening (MIO) over the full 10-week period that was significantly greater than that of the other two groups.

Postcraniotomy Hypomobility

Mandibular hypomobility after intracranial surgical procedures is an uncommon yet reported phenomenon.^{28,29} Mechanistically, this problem is secondary to neurosurgical procedures performed through the temporal bone requiring an incision of the temporalis muscle. Subsequent fibrosis of the muscle may then result in limited opening, which is best treated with coronoid resection followed by vigorous physical therapy. The incidence of this problem is not known, but a review by Kawaguchi and colleagues reported limited mouth opening in as many as 33% of patients undergoing frontotemporal craniotomy procedures.³⁰ Although most are self-limiting, persistent hypomobility can severely compromise subsequent airway and anesthesia management in these

FIGURE 52-5 Patient with a history of high-dose radiation therapy and subsequent reirradiation for recurrence of nasopharyngeal carcinoma. Note the severe temporal atrophy and the limitation in opening.

patients and needs to be recognized. The maximal opening is not improved with the use of muscle relaxants or local or general anesthesia. Patients who have undergone skull base surgery may also manifest severe hypomobility postoperatively. If such surgery requires the dissection of the temporalis muscle inferior to the zygoma, pseudoankylosis of the mandible may be encountered.

Inflammatory and Rheumatologic Causes

Ankylosing spondylitis (Bekhterev's disease) is a chronic and progressive inflammatory condition most commonly affecting the sacroiliac joints and the spine. The male-to-female ratio of incidence is reported to be 2.4:1, and the severity and extension of the disease in male patients is found to be more severe. TMJ involvement in ankylosing spondylitis has been reported in between 1 and 22% of affected individuals and can include severe bony deformation and ankylosis.^{31,32} The most commonly reported radiographic findings in the

condyle and glenoid fossa region include flattening, erosions, sclerosis, osteophytes, subcortical cysts, and bony erosion at the insertion of the masseter (angle of the jaw) and temporalis muscles (coronoid process). One large prospective study evaluating 50 patients with ankylosing spondylitis did not show any correlation between the bony severity noted in the cervical spine and TMJ abnormalities.³³ These authors reported a 22% incidence of TMJ involvement, either clinical or radiographic. Because the majority of patients reported no pain or limitation in function, the radiographic findings included in this study may well have represented early changes in the disease process.

TMJ involvement in rheumatoid arthritis follows the same destructive path as do other joints. Generally, the severity of joint dysfunction is correlated with the stage of rheumatoid arthritis. Radiographically, the most common findings in the condylar region are the following: sclerosis (75%), erosion (50%), and flattening (30%).³⁴ These bony changes commonly result in progressive malocclusion secondary to the loss of ramus/condyle height and subsequent apertognathia. Juvenile rheumatoid arthritis is chronic arthritis diagnosed in childhood before the age of 16 years. It is estimated that > 60% of patients with juvenile rheumatoid arthritis manifest TMJ involvement.³⁵ However, multiple authors point out that despite radiographic and morphologic changes in the joint, a minority of affected children (generally < 25%) report pain with function.^{36,37} Svensson and colleagues report that restricted mouth opening was a more common finding.³⁸ The duration of active disease and a history of pain with function correlate positively with progressive TMJ dysfunction. With active disease in growing children, abnormalities in facial growth, mandibular hypoplasia, and hypomobility are common problems (Figure 52-6).

Scleroderma (progressive systemic sclerosis) is a disorder of unknown etiology affecting multiple organ systems and char-

acterized by abundant fibrosis of the skin, blood vessels, and visceral organs. It is believed that abnormalities in small blood vessels result in the progressive thickening and fibrotic changes noted in affected tissues, particularly those of the gastrointestinal tract, heart, lung, and kidney as well as diffuse skin involvement. Mandibular movement can become severely limited in affected individuals secondary to facial skin fibrosis and atrophy of the muscles of mastication (particularly the masseter and medial pterygoid muscles).³⁹ Bony changes in the mandible are also reported and include severe resorption of the angles, condyles, and coronoid processes (osteolysis).⁴⁰ The bony lesions are believed to be of ischemic origin but may be exacerbated by the tightness of the tissue in the region of the mandibular angles causing pressure resorption as well. In addition to the severe limitation in jaw movement, the small mouth orifice and progressive malocclusion make oral function and access to dental care problematic for these patients.

Hypomobility following Orthognathic Surgery

Hypomobility following orthognathic surgery has been reported by multiple authors and appears to be most commonly associated with the bilateral sagittal split osteotomy.^{41,42} This postoperative limited opening has been commonly attributed to muscle atrophy and soft tissue scar formation. Atrophic muscular changes seem to be exacerbated by prolonged use of maxillo-mandibular fixation, and the advent of rigid internal fixation appears to have limited this problem. Intra-articular pathology (edema, hemorrhage) as well as condylar torque may also result in hypomobility. In such cases rigid internal fixation may predispose to this problem. Van Sickels and colleagues have hypothesized that condylar torque at the time of the bilateral sagittal split osteotomy may cause impingement of the condyle against the disk, causing a mechanical impediment to opening.⁴³

Management of hypomobility after orthognathic surgery depends on the underlying cause. Trauma to the muscles of mastication is best managed postoperatively by vigorous physical therapy protocols. Those patients who fail to improve within the first 3 months need to be carefully evaluated for an intra-articular source of the problem. Edema, bleeding, and fibrosis within the joint space can frequently be managed by arthrocentesis procedures, especially when recognized early. If a mechanical obstruction to opening is suspected, CT is a helpful diagnostic aid. Condylar torque is best treated by reoperation with appropriate positioning of the proximal segment.⁴⁴

General Treatment Considerations

The treatment goal for all hypomobility states is the restoration of normal and comfortable jaw motion and prevention of disease progression. Reversible causes such as muscular hyperactivity or spasm, infectious and inflammatory causes, and medication-induced limitations must be identified and treated. Restoration of function in cases of

FIGURE 52-6 Adult patient with a history of juvenile rheumatoid arthritis affecting the temporomandibular joints and resulting in a mandibular growth disturbance and hypomobility.

ankylosis can be difficult. Proper treatment requires excision of the involved structures and immediate reconstruction. Many operative techniques have been described in the literature, with varying and often less than satisfactory results. As mentioned above, understanding the etiology and anatomy of the problem is critical and can be greatly aided with CT.

The gap arthroplasty is a procedure that creates a new area of articulation distal to the fused TMJ and ankylotic segment.^{45,46} Advocates of this procedure describe its simplicity. However, the creation of a pseudoarticulation significantly shortens the ramus height, and the procedure is associated with a high degree of reported reankylosis. Development of postoperative malocclusion and a decreased range of motion are the most common problems associated with this procedure as reported by Rajgopal and colleagues.⁴⁷ Because of these limitations, the use of the gap arthroplasty to treat ankylosis has been largely abandoned.

Temporomandibular ankylosis is more commonly treated with complete excision of the ankylotic mass and, if required, by subsequent joint reconstruction. Our protocol for the treatment of ankylosis follows that documented by Kaban and colleagues, a sequential protocol for the treatment of TMJ ankylosis that is based on aggressive resection of the ankylotic mass.⁴⁸ Wide intraoperative exposure is required, and special attention is directed to the medial aspect of the joint to ensure that bony, fibrous, and granulation tissue are completely removed. In addition to this aggressive resection of the bony and fibrous mass, dissection and stripping of the temporalis, masseter, and medial pterygoid muscles followed by ipsilateral coronoidectomy are performed in all cases through the same incision. Long-standing ankylosis frequently results in muscle fibrosis and coronoid hyperplasia. After this resection is completed, the MIO is measured. If it is found to be < 35 mm,

a contralateral coronoidectomy is performed via an intraoral approach to attain the desired level of opening. Because complete resection of the ankylotic mass frequently results in substantial loss of ramus height, subsequent reconstruction must address this fact and attempt to restore occlusion as well as function. Commonly, a temporalis fascia flap and costochondral graft are employed to both line the glenoid fossa and create ramus height. The patient is placed into maxillomandibular fixation following the reconstruction, and the teeth are placed into a prefabricated occlusal splint. Fixation is maintained for approximately 10 days and after release a strict protocol of physiotherapy is employed. Overall results have been excellent with this approach. After 1 year MIO was maintained at > 35 mm in all 18 patients included in the report. Furthermore, absence of pain with function was reported in all but two patients (Figure 52-7).⁴⁸

Recently, the Kaban protocol has been modified to substitute ramus/condyle reconstruction using distraction osteogenesis, when possible, instead of costochondral grafting.⁴⁹ This protocol has the major advantage of eliminating the donor site operation and allowing for immediate vigorous TMJ mobilization. The surgical procedure for the release of the ankylosis is identical to that described above. After the release the jaw is mobilized and the glenoid fossa lined with a temporalis myofascial flap if the native disk is unavailable. The remaining mandibular stump is reshaped to create a narrow and rounded top. A corticotomy is created distally, leaving sufficient bone to serve as a transport disk. The distraction device is secured, the corticotomy completed, and the mobility of the segments tested. Distraction then proceeds at 1 mm/d until the desired length is achieved. The patient begins a program of active jaw motion exercises immediately postoperatively (Figure 52-8).

The use of total joint prostheses has an interesting history in the TMJ. Advocates

describe two major advantages over autogenous reconstruction: (1) the absence of a donor site and (2) the ability of the patient to return to function more quickly. However, multiple complications have been reported—some with devastating consequences for patients.⁵⁰⁻⁵² Foreign body reaction to any alloplast may occur. In its most severe form, extensive bony erosion in the area of the glenoid fossa has been found. Fragmentation of alloplastic material secondary to function with a migration of particles into contiguous tissue and regional lymph nodes has also been reported. Progressive wear may result in a loosening and fracture of the prosthesis. In addition, the lack of growth potential precludes the use of these joint-replacement systems in young children. Recurrent ankylosis after prosthesis placement has also been reported, with periprosthetic calcifications most commonly seen in younger patients.

TMJ reconstruction with a variety of autogenous tissues has been described. When the extent of bony resection does not severely shorten ramus height, autogenous interpositional grafts may be employed. These include skin, temporal muscle, cartilage, and fascia. A recent review by Chossegros and colleagues has demonstrated superior results (defined by the authors as an interincisal opening of 30 mm or greater over a follow-up period of 3 yr) using full-thickness skin grafts and temporalis muscle.⁵³ Various bone grafts (costochondral, sternoclavicular, iliac crest, and metatarsal head) have been used to reconstruct ramus height after the resection of ankylosis. First described in the 1920s, the costochondral graft for TMJ reconstruction was popularized in later years by Poswillo, and MacIntosh and Henny.^{54,55} Autogenous tissue (particularly the costochondral graft) has the advantage of being biologically acceptable and possessing growth and remodeling potentials that make it a particularly attractive reconstructive choice in the growing child. Potential problems with its use include fracture, resorption, donor site

morbidity, recurrence of ankylosis, and a variable growth behavior of the graft in situ.

Complications Associated with Treatment

Various complications have been reported secondary to the treatment of ankylosis. Dolwick and Armstrong caution that a severe limitation of opening can make the palpation of landmarks difficult and increases the surgical risks.⁵⁶ The aggressive bony removal and recontouring that is often required can increase the risk of development of an aural-TMJ fistula if the tympanic plate is displaced posteriorly. In addition, stenosis of the external auditory meatus and subsequent hearing impairment may follow tympanic plate displacement.

Recurrent ankylosis may result from inadequate initial treatment. It most commonly occurs on the medial aspect of the condyle where surgical access is most difficult. Such maneuvers as the postoperative use of nonsteroidal anti-inflammatory drugs and vigorous physical therapy limit problems with recurrent hypomobility.^{57,58}

In pediatric patients treated for ankylosis, the expected outcome may be less sanguine.⁵⁹ The improvement in interincisal opening, despite strict adherence to the above treatment protocol and compliance with physical therapy regimens, is often significantly less than 35 mm. Posnik and Goldstein reviewed the outcome of nine children and demonstrated a mean MIO of 24.8 mm in unilateral cases and

17.5 mm in bilateral cases measured an average of 2 years postoperatively.⁶⁰ The authors caution that improvement in bilateral congenital cases is particularly problematic and may be confounded by the associated neuromuscular and atrophic changes found in these patients.

Peripheral nerve injuries are possible sequelae of all TMJ operations, with the upper branches of the facial nerve being the most vulnerable. Parotid gland injury with subsequent sialocele and fistula formation has also been reported.

As previously described, the costochondral graft is the most commonly used autogenous material for TMJ reconstruction. However, its growth pattern can be unpredictable. Linear overgrowth

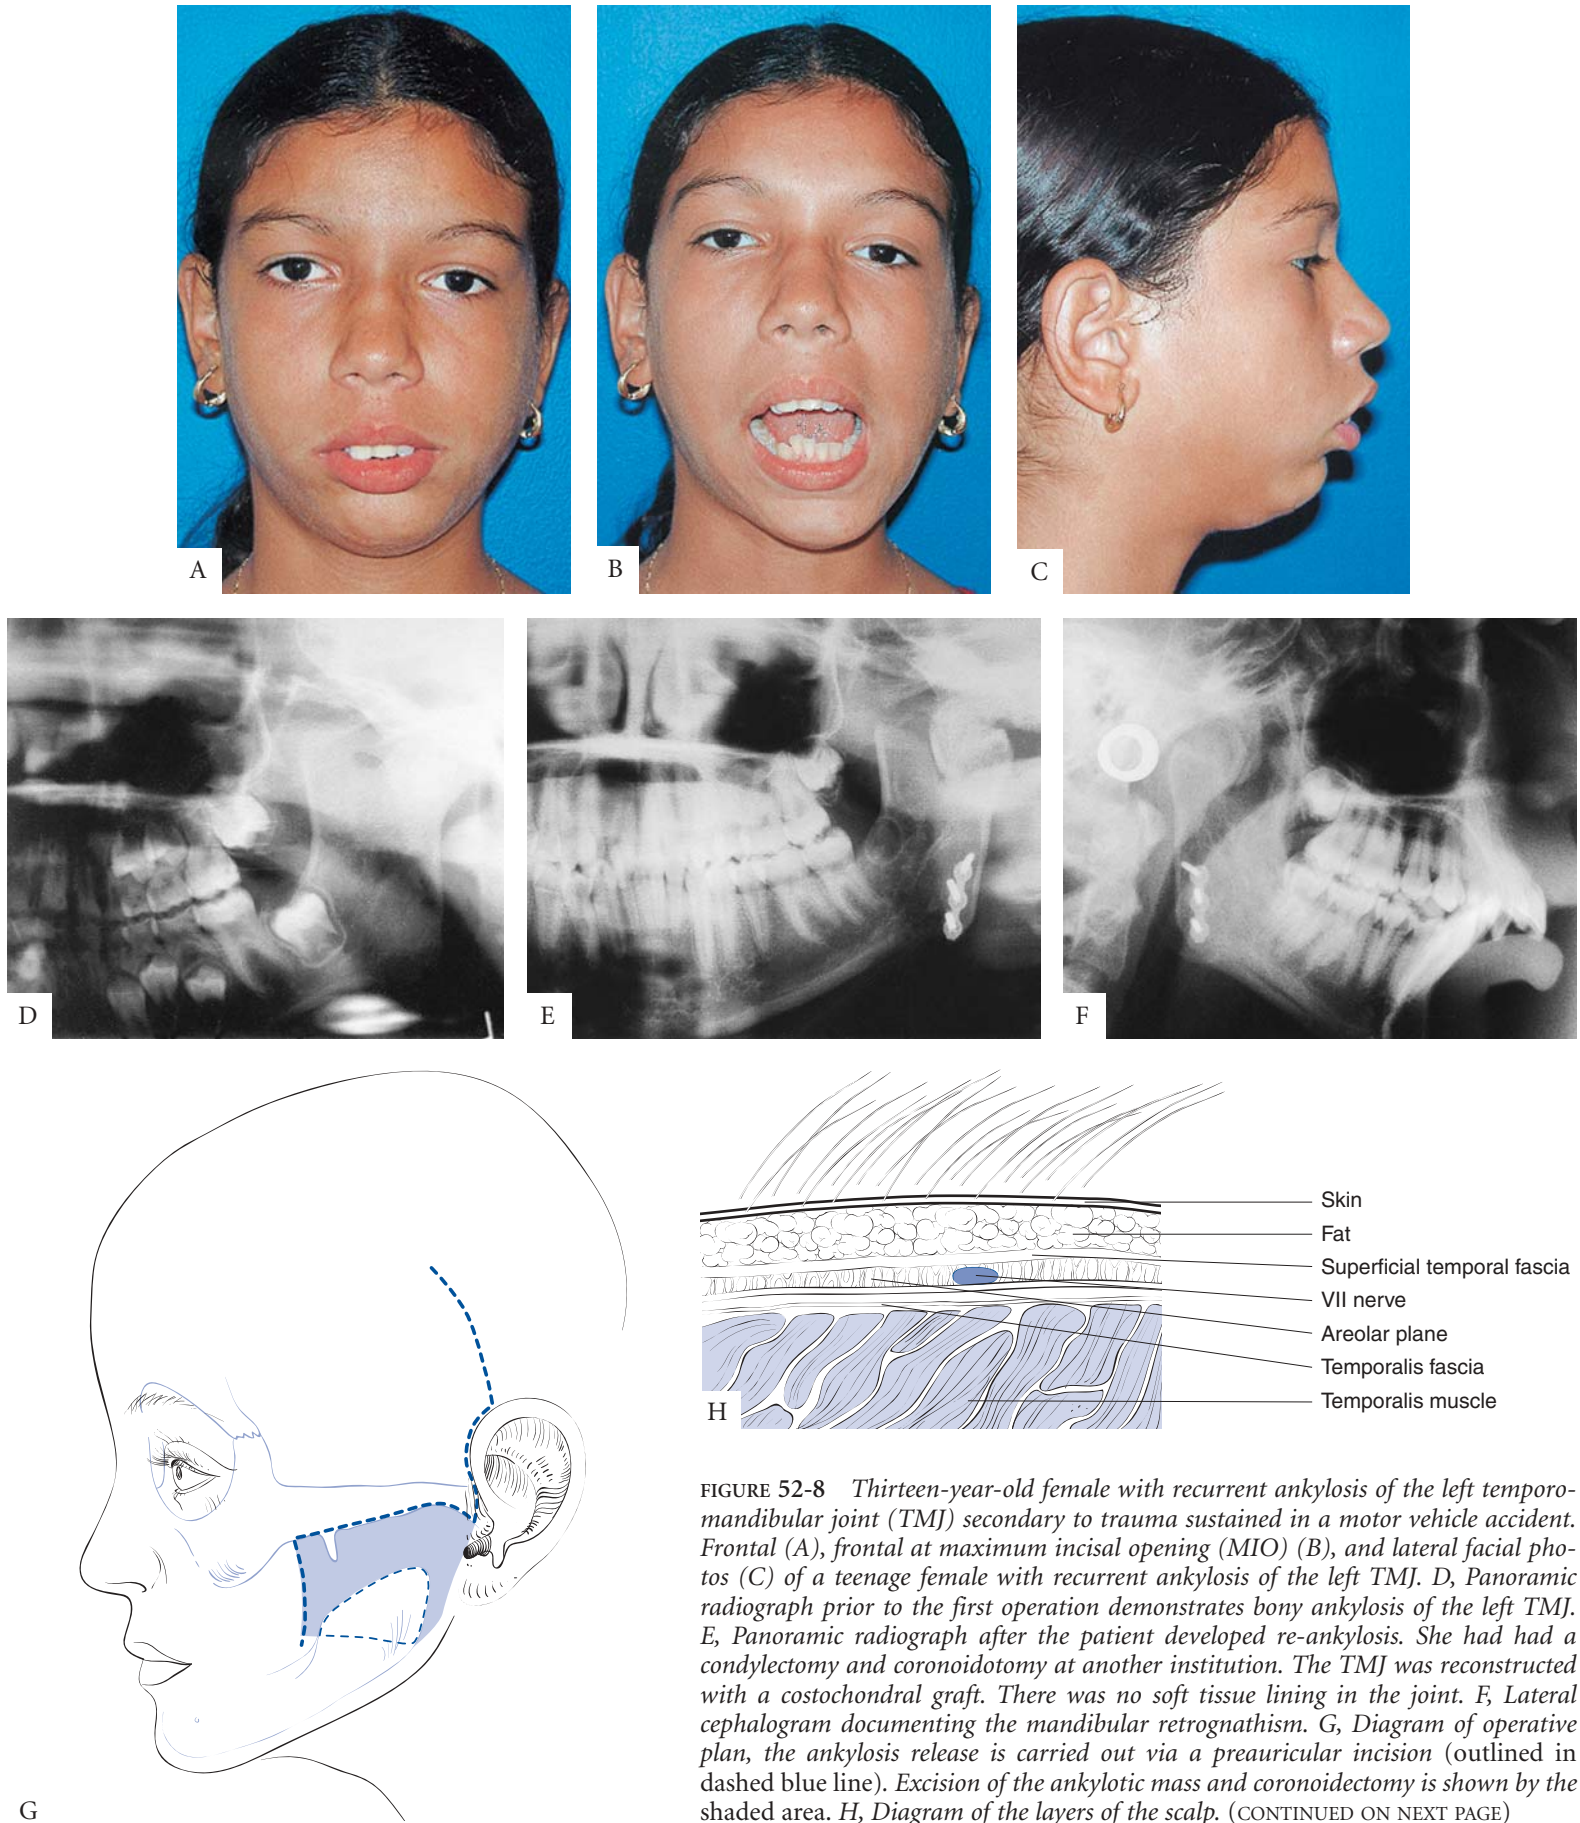

FIGURE 52-8 Thirteen-year-old female with recurrent ankylosis of the left temporomandibular joint (TMJ) secondary to trauma sustained in a motor vehicle accident. Frontal (A), frontal at maximum incisal opening (MIO) (B), and lateral facial photos (C) of a teenage female with recurrent ankylosis of the left TMJ. D, Panoramic radiograph prior to the first operation demonstrates bony ankylosis of the left TMJ. E, Panoramic radiograph after the patient developed re-ankylosis. She had had a condylectomy and coronoidotomy at another institution. The TMJ was reconstructed with a costochondral graft. There was no soft tissue lining in the joint. F, Lateral cephalogram documenting the mandibular retrognathism. G, Diagram of operative plan, the ankylosis release is carried out via a preauricular incision (outlined in dashed blue line). Excision of the ankylotic mass and coronoidectomy is shown by the shaded area. H, Diagram of the layers of the scalp. (CONTINUED ON NEXT PAGE)

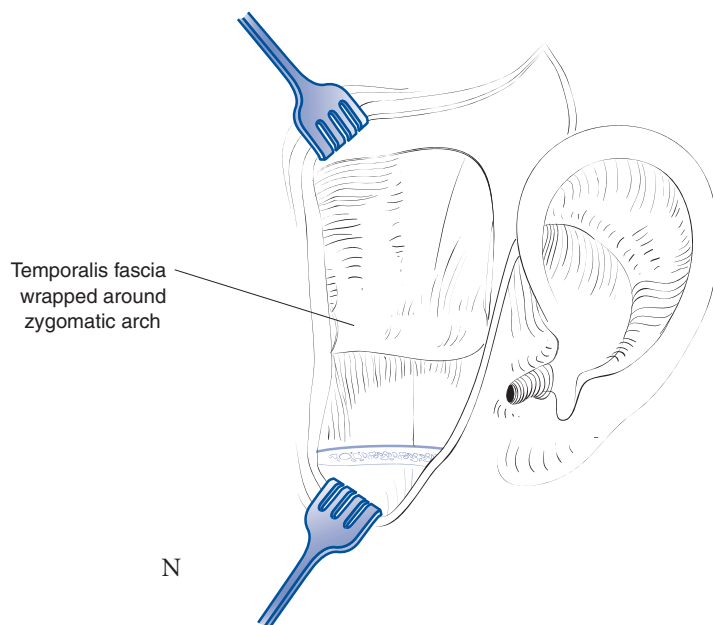

FIGURE 52-8 (CONTINUED) I, Intraoperative view after dissection was completed. Note the bony ankylotic mass and the coronoid process with obliteration of the sigmoid notch. J, Diagram of the bone removed (shaded area) and the proposed reconstruction using a distraction device (Synthes Maxillofacial, Paoli, PA) instead of a costochondral graft. K, Temporalis flap is outlined with malachite green. The flap is dissected and rotated over the arch (L) and sutured in place (M, N). O, Specimen: ankylotic mass and coronoid process. (CONTINUED ON NEXT PAGE)

FIGURE 52-8 (CONTINUED) Frontal (P), frontal opening (Q), and lateral (R) photographs at end distraction. The patient was mobilized and started on physical therapy immediately postoperatively. She was comfortable because there was no donor site operation and no period of maxillomandibular fixation. Lateral (S) and anterior-posterior (A-P) (T) designated as cephalogram and panoramic radiograph (U) at the end of distraction osteogenesis demonstrating the lengthened mandibular ramus. Frontal (V), frontal opening (W), and lateral (X) photographs 1 year after completion of treatment. The patient maintained her TMJ motion and will be beginning presurgical orthodontic treatment to correct her preexisting malocclusion. Open (Y) and closed (Z) intraoral views with the patient opening 39 mm at 1 year. (CONTINUED ON NEXT PAGE)

FIGURE 52-8 (CONTINUED) A-P cephalogram (AA) and panoramic radiograph (BB) at 1 year. The ramus lengthening is demonstrated by the space between the retained footplates. A–F, I, K, M and O–BB reproduced with permission and G, H, J, L, N adapted from Kaban LB. Acquired temporomandibular deformities. In: Kaban LB, Troulis MJ, editors. *Pediatric oral and maxillofacial surgery*. St. Louis (MO): Elsevier; 2004. p. 354–7.

with the subsequent development of asymmetry and malocclusion has been reported by multiple authors.^{61,62} The frequency is more common in the growing patient. Munro and colleagues reported 2 of 22 cases of considerable linear overgrowth with resultant chin deviation and development of a Class III malocclusion.⁶¹ Perrott and colleagues reported 3 of 26 cases of lateral bony overgrowth (tumor-like overgrowth), with an evident preauricular fullness and subsequent limitation of opening. However, no cases of linear overgrowth were found in that series of patients.⁶²

Postoperative Physical Therapy

Patients with hypomobility disorders require aggressive physical therapy programs, often in conjunction with surgical treatment, to maintain a functional MIO. Various rehabilitation programs have been described in the literature, and approaches include unassisted exercise, tongue-blade and finger-stretch exercises, manual exercisers, and mechanically assisted mandibular motion devices (Figure 52-9). Manipulation under general anesthesia may also be required in refractory or recurrent cases.

Most authors agree that the duration of physical therapy should be prolonged well after a desired MIO is achieved to prevent subsequent relapse.⁶³

Hypermobility

Classification

Mandibular subluxation occurs when there is a momentary inability to close the mouth from a maximally open position. It is defined as a self-reducing partial dislocation of the TMJ, during which the condyle passes anterior to the articular eminence. In distinction, dislocation may be considered a long-lasting inability to close the mouth. Subluxation of the condyle may be an early feature of TMJ pathology in a subset of patients. It is often associated with an abnormally wide opening while eating or yawning. Extended periods of mouth opening (eg, during dental treatment or endotracheal anesthesia) may also precipitate subluxation. Subluxation may occur secondary to acute trauma or following a seizure and is also associated with systemic diseases such as Ehlers-Danlos syndrome and Parkinson's disease.

Etiology

TMJ dislocation is defined as an internal derangement characterized by a condylar position anterior and superior to the articular eminence that is not self-reducing. Recurrent dislocation is a relatively unusual problem. Much like subluxation, the etiology is varied. It is observed most frequently in patients with neurologic and connective tissue disorders, those with TMJ dysfunction, and those being treated with phenothiazines and other neuroleptic agents (Table 52-2).

Extrinsic trauma, especially that sustained while the mouth is open, may result in dislocation. Wide opening of any type as well as capsular laxity may be etiologic. Muscular problems secondary to medication use or neurologic disorders may be associated. The problem may be unilateral or bilateral, and patients generally present with associated muscle spasm and pain.

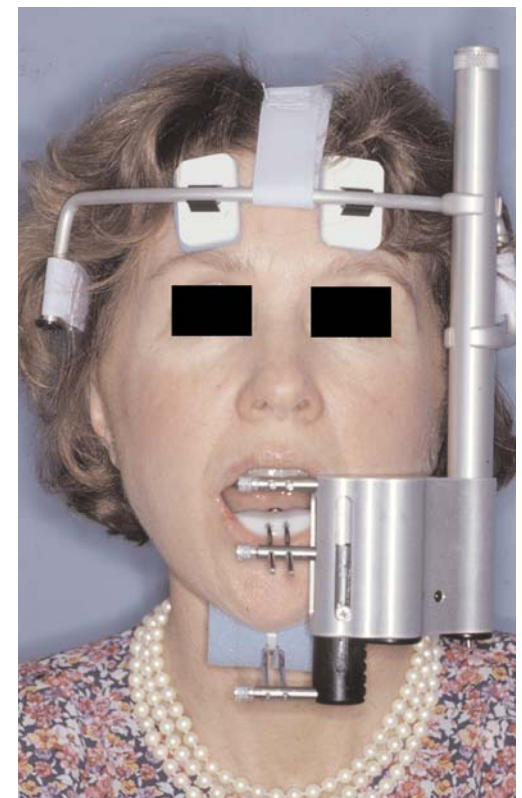

FIGURE 52-9 Photograph demonstrating a continuous passive motion device used in the postoperative management of hypomobility.

Table 52-2 Causes of Hypermobility

Intrinsic trauma: overextension injury
Yawning
Vomiting
Wide biting
Seizure disorder
Extrinsic trauma
Trauma: flexion-extension injury to the mandible, intubation with general anesthesia, endoscopy, dental extractions, forceful hyperextension
Connective tissue disorders: hypermobility syndromes, Ehlers-Danlos syndrome, Marfan syndrome
Miscellaneous causes: internal derangement, dyssynchronous muscle function, contralateral intra-articular obstruction, lost vertical dimension, occlusal discrepancies
Psychogenic: habitual dislocation, tardive dyskinesia
Drug induced: phenothiazines

Treatment Considerations

In the absence of pain, subluxation requires no specific treatment since it is self-reduced by the patient. When associated with wide mouth opening, conscious efforts to avoid this are usually successful at preventing recurrent subluxation. Patients are advised to modify their diets, and dental treatment is done over multiple shorter appointments. The use of bite-blocks during procedures can also be helpful. In cases in which extreme laxity in the joint results in continued problems, surgical intervention may be warranted.

Reduction of mandibular dislocation should be done precipitously before muscle spasm becomes severe and makes the procedure more difficult. Reduction is accomplished by pressing the mandible downward and then backward to relocate the condyle within the glenoid fossa (Figure 52-10). In acute cases this can generally be accomplished without the use of

FIGURE 52-10 Bimanual mandibular manipulation in a downward-posterior direction to disengage the condyle from its open-locked position posterior to the articular eminence. Adapted from Rotskoff KS. *Management of hypomobility and hypermobility disorders of the temporomandibular joint*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia: J.B. Lippincott Company; 1992: p. 2009

anesthesia. In cases of prolonged or chronic dislocation, the use of muscle relaxants and analgesics may be required. If reduction cannot be thus achieved, general anesthesia may be required. After reduction the mandible should be immobilized for several days to allow for capsular repair, muscle rest, and prevention of recurrence.^{64,65}

Chronic dislocation usually requires a more interventional approach. The use of

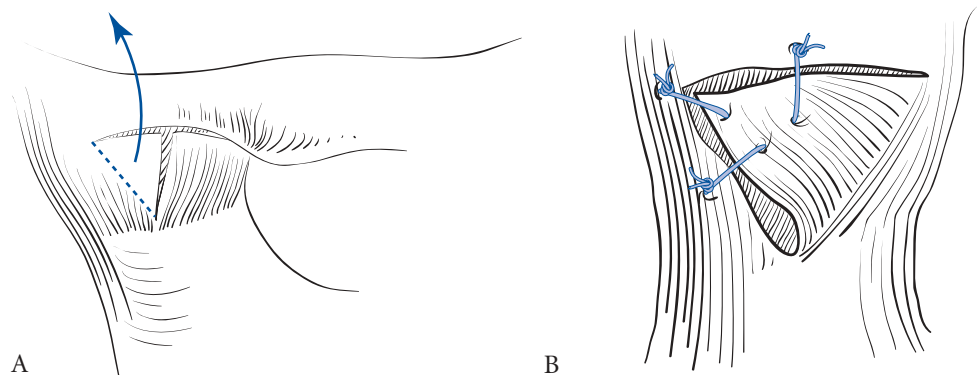

FIGURE 52-11 Capsular plication. The exposed lateral capsule is incised (A) and sutured back on itself (B) to tighten and limit capsular laxity. Adapted from Rotskoff KS. *Management of hypomobility and hypermobility disorders of the temporomandibular joint*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia: J.B. Lippincott Company; 1992: p. 2010

various sclerosing agents has been described in the past. However, caustic agents can result in progressive damage to other joint structures, and multiple reports of misapplications and complications have resulted in the abandonment of this technique. Surgical treatments of various types are reported. Identification of etiology is important when considering surgical correction. In cases of extreme joint laxity, mechanical tightening may be indicated. Plication procedures involve fastening the condyle to a fixed structure to maintain its position within the glenoid fossa. Certain authors advocate the creation of a mechanical impediment to translation by altering the conformation of the articular eminence. Procedures targeting a decrease in muscle pull can also be effective.

Plication procedures are aimed at limiting mandibular motion and may be accomplished in various ways. Removal of redundant capsular tissue (Figure 52-11) is a relatively simple method for addressing laxity, and a review by MacFarlane reported excellent long-term results.⁶⁶ Plication of the condyle to the temporal bone and of the coronoid process to the zygomatic arch have also been described. Multiple materials have been used for plication procedures, including both resorbable and nonresorbable sutures and wire. Miniplates and surgical anchors have also been used in both the lateral

pole of the condyle and the posterior roof of the zygomatic arch. Wolford and colleagues have described the threading of heavy suture material between the eyelets of the surgical anchors, thereby preventing condylar dislocation.⁶⁷

Mechanical impediments to condylar translation effectively deepen the glenoid fossa. Bone and cartilage grafts (cranial, iliac crest, rib, tibial) have been used for this purpose. Nonautogenous material has also been onlaid to the articular eminence. In 1943 LeClerc and Girald described a procedure for inferior displacement of the zygomatic arch to prevent translation (Figure 52-12).⁶⁸ Access was gained through an extended preauricular incision, and dissection of the zygomatic arch was performed. An oblique osteotomy downward and forward then allowed the arch to be moved inferiorly. Chossegros and colleagues reported excellent success using this technique in 36 patients with chronic and recurrent dislocation.⁵³

The eminectomy procedure was first introduced by Myrhaug in 1951 as a treatment for chronic and habitual dislocation of the condyle.⁶⁹ In addition to the standard open eminectomy, reports describing the use of the arthroscope for this purpose have recently appeared in the literature.⁷⁰ Both procedures involve the removal of a portion of the articular tubercle and eminence to allow the condyle to move freely.

Concerns regarding the use of the eminectomy procedure include the following: hypermobility of the joint with further damage to contiguous tissues; significant and often bothersome TMJ noise (clicking and crepitation) with function; the potential for facial nerve injury; recurrent dislocation; and inadvertent temporal lobe exposure (anatomic variant).⁷¹

Reported success rates of surgery to treat dislocation vary considerably. Recurrent dislocation following standard eminectomy procedures ranges from 7 to 33%.⁷²⁻⁷⁴ Patients with significant ligamentous laxity or predisposing conditions (eg, seizure disorders) are prone to recurrent problems. Arthroscopic eminectomy, owing to technical limitations, prevents the complete removal of the medial aspect of the eminence. The consequence of this in terms of recurrence remains to be elucidated.^{72,73}

If muscular hyperactivity is associated with chronic recurrent dislocation, removal of the insertion of the lateral pterygoid muscle (lateral pterygoid myotomy) may be an effective treatment. Bowman has reported good success with this procedure,⁷⁴ but subsequent animal studies have shown lateral pterygoid electromyographic activity returning to baseline several months after the procedure.⁷⁵ However, the long-term efficacy often attributed to this procedure may be sec-

ondary to scarring anterior to the joint capsule, thereby limiting condylar excursion.⁷⁶

The injection of botulinum toxin type A into the lateral pterygoid muscles has also been proposed as a treatment for chronic and recurrent dislocation of the mandible. Ziegler and colleagues reviewed 21 patients treated in this fashion. Injections were given on a 3-month basis with only 2 of 21 patients suffering further dislocations. No adverse side effects were reported in this series.⁷⁷ Botulinum toxin type A has an associated latency of 1 week, and its duration of action is between 2 and 3 months. Injections should not be done more often than every 12 weeks to avoid the development of antibodies. An injection dose of between 10 and 50 U into the targeted muscle is usually sufficient.

Clark reviewed the use of botulinum toxin for the treatment of mandibular motor disorders, as well as for the treatment of facial spasm, and expanded on the potential side effects of such treatment.⁷⁸ Although local side effects are unusual, the two most common problems encountered were alterations in salivary consistency and an inadvertent weakness of swallowing, speech, and facial muscles. These complications were more commonly reported with lateral pterygoid, soft palate, and tongue injections and were found to be dose dependent.

Summary

This chapter summarizes the spectrum of mobility problems that can affect the TMJ and contiguous structures. The varied etiologic factors associated with hypo- and hypermobility have been reviewed; an understanding of the etiology in each particular case is imperative for appropriate treatment to be rendered. Fortunately, improved imaging techniques, including three-dimensional CT, can be invaluable adjuncts to the history and physical examination. In cases of ankylosis, the extent and nature of the problem is best appreciated with these CT images. Altered anatomy and

FIGURE 52-12 LeClerc procedure. A, An oblique cut using a fissure bur is created anterior to the articular eminence to decrease the frequency of condylar dislocation by obstructing the path of condylar movement. B, The osteotomized segments of the articular eminence are made to overlap one another. Adapted from Rotskoff KS. Management of hypomobility and hypermobility disorders of the temporomandibular joint. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol. 3. Philadelphia: J.B. Lippincott Company; 1992: p. 2010

the extent of bony bridging can be assessed preoperatively. In addition to operative intervention, long-term success in the management of ankylosis requires aggressive physical therapy programs and longitudinal follow-up.

Hypermobility (both subluxation and dislocation) is similarly reviewed. Again, understanding the causative factors (ligamentous laxity, shallow eminentia, muscular hyperactivity) helps one to focus the treatment planning and to minimize problems with recurrence.

ORTHOGNATHIC SURGERY

Craniofacial Growth and Development: Current Understanding and Clinical Considerations

Peter M. Spalding, DDS, MS, MS

This chapter will provide a summary of the current understanding of prenatal and postnatal craniofacial growth and its relevance for clinical treatment. Although there clearly is awareness of the importance of genetic and environmental influences on craniofacial growth and development, the control and precise biologic mechanisms are not well understood and continue to be fertile areas of investigation. The chapter will review human morphogenesis, prenatal and postnatal growth and development, the factors that influence these phases of growth and development, and the orthopedic and orthodontic clinical considerations that will determine whether surgical intervention will be necessary to achieve optimum cosmetic and functional craniofacial treatment outcomes.

Prenatal Craniofacial Development

Human prenatal development can be conveniently divided into the embryonic period, from fertilization through the eighth week of development, and the fetal period, continuing from the ninth to the fortieth week at birth. The embryonic period is characterized by new tissue differentiation

and organogenesis, whereas the fetal period is distinguished by growth and expansion of the basic structures already formed.

During the first few days following the formation of the single-cell zygote at conception, four mitotic divisions occur to form the 16-cell morula. After entering the uterus the morula develops into a 100-cell blastocyst consisting of an outer (trophoblast) and inner (embryoblast) cell mass. The trophoblast further differentiates to form the placenta and other peripheral embryonic structures, whereas the embryoblast differentiates into the future embryo. At the end of the first week the blastocyst adheres to the uterine endometrium to begin implantation. During the second week the embryoblast forms a bilaminar disk composed of two germ layers: the ectoderm, forming the amniotic cavity floor; and the endoderm, lying beneath and forming the yolk sac floor. Later the ectoderm will form a variety of epidermal structures including dental enamel, oral mucosa and nasal epithelia. The endoderm will later form the pharyngeal epithelium. By the end of the second week the endoderm develops a thickened area called the prechordal plate,

located at the cranial end of the bilaminar disk, that prefaces the development of the head (Figure 53-1).

Embryonic Period

Germ Layer Formation Craniofacial embryogenesis begins during the third week of gestation, when gastrulation and neurulation occur. Gastrulation is the process whereby the bilaminar disk is converted into a trilaminar one with the appearance of the third germ layer, the mesoderm, forming between the other two from ectodermal cell proliferation and differentiation in the caudal area of the disk. The prominence created from this proliferation forms a craniocaudal midline furrow termed the primitive streak. Cell proliferation and differentiation of the cranial end of the primitive streak forms the notochord around which the axial skeleton will form.

Neural Tube Formation Neurulation, occurring at the same time as gastrulation during the third week and continuing through the fourth week, is a process that results in the formation of the neural tube,

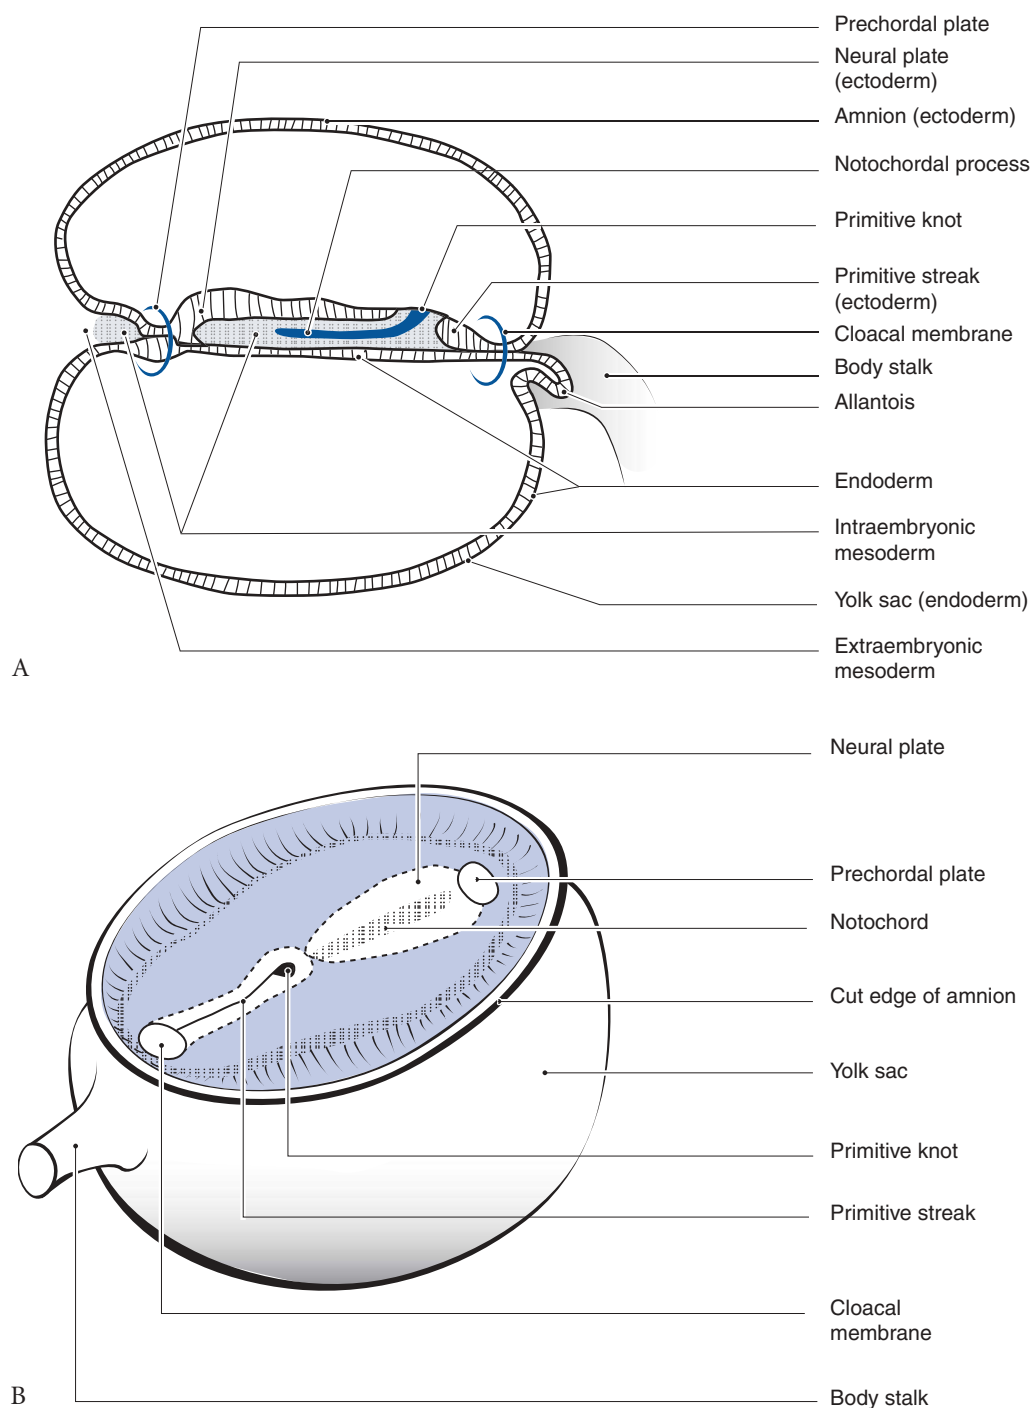

FIGURE 53-1 Embryo 14 days old. A, Longitudinal section showing amnion (above) and yolk sac (below). Adapted from Sperber G. *Craniofacial development*. Hamilton (ON): BC Decker Inc; 2001. p.19. the primordium of the central nervous system. Neurulation is characterized by development of the neural plate from the ectoderm overlying the notochord. As the neural plate grows caudally toward the

primitive streak, the lateral edges of the neural plate rise up to create neural folds, forming the neural groove between them. Mesoderm on either side of the groove develops into paired blocks of tissue called

somites (ultimately 48 somite pairs will develop). In the fourth week the neural folds begin to fuse at the midline in the central part of the embryo, at the level of the fourth to fifth somite, to form the neural tube (Figure 53-2). The neural tube continues to form toward the cranial and caudal ends, completing caudal formation by the time about 20 somite pairs are present. The anterior portion of the neural tube develops into the forebrain, midbrain, and hindbrain. After neural tube closure is complete on day 28, the two hemispheres of the brain begin development, increasing in size to eventually cover the roof of the brain stem. The otic, optic, and olfactory placodes develop in association with the forebrain neuroectoderm.

Cell Population Origin, Migration, and Interaction By the end of the fourth week multipotential neural crest cells arising from the neural folds must translocate or migrate from the dorsal margins of the closing neural tube to specific locations along hyaluronate-rich fibronectin-lined extracellular pathways.¹ The migration of neural crest cells follows a proper sequence and distinct pathways over extensive distances, but there is evidence that the cells have an ability to differentiate into a variety of derivatives (Figure 53-3).² There is growing evidence that neural crest cell differentiation is not predetermined but dependent on their epithelial-mesenchymal cellular interactions with tissues along the route to their final destinations.³ Multiple genes, in particular a class of homeobox-containing transcription factors, affect subpopulations of neural crest cells that help regulate their migration and determine the pattern and position of structures within the pharyngeal arches.⁴ All of the skeletal and connective tissue of the face, with the exception of dental enamel, is derived from neural crest cells, whereas skeletal and connective tissue of the trunk is mesodermal in origin. Many craniofacial malformations are produced from faulty neural crest formation or

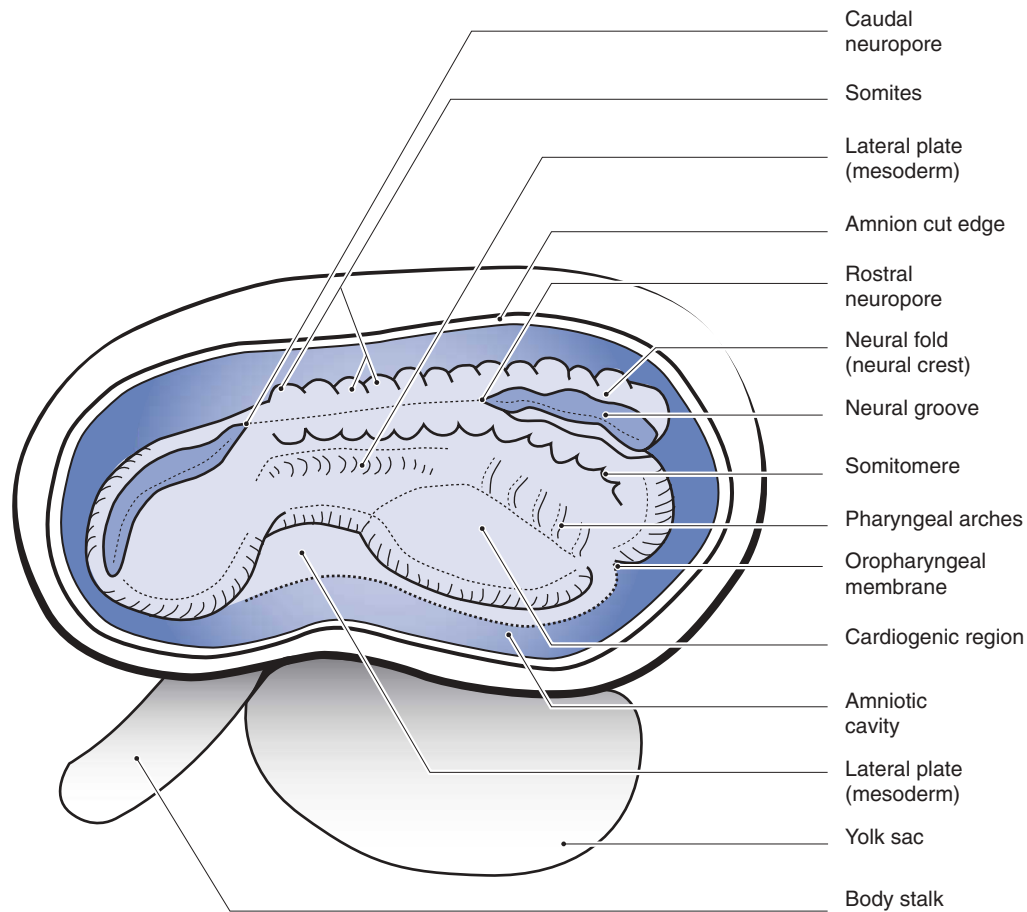

FIGURE 53-2 Longitudinal section of amnion in a 23-day-old embryo illustrating the fusion of neural folds and the initial formation of somites. Adapted from Sperber G. *Craniofacial development*. Hamilton (ON): BC Decker Inc; 2001. p.21.

migration, loss of neural crest cells, or flawed epithelial-mesenchymal interaction during this fourth week of gestation.

Development of Facial Primordia The pharyngeal arches, which give rise to most of the head and neck structures, develop during the fourth week as a result of neural crest migration (Figures 53-3 and 53-4). They consist of four bilaterally paired arches on the ventral external surface of the human embryo. Facial development occurs between the fourth and eighth weeks of gestation. Development of the face begins with five prominences or primordia surrounding the stomatodeum or primitive mouth cavity. The primordia form from the first pair of pharyngeal arches arising from neural crest ectomesenchyme and include the single median frontonasal primordium, the paired maxillary primordia, and the paired mandibular primordia. Recent studies indicate that these facial primordia may be initiated through different morphogenetic mechanisms. They are composed of different neural crest cells, have their outgrowth regulated by different

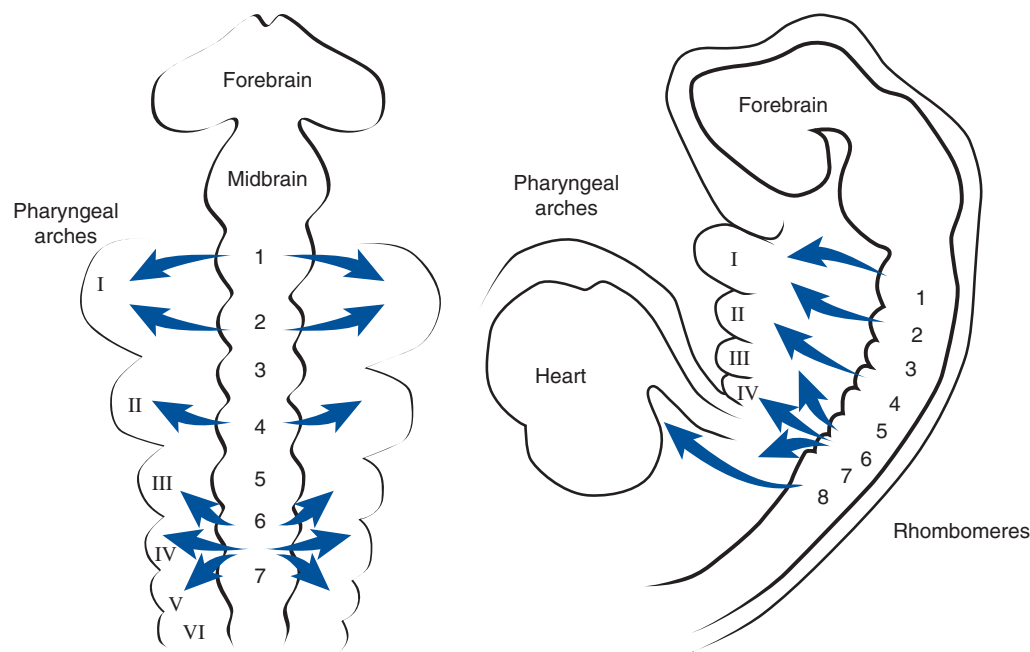

FIGURE 53-3 Illustration of neural crest migration pathways from rhombomeres 1 to 7 to pharyngeal arches I to VI, from dorsal (left) and lateral (right) views. genes, and have different responses to teratogenic agents.⁵ The facial primordia merge when the epithelium between them breaks down, followed by invasion of the mesenchyme and coalescence of the adjoining prominences (Figure 53-5). Initially the mandibular primordia merge in the midline to form the chin and lower lip. At the same time nasal placodes form in the inferior and lateral portion of the frontonasal primordium. On either side of

these nasal placodes, medial and lateral nasal primordia develop. The medial nasal primordia move toward each other and merge in the midline early in the sixth week, forming the central part of the upper lip and the primary palate, including the maxillary incisors and their surrounding alveolar bone. There still is some controversy regarding the origin of the central part of the upper lip, which some believe is of frontonasal primordial origin.⁶ The

maxillary primordia move medially as well, merging with the lateral and medial nasal primordia during the sixth week, to complete formation of the upper lip. At this same time the maxillary and mandibular primordia merge laterally, determining the width of the mouth. Merging of facial primordia requires disintegration of surface epithelia in order to permit the underlying mesenchymal cells to unite (Figure 53-6). The groove between the primordia is gradually filled out by proliferation of the mesenchyme so that the primordia appear to merge. Facial clefting is a result of failure of epithelial disintegration and lack of merging. Facial primordial growth and merging is dependent on ectodermal-mesenchymal interactions that appear to be regulated by the secreted protein sonic hedgehog (SHH).⁵ Mutations in SHH that prevent its signaling during early neural plate patterning cause midline defects that range from hypotelorism and cleft lip/palate to holoprosencephaly and cyclopia.⁷ There is also evidence that adequate epidermal growth factor receptor signaling is necessary for sufficient secretion of matrix metalloproteinases for normal facial development.⁸ From 5 weeks' gestation to the early part of the fetal period at 9 weeks, there is medial migration of the eyes, assisted by frontal and temporal lobe expansion and greater proliferation of the lateral facial regions relative to the central face, resulting in facial expansion and interocular reduction.

The nasal placodes that formed at about 5 weeks each are separated inferiorly by a nasal groove. With continued proliferation of mesenchyme, the placodes submerge to form the nasal pits, the precursors to the anterior nares. As the nasal pits continue to submerge with the proliferating mesenchyme, they are eventually separated from the stomatodeum by only a thin oronasal membrane. This membrane will rupture at the beginning of the seventh week, forming a continuous nasal and oral cavity.

Formation of Neurocranium and Viscerocranium Formation of the craniofacial bones begins with development of the cartilaginous and membranous precursors to the neurocranium and viscerocranium during the latter part of the fifth week of gestation (Figure 53-7). The membranous neurocranium (desmocranium) that will give rise to the flat bones of the calvaria is connective tissue derived from the paraxial mesoderm and neural crest. The cartilaginous neurocranium (chondrocranium) that will form the cranial base is cartilage from neural crest origin. Cartilage maturation occurs in a caudal-rostral sequence. The membranous viscerocranium that will give rise to the maxilla, zygomatic bone, squamous temporal bone, and mandible is derived from the neural crest. The cartilaginous viscerocranium that will form the middle ear ossicles, styloid process of the temporal bone, hyoid bone, and laryngeal cartilages is from neural crest ectoderm.

Endochondral ossification centers occur in the cartilaginous components and intramembranous ossification centers form in the membranous components of the neurocranium and viscerocranium. Osteoblast differentiation with the onset of mineralization results from a rapid angiogenic process with vascular ingrowth closely surrounding the center of ossification. The earliest ossification of the craniofacial bones begins in the seventh and eighth weeks of gestation. There are eventually 110 ossification centers, nearly all of which appear between 6 and 12 weeks' gestation, that develop in the embryo to form 45 bones at birth, which ultimately form 22 bones in the adult.

Ossification The onset of ossification generally follows the chronologic sequence of mandible, maxilla, palatine, cranial base, and cranium, with intermembranous centers usually preceding endochondral

centers.⁹ Ossification of the mandible begins in the mental foramen region. Endochondral ossification of Meckel's cartilage occurs anteriorly to this area and intramembranous ossification occurs posteriorly. The condylar cartilage forms at the posterior end of this intramembranous portion, independently of Meckel's cartilage. Maxillary ossification begins in the area of the infraorbital foramen. Intramembranous ossification occurs anteriorly and posteriorly to this region. The vertical portion of the palatine bone then begins intramembranous ossification in the region of the palatine nerve, followed by ossification of the anterior, then posterior borders of the incisive foramen, spreading through the hard palate from the canine area. Following ossification of the main portion of the mandible and maxilla, during the sixth week of gestation, endochondral ossification of the cranial base occurs in the midline from the foramen magnum to the nasal bone, and intramembranous ossification occurs laterally. Finally intramembranous ossification of the cranial bones follows.

Final Tissue Differentiation Interaction between pharyngeal endoderm and neural crest tissue, followed by oral ectoderm proliferation, produces identifiable odontogenic tissue by the end of 4 weeks' gestation. There are four origin sites of odontogenic epithelium for both the maxillary and mandibular arches, appearing at the end of 5 weeks' gestation. The primary anterior and first molar tooth germs appear at 6 weeks' gestation, followed by development of the primary second molar germs at 7 weeks. Apposition of bone on the alveolar margins of the maxilla and mandible in the presence of developing tooth germs form the initial alveolar processes.

The latest orofacial structure to reach completion at the end of the embryonic period is the secondary palate, developing from the paired lateral palatine shelves of

FIGURE 53-7 Lateral view of 20-week-old embryo illustrating initial development of the cartilaginous and membranous neurocranium and viscerocranium. Adapted from Moore KL, Persaud TVN. *The developing human: clinically oriented embryology*. 5th ed. Philadelphia (PA): W.B. Saunders; 1993. p. 361.

the maxilla. These shelves are oriented vertically with the tongue interposed, but the tongue and floor of the oral cavity descend as the nasal chambers expand laterally and inferiorly (Figure 53-8). As this occurs the palatal shelves become elongated and elevate medially toward each other, beginning fusion at the end of the eighth week and completing in the ninth week of gestation. There is evidence that transforming growth factor (TGF)- β 3 is intimately involved in regulating secondary palatal fusion by mediating the breakdown of the midline epithelial seam prior to fusion.¹⁰

Fetal Period

The fetal period begins during the eighth week, at 60 days' gestation, lasting until birth at 40 weeks, and overall somatic

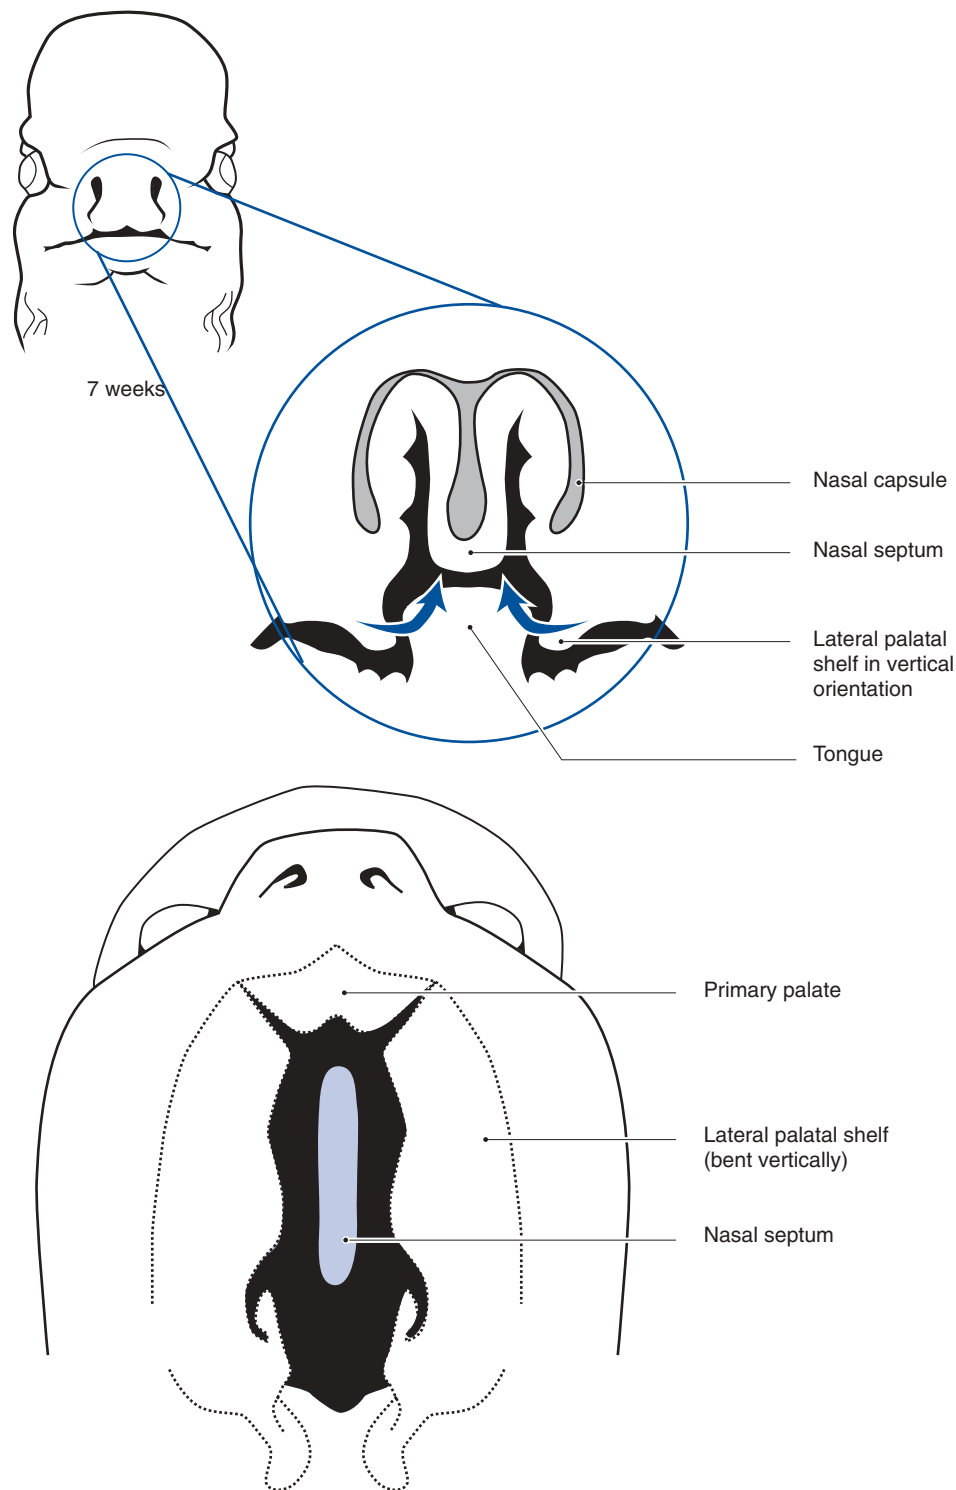

growth follows a cephalocaudal growth gradient (Figure 53-9). There is a prenatal growth spurt between 20 and 30 weeks' gestation with the peak growth velocity at 27 to 28 weeks being approximately 2.5 cm per week. The prenatal spurt in weight is slightly later at 30 to 40 weeks' gestation with a peak at 34 to 36 weeks.¹¹ The rate steadily decreases during the last trimester and continues to decline after birth until adulthood, with two exceptions. The first is a small "midgrowth" spurt that occurs in many children at 6 to 8 years old that has been attributed to increased adrenal secretion of androgenic hormones. The second is a dramatic endocrine mediated "pubertal growth" spurt during adolescence. Growth of the craniofacial complex during the fetal period is characterized by a

constant rate during the second trimester. The craniofacial skeletal components increase more in the anteroposterior dimension than in the vertical or transverse, with the exception of the mandible which increases more in the transverse dimension in order to maintain appropriate articulation.¹²

During the fetal period the neurocranium undergoes precocious development relative to the viscerocranium with earlier brain and neurocranial bone vault growth than facial and masticatory portions of the skull. This results in an early proportional predominance of the neurocranium over the face that only reduces to an 8:1 proportion by birth. The brain nearly doubles in size from 4 months to birth, achieving about 25% of its adult dimension. The formation and maintenance of cranial sutures are regulated by tissue interactions with the underlying dura mater as the brain develops.¹³ A number of growth factors have been identified that regulate cranial bone growth and suture fusion, including TGF- β 1, TGF- β 2, and TGF- β 3, bone morphogenetic protein (BMP)-2, BMP-7, fibroblast growth factor (FGF)-4, insulin-like growth factor (IGF)-I, and SHH.^{14,15} Transcription factors MSX2 and TWIST also play a role in suture development, binding to target effector genes to determine their expression.¹⁶ The eyeballs grow concurrently with the early brain growth, increasing facial expansion and separating the neural and facial skeletons to increase skull height.

The cranial base growth parallels the rapid growth of the cranial vault during the fetal period. The anterior cranial base grows sevenfold while the posterior cranial base increases fivefold. The intraethmoidal and intrasphenoidal synchondroses close before birth.

The ossification centers that begin the formation of the facial bones late in the embryonic period enlarge during the early fetal period until most of the bones have developed into a definitive shape by

A

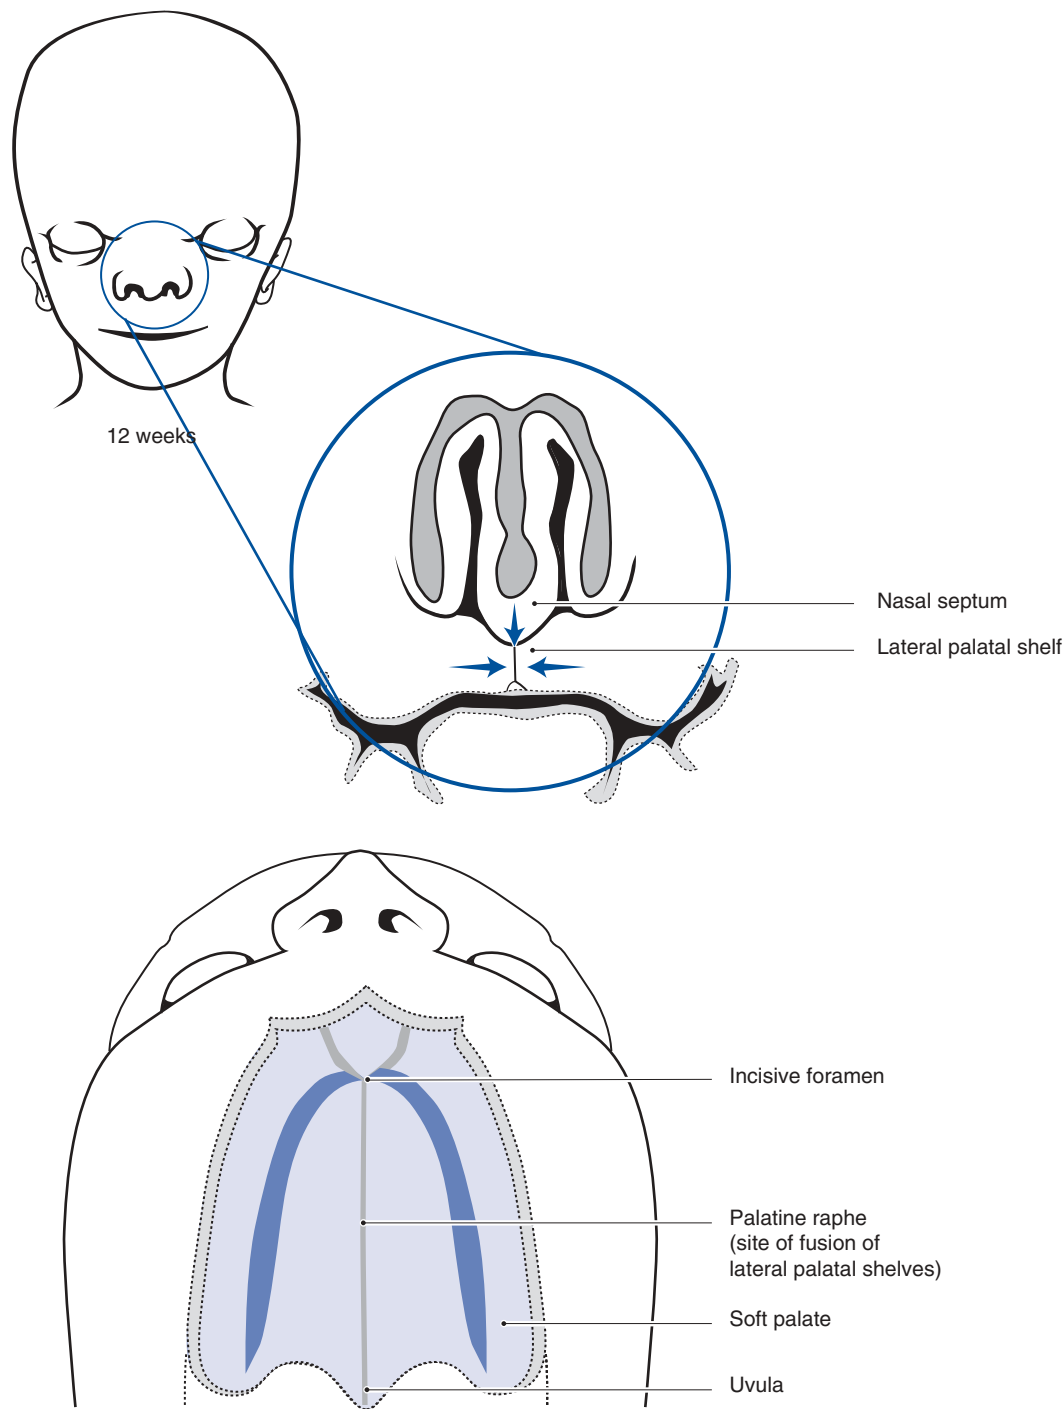

FIGURE 53-8 Frontal view of face, coronal section of the stomodeum, and inferior view of the palate in 7- and 12-week-old embryos. A, Embryo at 7 weeks showing palatal shelves vertically oriented. Adapted from Sperber G. *Craniofacial development*. Hamilton (ON): BC Decker Inc; 2001. p. 41, 114. (CONTINUED ON NEXT PAGE)

14 weeks. At this time they begin to remodel as they continue to grow by intramembranous and/or endochondral ossification. The anterior aspects of the

maxilla, mandible, and zygoma of the fetal and early postnatal face undergo deposition. This early anterior deposition is necessary to permit adequate osseous mass for

the developing tooth buds of the primary and permanent dentitions. Although the tooth germs start to develop as early as 6 weeks' gestation, the onset of dental mineralization does not begin until ossification has occurred. The maxilla demonstrates a rapid height increase associated with dental development.¹⁷ Once the primary teeth have erupted, these same anterior areas undergo resorption rather than deposition to produce the descent of the maxilla with continued growth. Meanwhile the posterior, infraorbital, and lingual surfaces of the maxilla are depository in both fetal and postnatal development. The fetal temporal bone grows faster in height than width while the lateral and inferior margins of the zygomatic bone grow faster than its orbital margin.¹⁷

The paranasal sinuses, including the maxillary, sphenoidal, frontal, and ethmoidal, begin developing at the beginning of the fetal period. Pneumatization begins first with the maxillary sinus, starting at 5 months' gestation. It is proposed that a septomaxillary ligament, attached to the sides and anteroinferior border of the nasal septum and inserted in the nasal spine, transmits septal growth, pulling the maxilla downward. Between the tenth week of gestation and birth, the nasal septum increases its vertical height sevenfold. The nasal septum growth, together with neural growth and facial sutural growth, transposes the maxilla inferiorly and anteriorly. The frontomaxillary, frontonasal, frontozygomatic, frontoethmoidal, and ethmoidolmaxillary sutures grow predominantly in a vertical direction. The temporozygomatic and nasomaxillary sutures contribute most of the anteroposterior change. The intermaxillary and zygomaticomaxillary sutures provide most of the transverse expansion of the face. Overall the middle and lower thirds of the face develop primarily in a downward and slightly forward direction away from the cranial base due to brain development, maxillary and palatine sutural growth, and possibly nasal septum growth.

B

FIGURE 53-8 (CONTINUED) B, Embryo at 12 weeks showing fusion following elevation of palatal shelves. Adapted from Sperber G. *Craniofacial development*. Hamilton (ON): BC Decker Inc; 2001. p. 41, 116.

Although the midsagittal part of the middle face entirely consists of nasal septal cartilage during the fetal period, ossification leaves only a small anterior part of this cartilage remaining postnatally. Currently there is controversy regarding the

role of the nasal septum in postnatal facial growth. Some believe it is limited to a compensatory and biomechanical role, and others believe it serves a more extensive role, particularly in promoting vertical maxillary growth.

Although the mandible is larger than the maxilla during the embryonic period, the mandible approximates the size of the maxilla within the first month of the fetal period. The three secondary cartilages of the mandible do not appear until the tenth and fourteenth weeks of gestation, forming on the lateral and superior aspects of the condylar processes. This secondary type of cartilage differs morphologically from epiphyseal and synchondrosal cartilage.¹⁸ Two of these secondary cartilages forming at the mental protuberance and the coronoid process ossify before birth, leaving only the cartilage on the condylar head as a site of postnatal mandibular endochondral growth. This cartilage never undergoes complete ossification, providing a means for absorbing functional forces and retaining growth potential throughout life. Between the thirteenth and twentieth weeks of gestation, the mandible lags behind the maxilla again while there is a transition from Meckel's cartilage to condylar cartilage as the primary growth site. During the third trimester there is a significant deepening of the corpus in association with the developing dentition. The mandibular ramus growth rate is greater than the growth rate of the mandibular body during this time.¹⁹ At the time of birth the mandible usually is equal in size again to the maxilla, although it is often in a retrognathic position relative to the maxilla.

Development of the permanent tooth germs begins at 16 weeks' gestation, with the first permanent molar germs developing posteriorly from the dental lamina followed by the permanent anterior tooth germs emerging from the lingual side of the primary enamel organs. At birth the primary tooth crowns are still not completely calcified, as the first permanent molars begin to calcify.

Postnatal Craniofacial Development

Skeletal Development

Development and completion of craniofacial growth follow the overall somatic

FIGURE 53-9 Changing fetal body proportions with all stages drawn to the same total height. At the start of the fetal period, the head is about half the length of the fetus, and by birth, it is one-quarter the length. Adapted from Moore KL, Persaud TVN. *The developing human: clinically oriented embryology*. 5th ed. Philadelphia (PA): W.B. Saunders; 1993. p. 97.

cephalocaudal growth gradient throughout prenatal and postnatal growth, with cranial vault growth completing before the cranial base, followed by the nasomaxilla and finishing with the mandible. During postnatal growth the neurocranium continues to develop ahead of the viscerocranium (Figure 53-10). It increases from about 30% of its ultimate adult size at the time of birth to 50% by 6 months of age, and 75% by 2 years of age, and nearly 90% by 3 years of age. By 5 years of age, the orbits have reached nearly 80% of their adult size.²⁰ This is why a child of this age appears to have a disproportionately large cranium and eyes. After birth the neurocranium increases about five times in size, whereas the viscerocranium increases about ten times in size. There is also a difference in the amount of postnatal increase in the three dimensions, with the vertical increasing by about 200%, the anteroposterior by somewhat less, and the transverse by the least at approximately

75%. By 10 years of age the neurocranial growth is nearly 95% complete, while facial growth is only about 60% complete.

The craniofacial complex can be divided conveniently into four primary units: the cranial vault, the cranial base, the nasomaxilla, and the mandible. Each of these units has its growth regulated to some extent by both intrinsic and extrinsic

controls. Our understanding of postnatal craniofacial growth has developed in part from cross-sectional anatomic and histologic studies of human cadavers and skeletal material. What has been particularly helpful in supplementing this material is a number of North American longitudinal craniofacial growth records and longitudinal implant (used for stable reference points) studies that were gathered from the 1940s to the mid-1960s before radiation hygiene and human subject research standards became more stringent.²¹

Cranial Vault At birth the cranial bones are separated by sutures with fontanelles where the corners of the bones meet, permitting compression of the skull during the birthing process (Figure 53-11). Postnatal bone growth results in narrowing of the sutures with all of the fontanelles closing within the first 2 years. The pressures exerted by the developing brain determine the size and shape of the cranium. As the brain expands, the pressure creates tension across the sutures and compression against the cranial bones, resulting in intramembranous bone growth by suture and surface apposition. Remodeling of the cranial bones to a flatter shape is necessary to adapt to the expanding surface of the brain. This occurs primarily from endocranial resorption and ectocranial apposition. Although suture apposition

FIGURE 53-10 Changing proportions of the postnatal skull with all stages enlarged to the same skull height and oriented in the Frankfurt horizontal plane with skull height divided into fifths. plays a larger role than surface apposition in overall cranial vault capacity, the post-natal shape primarily is determined by extrinsic factors.

By 6 to 7 years of age the inner table of the cranial bones becomes stable due to the cessation of cerebral growth. However, the outer table continues to remodel in response to extracranial muscular forces. The temporal muscles tend to laterally compress the cranium, forming temporal sulci and zygomatic arches. The lateral and posterior cervical muscles insert primarily on the squamous part of the temporal and occipital bones, influencing their shape. Even after attainment of the adult form, the cranial bones continue to thicken during adulthood.

Cranial Base Compared with the other craniofacial units the shape of the cranial base is relatively stable during growth, due likely to its greater intrinsic growth potential. Perhaps more than any other cranio-

facial area, growth of the cranial base is genetically predetermined and influenced the least by functional matrices.^{22,23} However, prenatal brain growth may provide a minor extrinsic influence, causing some flattening of the cranial base, since this does not occur with anencephaly. In addition there is recent evidence that chondral growth of the cranial base can be altered with mechanical forces.²⁴

The anterior cranial base matures earlier than the posterior cranial base with the posterior intraoccipital synchondroses closing during the second and third years postnatally and the anterior intraoccipital synchondroses closing at 3 to 4 years of age (Figure 53-12). The sphenothmoidal synchondrosis closes at about 6 years of age. Although the sphenoccipital synchondrosis is not a main growth site before birth, it provides the greatest contribution to cranial base growth postnatally, delaying fusion until adolescence. The prolonged postnatal growth period of the

spheno-occipital synchondrosis permits posterior growth of the maxilla to provide adequate bone for the developing posterior or permanent teeth and adequate space for the nasopharynx. In addition to endochondral bone growth, intramembranous remodeling of the cranial base occurs, including apposition on the basioccipital bone and anterior margin of the foramen magnum, resulting in continued lengthening of the posterior cranial base even after adolescence. Enlargement of the sella turcica continues postnatally, with the anterior wall stabilizing at about 6 years of age and the posterior wall continuing to resorb until late adolescence.

Nasomaxilla The prenatal precocity of neurocranial growth relative to the face becomes less predominant postnatally. Nevertheless considerable postnatal displacement of the nasomaxilla downward and forward occurs due to continued growth of the brain and cranial base. This

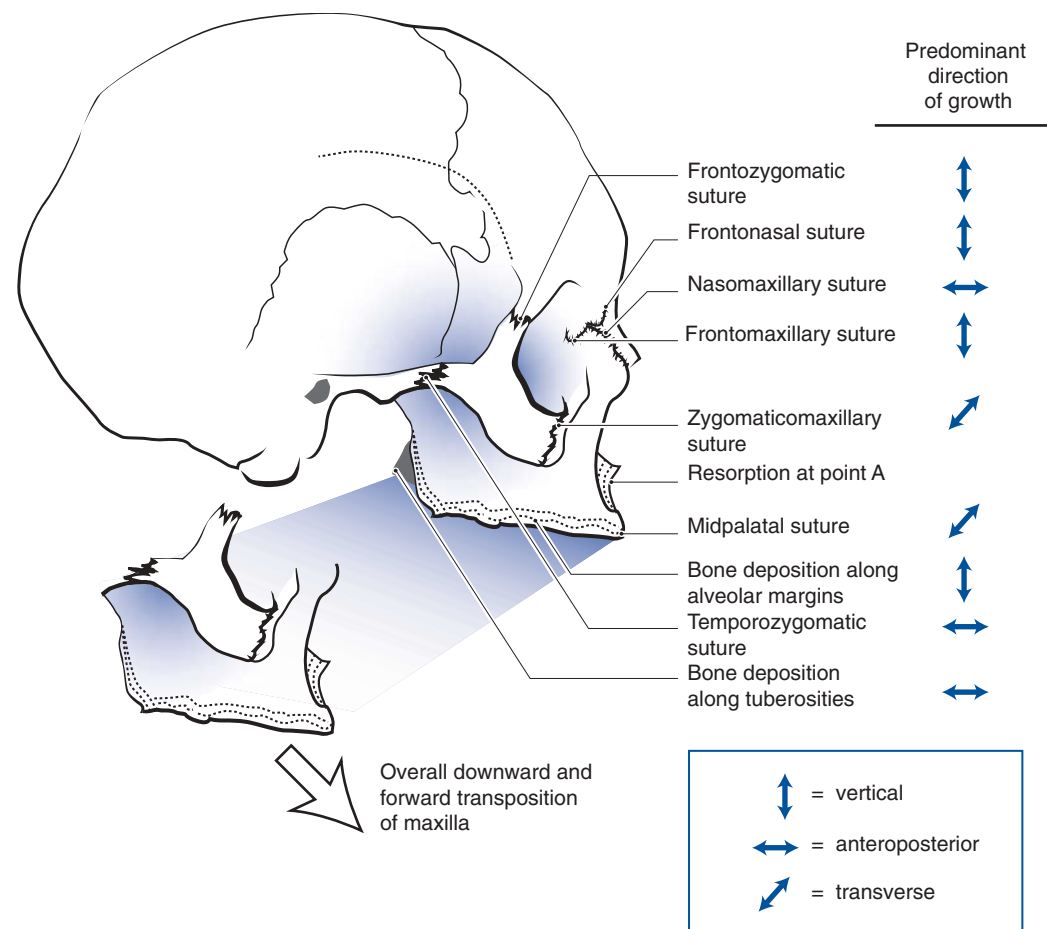

FIGURE 53-12 Midsagittal neonatal cranial base showing sutures and synchondroses. Adapted from Mooney MP, Siegel MI.⁵¹

inferior and anterior maxillary transposition is augmented by the sutural growth between the cranial base and maxilla and growth of the nasal septum. Following birth the vertical growth of the maxilla continues with contributions from the frontomaxillary, frontonasal, frontozygomatic, frontoethmoidal, and ethmoidal-maxillary sutures and possibly the nasal septum (Figure 53-13). The vertical descent of the maxilla is further increased by remodeling with resorption on the nasal surfaces and the simultaneous apposition on the oral surfaces. Anteroposterior growth continues with temporozygomatic and nasomaxillary sutural growth and transverse growth from intermaxillary and zygomaticomaxillary sutures. The resulting downward and forward translation displaces adjacent bones and permits adequate space for the developing nasopharynx and growth at the posterior aspect

FIGURE 53-13 Nasomaxillary intramembranous growth at various sites, resulting in an overall downward and forward transposition of the maxilla relative to the cranial base. Adapted from Sperber G. Craniofacial development. Hamilton (ON): BC Decker Inc; 2001. p. 107.

of the maxilla and maxillary tuberosities to provide adequate space for the development and eruption of the maxillary molars. Following the postnatal growth of the facial sutures, they serve as sites of fibrous union where some remodeling still can take place. In fact a number of cranial and facial sutures are interdigitated but still not fused even beyond 50 years of age.

Growth determinants for postnatal nasomaxillary growth are not well understood and include a variety of intrinsic and extrinsic factors. Passive displacement secondary to brain and cranial base growth, and perhaps nasal septal growth guidance, are the most significant influences on the downward and forward movements of the maxilla after birth until about the seventh postnatal year. From that age through adolescence these influences dramatically decrease as sutural growth and surface intramembranous growth predominate. Maxillary growth also depends to some extent on various functional matrices. The orbits' early response to eyeball growth and their functional movement, the influence of respiration on the nasal cavity, the influence of oral function in determining tuberosity, palatal and alveolar development, and the surrounding facial soft tissues all contribute functional roles in determining growth and remodeling of the nasomaxilla.²⁵

Significant remodeling must occur in order to maintain the general shape of the maxilla as it is displaced downward. As mentioned above, resorption of the nasal side of the maxilla, providing nasal cavity enlargement, occurs concomitantly with apposition on the oral side, resulting in descent of the maxilla. Although secondary pneumatization of the maxillary sinus begins prenatally, it does not occur for the other paranasal sinuses until after birth (first 2 years for ethmoidal and frontal sinuses and 6 to 7 years for sphenoidal sinuses). The vertical growth of the maxillary alveolar process is rapid during dental eruption, surpassing the vertical

descent of the palate threefold. The alveolar development contributes to the depth and width of the palate and vertical height of the face. Considerable resorption of the anterior surface of the maxilla minimizes the overall forward displacement of the maxilla and creates a deeper supra-alveolar concavity while increasing the relative prominence of the anterior nasal spine. Transverse growth occurs by lateral displacement of the maxillary bodies by means of the midpalatal suture and bone resorption on the lateral borders of the nasal cavity. Transverse development of the maxillary alveolar process continues with buccal eruption of the posterior teeth. Growth of the midpalatal suture ends after the first two postnatal years, but the suture remains patent until late adolescence, with fusion usually not being complete until the third decade.

Mandible The mandible has the most delayed growth and the most postnatal growth of all the facial bones. Although usually in a retrognathic position relative to the maxilla at birth, there is rapid postnatal growth that corrects this discrepancy. The right and left bodies of the mandible are still separate at birth, uniting at the midline mental symphysis during the first year of life. The primary sites of mandibular postnatal growth are the endochondral apposition occurring at the condylar cartilages, and the intramembranous apposition on the posterior aspects of the rami and the alveolar ridges (Figure 53-14). Remodeling in the form of resorption of the anterior surface of the condyle, the anterior contours of the ramus, and the inner surface of the mandibular body are integrated with the posterior apposition. The growth of the condylar cartilages contributes most of the total ramus height, whereas growth of alveolar bone contributes about 60% to the mandibular body height.²⁶ Proliferation of condylar cartilage results in superior and posterior growth of the condylar heads, displacing

the mandible downward and forward in concert with the maxilla. Condylar growth appears to involve the sequential involvement of transcription factor SOX9, expressed by chondrocytes, which regulates the synthesis of Type II collagen, Type X collagen secreted as matrix, and vascular endothelial growth factor secreted to regulate the neovascularization of the cartilage.²⁷ At birth the inclination of the mandibular condyles is more horizontal, resulting in a greater increase in length than height. During childhood the inclination becomes more vertical so that condylar growth results in a greater increase in height than length. However, there is great variability in this inclination within the general population, influencing the degree to which the mandibular growth is expressed in a forward anteriorly rotating, as opposed to downward posteriorly rotating, direction. Simultaneous remodeling of the inferior mandibular border tends to reduce the effect of this rotation on facial morphology. Although minimal maxillary growth occurs after about 10 years of age, mandibular growth continues longer, to

FIGURE 53-14 Mandibular intramembranous and endochondral growth, resulting in an overall downward and forward transposition of the mandible relative to the cranial base. An outline of the fetal mandible is superimposed on the adult mandible for size and shape comparison. Adapted from Sperber G. *Craniofacial development*. Hamilton (ON): BC Decker Inc; 2001. p. 130.

the end of adolescent growth. This differential growth, typically characterized by a peak in the rate of mandibular growth at puberty, usually results in the final correction of the mandibular position relative to the maxilla.

If the cranial base is the craniofacial skeletal unit whose growth is least determined by extrinsic factors, the mandible is the opposite extreme with its growth highly dependent on the postnatal functional demands placed on it. It has a great capacity to adapt to mandibular displacement and accommodate to lingual and labial soft tissue and muscular function. The condylar inclination, dictating the type of mandibular rotation, is determined by these secondary functional influences. The relevant functional matrices include the lateral pterygoid attached to the condylar neck, the growth and function of the tongue, the masticatory muscles attached to the buccal and lingual aspects and to the coronoid process, and the facial soft tissue and musculature, all influencing the ultimate size and shape of the mandible. For this reason the mandible, more than any other part of the craniofacial complex, may have a low intrinsic growth potential that is significantly increased and regulated in response to functional demand.

Dental Development

The alveolar processes contribute a great portion of the vertical height of the lower face. Their development is entirely dependent on the presence and eruption of the primary and permanent dentition. Just as vertical appositional alveolar growth accompanies vertical dental eruption, transverse apposition complements transverse dental eruption. This minor contribution to the transverse dimension of the alveolar processes continues until about 7 years of age, with eruption of the permanent incisors. Further transverse dentoalveolar growth is minimal, occurring with eruption of the premolars and canines. Facial growth and the concomitant

increase in the size of the jaws occur posteriorly, creating additional space for the dentition only in the molar region.

Eruption of the maxillary teeth enhances the vertical dimension of the maxilla with posterior development of the maxillary tuberosities to accommodate the development and eruption of the maxillary posterior teeth. In the mandible, resorption of the anterior ramal borders provides room for the development and eruption of the mandibular posterior teeth. Eruption of the mandibular teeth enhances the vertical growth of the mandible and also contributes to the height of the face. However, compensatory condylar growth must occur to prevent the mandible from rotating posteriorly as the maxilla grows downward and the dentition erupts. Dental emergence into the oral cavity begins at approximately the sixth postnatal month, and the primary dentition is established by 2.5 years of age. The primary incisors begin to exfoliate at 6 to 7 years of age, and the permanent dentition begins to emerge with eruption of the mandibular incisors and first molars. The permanent dentition is established by 12 to 14 years of age except for the eruption of the third molars, contributing to the vertical dimension of the lower face during adolescent growth.

Facial Development

The growth of the facial soft tissue follows the underlying facial bones but is not directly correlated with bone growth. Facial soft tissue is thicker relative to the underlying skeletal tissue in the young child due to subcutaneous fat. This is one of the reasons it is more challenging to assess potential underlying skeletal discrepancies in the young child based only on a clinical appraisal. The thicker soft tissue envelope, together with the relative retrognathic position of the mandible, creates a more convex profile in infancy and early childhood. Lip thickness increases until it reaches a maximum at the end of

the pubertal growth spurt, then decreasing in late teens and adulthood.^{28,29} These later changes, combined with continued forward nasal growth as well as anterior mandibular and chin projection, leave the lips with a more retrusive appearance and the nose and chin with a more prominent appearance. These changes usually create a flatter facial profile in older adolescents and adults. This tendency is even greater on average in males than females, due to the less common presence of subcutaneous fat, combined with more nasal growth and anterior mandibular and chin projection in males.

The facial soft tissue also follows the cephalocaudal growth gradient, with the soft tissue of the lower face growing more in magnitude and duration than the upper face. The vertical length of the upper lip is a smaller proportion of lower face height in the preadolescent, often resulting in lack of resting lip apposition. During and following pubertal growth the upper lip proportion increases with greater vertical lip growth than the underlying vertical skeletal growth, creating a more likely chance of resting lip apposition in adults.³⁰

There is significant growth in the length of the nose during adolescence, influencing the facial balance between the nose, lips, and chin.³¹ In fact the vertical nasal growth is much greater than anteroposterior or transverse nasal growth. Nasal growth during adolescence is primarily limited to cartilage and soft tissue since the nasal bones usually have completed growth earlier. The nasal shape often changes prior to adolescence with the upper nasal dorsum developing superiorly and anteriorly, with the lower nasal dorsum more often following the lower facial growth pattern. In other words, individuals who have a more anterior and superior rotational pattern of lower face growth will exhibit a similar rotation of the lower nasal dorsum. There is some evidence that skeletal Class II jaw relationships usually demonstrate a more prominent nasal

bridge and convex dorsum than balanced jaw relationships.³²

The upper third of the face grows the most rapidly early in life due to brain growth and achieves its ultimate size earliest, finishing most growth by 12 years of age. Orbital height already reaches 55% of its adult height at birth and 94% by 7 years of age.³³ The middle and lower thirds of the face are less affected by brain growth, growing more slowly and for a longer time. Most of the middle third growth is completed later during puberty, with the lower third of the face continuing to grow beyond puberty into adulthood.

In addition to this vertical sequential growth gradient, craniofacial growth does not take place at an equal rate in the three planes of space. The completion of growth follows a sequence where transverse growth finishes first, followed by anteroposterior and finally vertical growth. The face reflects the early transverse neural expansion of the cranium, the early fusion of the mandibular symphysis, and the early growth cessation of the midpalatal suture during the first few years of life. This presents clinically as a disproportionately wide face relative to the height in the infant and young child. As the maxilla and mandible displace and grow downward and forward, the anteroposterior and vertical growth begin to take proportionately greater roles. The growth rate of the maxilla slows down after about 10 years of age, and together with anterior maxillary resorption, reduces the relative anterior projection of the midface. The maxillary length reaches maturity prior to the upper facial height, which is followed by mandibular length and finally ramus height.³⁴ The somewhat retrognathic position of the mandible at birth is usually corrected early in postnatal life. The mandible grows for a longer duration than the maxilla, typically undergoing a growth spurt at puberty. Anteroposterior growth is accompanied and then followed by vertical facial growth, often continuing well beyond puberty, even in to the third and fourth decades.

There are gender differences in facial growth, with males characteristically having volume changes of greater magnitude than females. Females have much less nasal growth on average, with many not even exhibiting a pubertal nasal growth spurt, in contrast to males who characteristically have a nasal growth spurt throughout puberty. Females have earlier soft tissue growth that follows their earlier puberty and they have greater lip thickness at all ages. The flattening of the facial profile during adolescence is less dramatic in females, due in part to their fuller lips, but also due to females having less forward mandibular growth projection and chin growth. Females have on average more late vertical maxillary growth than males. If mandibular growth is not matching these late maxillary changes, the mandible translates downward and backward, resulting in a more convex profile. Not only are male facial volume changes on average greater in magnitude, but the duration of the changes is longer, and there is more predominance of volume increase in the lower third of the face.³⁵ Males are on average more likely to have late mandibular growth that may be beneficial in improving a maxillary protrusion or mandibular retrusion, but is disadvantageous when a mandibular prognathism or maxillary retrusion is present prior to late growth.

Growth and Facial Changes during Adulthood

There has been awareness since the late nineteenth century that human growth continues beyond adolescence, at least until the fourth or fifth decade of life.³⁶ Nevertheless investigators in the mid-twentieth century were surprised to find that facial growth continues into the sixth decade of life.³⁷ More recently it was found that the craniofacial complex remodels throughout adulthood, with thickening of the frontal region of the cranium and a symmetric modest increase in the size of the cranium, cranial base, maxilla, and mandible.^{38,39}

During the past two decades there have been a number of longitudinal craniofacial growth studies that have examined changes during adulthood.⁴⁰⁻⁴⁴ Evaluation of the serial cephalometric radiographs revealed that craniofacial growth continues with increases in both anteroposterior and vertical dimensions at all age levels, similar to the changes seen during adolescence, but of a much lesser magnitude and rate. Females grow less and their craniofacial growth is expressed more vertically with posterior mandibular rotation, whereas males tend to grow with anterior mandibular rotation during adulthood, thereby straightening their profile (Figure 53-15).

Typical lip changes during adulthood include less prominence with decreased thickness and thinning of the vermilion, with male lips continuing to appear more retrusive with age. Female lips generally do not become more retrusive and their lower lip thickness tends to increase slightly. The lips become positioned more inferiorly, resulting in less vertical display of maxillary incisors and less lip separation.⁴⁵ The nose continues to increase in size in all dimensions, but more so in males, with the nasal tip dropping inferiorly.⁴⁶ There is deepening of the nasolabial folds and the oral commissures tend to sag inferiorly. There is more prominence of the pogonion due to continued soft tissue increase, but this is typically limited to males.

The biologic regulator mechanism for initiating and directing craniofacial growth and dental eruption timing, pattern, and rate remains a poorly understood phenomenon. It is clear that it is a complex mechanism, influenced by an intricate interaction of genetic, epigenetic, and local environmental factors.

Factors Influencing Craniofacial Growth

Craniofacial growth is a complex process influenced by both prenatal and postnatal genetic and environmental factors. The principal influence on craniofacial growth

FIGURE 53-15 Composite lateral cephalometric views of female and male showing longitudinal growth changes from young adult (broken line at mean age 17) to middle age adult (solid line at mean age 47 to 51). Note the continued downward and forward skeletal and soft tissue growth with relative flattening of the lips. Adapted from Behrents RG.⁴⁰

and morphogenesis is one of multifactorial genetic control. However, the interaction of this genetic control with environmental factors is a complex one, and it is usually impossible to accurately differentiate between these influences.

Prenatal Factors

Prenatal defects of craniofacial development can be classified conveniently into three categories: (1) malformation—a morphologic defect of an organ, part of an organ, or larger region of the body resulting from an intrinsically abnormal developmental process, which is intrinsically

determined due to the genome or a teratogen, and occurs during the embryonic period; (2) deformation—an abnormal form, shape, or position of a part of the body caused by mechanical forces, which is influenced directly by the fetal environment; and (3) disruption—a morphologic defect of an organ, part of an organ, or a larger region of the body resulting from the extrinsic breakdown of, or an interference with, an originally normal developmental process, which also occurs during the fetal period and may result from intrauterine pressure as well, but can be of metabolic, vascular, and/or teratogenic origin.⁴⁷

Genetic Craniofacial malformations arise from disturbance in morphogenesis as early as the germ layer formation to the final formation of organ systems at the end of the embryonic period. The fourth to eighth weeks' gestation is a particularly critical time because this is the period when neural crest migration is at its most active, the facial primordia and dental laminae are forming, and neurovascular bundles are being generated prior to facial bone ossification. Malformations are caused from chromosome abnormalities or single gene mutations, or are multifactorial (genetic and/or teratogenic) in origin. Growth retardation, premature death, and mental retardation seem to be more frequent in autosomal recessive or X-linked syndromes.⁴⁸ Craniofacial malformations range from acephaly to mild facial defects such as a microform cleft or notching of the lip. Cranial malformations include premature or delayed fusion of the cranial sutures, due to mutations in fibroblast growth factor receptors and the transcription factor MSX2, associated with syndromes such as trisomy 21 and cleidocraniodysostosis or with simply a deformation craniosynostosis.^{49,50} Cranial base malformations usually are related to malformations that affect cartilage growth such as achondroplasia. Apert, Crouzon, and Pfeiffer syndromes involve premature fusion of multiple facial and cranial sutures as well as cranial base synchondroses.⁵¹ Many facial malformations originate from a deficiency, incomplete migration, or failure in cytodifferentiation of neural crest tissue during embryogenesis.⁵² The result is a failure in normal formation of the skeletal and connective tissue portions of the facial primordia. Nasomaxillary malformations include deficiencies and/or absence of facial bones that occur in ectodermal dysplasia or mandibulofacial dysostosis, as well as facial clefts that are associated with over 250 syndromes. The most common craniofacial malformation is unilateral cleft lip,

affecting 1 in 700 to 800 births. Malformations that affect the mandible range from the rare absence (agnathia), to various forms of micrognathia, associated with a number of syndromes, such as mandibulo-facial dysostosis (Treacher Collins syndrome) or Turner syndrome, to macrognathia, associated with hyperpituitarism or hemifacial hypertrophy.

Two more common chromosomal disorders that result in growth retardation are Down syndrome and Turner syndrome, both of which are characterized by short stature and brachycephaly. The protruding tongue typical of Down syndrome usually results in an anterior open bite, whereas a narrow high-arched palate often is seen with Turner syndrome. The Russell-Silver syndrome is a chromosomal disorder characterized by poor fetal and postnatal growth and small triangular facies. Other syndromes associated with prenatal growth retardation include Bloom syndrome, de Lange syndrome, leprechaunism (mutations of the insulin receptor gene), Ellis-van Creveld syndrome, Aarskog syndrome, Rubenstein-Taybi syndrome, Perheentupa syndrome, Dubowitz syndrome, and Johanson Blizard syndrome.⁵³

Single-gene disorders that result in fetal overgrowth include Sotos syndrome, Weaver syndrome, and Beckwith-Wiedemann syndrome. Sotos syndrome includes craniofacial features of macrocephaly, dolichocephaly, a prominent forehead, hypertelorism, prominent ears, high-arched palate, and mandibular prognathism. The Beckwith-Wiedemann syndrome, another example of uniparental disomy, is associated with excessive somatic and specific organ growth (eg, macroglossia) apparently caused by excess IGF-II. In spite of the overgrowth with these disorders that extends from the fetal period into early childhood, both lead to early epiphyseal fusion, resulting in adult short stature. Klinefelter syndrome (XXY) is a chromosomal disorder that leads to postnatal extended growth from pubertal failure, resulting in tall adult stature.

An example of a single-gene growth disorder is achondroplasia, the most common form of human dwarfism, which is autosomal dominant with complete penetrance, involving mutations in the *FGFR3* gene. Since the primary cartilage of the cranial base synchondroses is affected, and not the secondary cartilage of the mandibular condyles, midfacial hypoplasia resulting in a Class III skeletal discrepancy is the usual facial outcome. A single-gene disorder that leads to postnatal overgrowth resulting in tall adult stature is Marfan syndrome.

Environmental Prenatal environmental growth factors are those not directly determined by the genome, including cytoplasmic and extracellular contents in the embryo or fetus and the placenta, influenced by the mother and her interaction with the external environment. Some of these environmental factors may be internal (such as focal embryonic hemorrhages) or external (from maternal malnutrition, metabolic factors, and disease, or exposure to pollutants, chemicals, drugs, infectious agents, or radiation), and may impair normal growth or act as teratogens during either the embryonic or fetal period if the maternal exposure is large or frequent enough (Figure 53-16).

Cytomegalovirus and rubella are examples of pathogens that can cause microcephaly, hydrocephaly, and microphthalmia. Glucocorticoids, phenytoin, ethyl alcohol, tobacco smoke, aspirin, and retinoic acid (a vitamin A metabolite) are examples of an ever-increasing number of substances that are being identified as teratogens, causing cleft lip and palate as well as other craniofacial anomalies.⁵⁴ Teratogens have distinct mechanisms of action and are selective to certain target cells, but the severity of the resulting malformation is variable. It is speculated that the range of phenotypic effects caused by a teratogen is due to factors that include the concentration or method of delivery, the timing and

duration of exposure, variations in susceptibility, and synergistic interactions among teratogenic compounds.⁵⁵ Even in the absence of any detectable malformations, serious long-term physical and mental development can result from drug intake during pregnancy.

When the fetal period begins, environmental factors can still have a profound growth effect on the developing fetus. Maternal malnutrition adversely affects fetal growth.⁵⁶ Maternal diet composition is relevant, with a high-protein diet being associated with increased linear fetal growth and a high-fat diet linked to an increased birth weight. Maternal consumption of alcohol, recreational drugs, or tobacco all have an important negative influence on growth in utero as well as during the first year of life.⁵⁷⁻⁵⁹ Even maternal exposure to passive tobacco smoke reduces fetal growth.⁶⁰ Frequent high maternal noise exposure has been shown to adversely affect prenatal growth, perhaps related to the stress imposed.⁶¹ Maternal pathology such as rubella is particularly detrimental if it occurs in the first trimester, causing a growth deficit with no long-term recovery.⁶²

Intrauterine pressures can result in deformations or disruptions. Intrauterine restrictions can result in mild to severe deformations that can present as mild facial or cranial asymmetry. Some isolated forms of craniosynostosis, causing cranial deformations such as plagiocephaly, may be caused from intrauterine mechanical factors.⁶³ These deformations may resolve after birth with catch-up growth but usually require orthopedic or surgical intervention during infancy. Another deformation is the Robin sequence whereby retrognathia from posterior restraint of the mandible forces the developing tongue into a posterior position, often acting as a mechanical obstruction that prevents elevation of the palatal shelves, resulting in an isolated cleft palate. A disruption is a typically more serious anomaly than a deformation, from the

FIGURE 53-16 Susceptibility to teratogens during periods in prenatal human development. During the first two weeks' gestation, damage from the teratogen results in death of the conceptus, or damages only a few cells, allowing recovery by the embryo to develop without birth defects. Dark blue indicates highly sensitive periods when major defects may be produced (eg, amelia, absence of limbs). Light blue indicates less sensitive periods when minor defects may be produced (eg, hypoplastic thumbs). Adapted from Moore KL, Persaud TVN. *The developing human: clinically oriented embryology*. 5th ed. Philadelphia (PA): W.B. Saunders Co.; 1973. p. 156.

standpoint of both treatment and future growth, because it presents as a morphologic and functional defect that requires surgical repair. An example of a disruption is where a strand of torn amnion or amniotic band is swallowed by the fetus, resulting in a facial cleft that is not located at a site of embryonic fusion.

The hormonal regulation of fetal growth is not well understood. Fetal androgens appear to be growth promoters. At midgestation the level of gonadotropin is similar to pubertal levels.⁶⁴ Although there is some evidence that estrogen promotes fetal bone development, there are also data that suggest that it inhibits fetal

growth.^{65,66} There is a marked and progressive increase in prolactin during late gestation. Before 12 weeks' gestation, maternal hypothyroidism can have long-term deleterious effects on hearing and intelligence, but neither maternal nor fetal hypothyroidism has an appreciable effect on fetal length or weight. However, when both conditions are present, linear growth is still unaffected but there is incomplete pulmonary, cardiovascular, and skeletal maturation.⁶⁷ Although poorly understood, insulin appears to have an important role in regulation and promotion of fetal growth. Maternal diabetes increases fetal length and weight, whereas fetal

insulin deficiency results in decreased length and weight at birth.⁶⁸

Although growth hormone (GH) is essential for postnatal growth, growth in utero and probably in the first 2 years of life is largely GH independent.^{69,70} Nevertheless IGF-I and -II play important roles in determining fetal growth, but the specific nature of these roles are not well understood. IGF-II is important in supporting fetal growth during early gestation whereas IGF-I has a greater role during later gestation and especially in postnatal life.⁷¹ The fetal roles of growth factors such as nerve, epidermal, and platelet-derived growth factors also remain unclear. Other

fetal growth factors include hematopoietic growth factors, fibroblast growth factors, vascular endothelial growth factor, and members of the TGF- β family.⁷²

The placenta functions as an additional endocrine organ, providing a secondary source of hypothalamic, pituitary, adrenal, and gonadal hormones and growth factors.⁷³ Placental GH and lactogen can alter the production of maternal IGF-I.⁷¹ Maternal IGF-I in turn affects placental nutrient transport, increasing fetal growth.⁷⁴ Lactogen regulates maternal glucose, amino acid, and lipid metabolism, facilitating nutrient transport to the fetus. Disruption of placental GH or lactogen production can occur from vascular disease, infection, or intrinsic placental abnormalities, impairing fetal growth.⁷⁵

Postnatal Factors

The size of infants in the first months of life is more related to the prenatal environment than parental height. If prenatal factors caused only mild growth attenuation and it occurred during the last trimester, then postnatal catch-up growth is feasible.

An area of craniofacial growth can be differentiated as a growth center or growth site. A growth center is where there is primarily intrinsic genetic growth control with a minimal environmental or functional role. Although a growth site also is controlled to some extent by genetic programming, it is more vulnerable to extrinsic growth control, being dependent more on the functional influence of the surrounding tissues. Cranial base synchondroses, where endochondral ossification of primary cartilage occurs, represent growth centers. The role of the cartilaginous nasal septum as a growth center or site remains controversial. There is a clearer understanding that the endochondral growth of the secondary cartilage of the mandibular condyles acts as a growth site, being greatly influenced by mandibular and soft tissue function. Areas of membranous bone growth resulting from sutural or periosteal

ossification are primarily growth sites and represent the bulk of the remaining craniofacial complex. There are exceptions, such as craniosynostosis, that can be due to an underlying genetic cause. Membranous ossification by sutural and periosteal remodeling is essentially the only type of craniofacial bone growth that occurs after adolescence throughout adulthood.

Genetic Heritability appears to have an effect on somatic growth, from a greater to lesser extent in the following order: skeletal length, skeletal breadth, weight, circumference, and skin folds. By the same token skeletal tissues respond less to changes in the nutritional environment than soft tissues.⁷⁶ The timing and pace of maturation is also genetically controlled to a large degree. The extent to which heredity is the cause of postnatal growth that results in jaw discrepancies is controversial. It appears that the genetic influence is particularly important for excessive mandibular growth and excessive vertical facial growth.^{77,78} It is speculated that probably no more than 50% of facial skeletal variation is due to the genetic component with the remaining half or more due to environmental influence.⁷⁹ Functional forces have a crucial influence in modifying craniofacial bone growth. Although genetic influence is important, the membranous viscerocranium is determined to a great extent by functional influences, with these extrinsic factors having the greatest control over mandibular growth.

Environmental There is a multitude of postnatal environmental factors that interact with genetic control mechanisms, including functional, traumatic, endocrine, nutritional, pathologic, psychological, cultural, and climatic, or seasonal factors.

The functional environment is determined by neuromuscular behavior necessary for survival such as respiration, mas-

tication, deglutition, speech, and posture. However, it is clear that functional influences at rest (ie, postural activity or the presence of a pathologic mass) are much more important than transient muscle contractions and mandibular movement in influencing craniofacial growth.⁸⁰ Chronic pressure alters regional skeletal growth and may be used to improve or correct some craniofacial deformities.⁸¹ Habitual behavior such as non-nutritive sucking and other oral or postural habits also may have an impact on growth if it is present with great enough frequency and duration.^{82,83} Mastication limited to one side for sufficient duration can cause asymmetric mandibular growth.⁸⁴ There is some evidence that diet consistency has an effect on mandibular morphology.^{85,86}

The extent of masticatory muscular and dental development can modify the morphology of skeletal superstructures, including the temporal fossae and sagittal crests, the zygomatic arches, the lateral pterygoid plates, the angular and coronoid processes and rami of the mandible, and parts of the temporomandibular joints.⁸⁷ The size and function of masticatory muscles has been correlated with facial morphology.⁸⁸⁻⁹⁰ Other studies have demonstrated an atrophic effect from muscle denervation.^{91,92} However, it also is clear that external craniofacial bone growth nevertheless can occur in the absence of any muscle function.^{93,94}

Growth deficiency due to neuromuscular deficits can occur in muscle weakness conditions such as muscular dystrophy. The difficulty in returning function to the area makes such conditions particularly resistant to treatment. However, if the muscle is normal, it appears that the normal force range of masticatory muscular function in the general population does not significantly affect facial growth.⁹⁵ Long-term impairment of nasal breathing historically has been viewed as a cause of long face deformity, but this assumption continues to be controversial.⁹⁶ There is

less disagreement about a relationship between nasal obstruction and facial deformity than there is with the extent and duration of mouth breathing necessary to cause a deformity.

Postnatal surgery during infancy for congenital malformations such as cleft lip and palate introduces scarring that is responsible for some midfacial growth attenuation. Typical surgery to close palatal clefts requires that mucoperiosteal flaps be raised and moved medially and posteriorly. This results in denuded bony areas that will heal with the formation of scar tissue bands of variable size and elasticity. This scar tissue usually connects across the maxilla and includes the palatal bones and possibly the pterygoid plates. It is thought that the presence of this scar tissue during postnatal growth compromises midfacial growth.⁹⁷ The longer postnatal surgery can be delayed, the less growth is affected.

Perinatal or postnatal trauma to the craniofacial complex can modify growth if there is limitation of blood supply or mechanical constriction due to scarring. Extensive midfacial trauma can cause midface growth deficiency as a result of the loss of intrinsic nasal septal growth or from a structural collapse that prevents normal morphologic expression of growth.⁹⁸ Untreated burns of the head and neck can cause significant craniofacial dysmorphology.⁹⁹ Neurologic damage may lead to muscle paralysis that can alter craniofacial form due to decreased muscle function. There should be caution when considering early craniofacial reconstructive surgery, since the surgery itself may produce additional scarring that can exacerbate the growth attenuation. There is no evidence that the use of rigid plate fixation for trauma reconstruction causes restrictive growth effects in addition to the trauma alone.¹⁰⁰ With trauma involving the mandible, mandibular function must be maintained, often requiring physical therapy

and the use of a functional appliance. As long as mandibular ankylosis is prevented, surgery should be avoided when treating condylar fractures in children.¹⁰¹

Endocrine disturbances originating from pathology or the environment are among the most potent regulators of postnatal growth. The primary growth promoting hormone, GH, is secreted by the pituitary and regulated by somatostatin and GH-releasing hormone release from the hypothalamus. Studies have demonstrated increased GH secretion throughout the day and night in the newborn. However, IGF-I levels are lower at birth and gradually increase during childhood and into adolescence, indicating an early immaturity in the feedback loop. Although the growth process in utero and in the first months after birth is more nutritionally dependent than GH dependent, this changes during the first year of life, with full GH dependence attained during the second year.⁷⁰ GH has been shown to have a direct stimulatory effect on cartilage growth, whereas IGF-I acts as a secondary stimulatory effector.¹⁰²

Most of our present understanding of the endocrine influence on craniofacial growth has developed from assessing children who have diagnosed endocrine disorders. GH-deficient children have excess subcutaneous fat and overall delayed facial and cranial base development, resulting in infantile, but proportional, facies. Dental development is delayed as well but to a much lesser degree than facial or somatic growth. In contrast the craniofacial growth is disproportionate in an autosomal recessive condition known as Laron syndrome where there is IGF-I deficiency in spite of increased serum GH levels.¹⁰³ There is a normal calvarium with small facial bones, resulting in the forehead appearing large and prominent relative to the small recessed face.¹⁰⁴ This suggests that some areas of the face are more directly affected by GH than IGF-I.

GH excess, usually a consequence of a pituitary adenoma, results in gigantism if it occurs prior to the end of adolescence and presents with overall larger craniofacial dimensions. Acromegaly is the outcome if the GH excess is produced following adolescence, characterized by increased periosteal bone that includes cranial thickening, increased size of the frontal sinuses, prominent supraorbital ridges, and nasal enlargement as well as renewed mandibular condylar cartilage growth, leading to mandibular prognathism.

Hypothyroidism will decrease GH release and results in delayed bone and dental development.¹⁰⁵ The craniofacial outcome of this deficiency differs from GH deficiency primarily by the smaller cranium. Anabolic steroids increase craniofacial growth but may lead to excessive anterior maxillary growth in high doses.¹⁰⁶ Testosterone, GH, and IGF-I accelerate endochondral and intramembranous craniofacial skeletal growth as well as stature height. Estrogen appears to decrease endochondral growth.^{107,108}

Although glucocorticoid production is necessary for normal growth, glucocorticoid therapy in the prepubertal child must be carefully managed to avoid its inhibitory effect on GH and IGF-I production, resulting in short stature.¹⁰⁹ Though there are no clinical studies indicating the effect on craniofacial growth, animal model studies have suggested a retarding effect on mandibular condylar cartilage growth and acceleration in dental eruption.^{110,111}

Poor nutrition, hygiene, and health adversely affect growth. Insufficient caloric and protein intake is the most common cause of growth failure worldwide.¹¹² Growth deficiency from malnutrition is proportional to the severity of the nutritional deficit. Malnutrition is associated with increased GH but decreased production of IGF-I, reallocating calories from anabolic to survival requirements.¹¹³ It is estimated that 55% of the morphologic variation of the cranium is due to nutritional factors.¹¹⁴

Because of the early rapid growth of the brain, the cranium is affected more by infant malnutrition than the rest of the craniofacial complex. The size of the neurocranium decreases in rats subjected to malnutrition.¹¹⁵ A diet deficient in calcium and vitamin D resulted in cranial dimensional changes in rats.¹¹⁶ It is thought that maternal vitamin A deficiency alters endocrine function that causes a disturbance in chondrogenesis, reducing the cranial base.¹¹⁷ Nasomaxillary hypoplasia in humans can be related to maternal vitamin K deficiency induced in rats, causing limited nasal septal cartilage growth.¹¹⁸ Protein malnutrition in rats decreases the length of the skull relative to the width.^{119,120} Voluntary undernutrition has become more common during adolescence, especially with females trying to decrease weight for athletics and those with anxiety about obesity. This may develop into extreme eating disorders such as anorexia or bulimia, which may result in impaired growth, delayed puberty, and osteopenia.¹²¹

Chronic disease such as congenital heart disease, malabsorption syndrome (eg, chronic inflammatory disease, cystic fibrosis, celiac disease), chronic renal or liver disease, chronic anemia, inborn errors of metabolism, chronic infections (eg, tuberculosis, acquired immunodeficiency syndrome), severe asthma, or other chronic pulmonary disease can adversely affect growth.¹²² There are a variety of mechanisms causing the growth deficits from these conditions, including reduced nutritional intake, metabolic disbalance, hypoxia, chronic metabolic acidosis protein loss, and often the treatment for the pathology itself.¹²³ Medications that limit potential growth include chronic adrenal steroid therapy (used for asthma, nephritic syndrome, lupus, and other chronic diseases) and cytostatics (for cancer treatment). Irradiation of the head and face for childhood cancer can result in severe hypoplasia of soft and hard tissues.^{124,125} If cranial irra-

diation is required in cases of leukemia and tumors of the central nervous system, hypothalamic function can be damaged, affecting the release of hypothalamic and pituitary hormones, notably GH.

Chronic psychological trauma, emotional deprivation, or psychosocial stress can have a profound effect on somatic growth, causing a functional and reversible GH deficiency, often mimicking growth disorders that are caused from endocrine or nutritional deficiencies.¹²⁶

Additional less important factors have been shown to have a significant influence on postnatal growth and development. These include climate, altitude, exposure to environmental pollutants, and noise.¹²⁷⁻¹³⁰ Future research will increase our understanding of the role that these and other yet unidentified environmental factors play in altering human genetic growth potential.

Orthopedic and Orthodontic Clinical Considerations

Orthopedic Treatment for Growth Modification

Just as our understanding of craniofacial growth is continually evolving, the application of this knowledge to clinical practice is also in a constant state of flux. This application is particularly important in order to determine the appropriate use of growth modification for treatment of craniofacial skeletal discrepancies.

A harmonious esthetic facial appearance and balanced dentoskeletal segments facilitating a functional occlusion are both goals that orthodontists and oral maxillofacial surgeons work to achieve by means of orthodontic treatment combined with orthognathic surgery. However, before a surgical correction is contemplated in a growing patient, a determination should be made if the patient is a candidate for orthopedic treatment that may modify craniofacial growth to improve the skeletal imbalance to a favorable esthetic and func-

tional outcome without the need for orthognathic surgery. It is well known that craniofacial orthopedic devices can generate forces that cause stress in sutures capable of modifying suture growth.¹³¹ As indicated earlier in the chapter, almost 50% of the total cumulative growth of the midface and mandible remains between the ages of 10 years and adulthood, making it possible to have an orthopedic treatment effect on the jaws during this time.

In spite of over a century of clinical experience with orthopedic facial appliances, it remains controversial as to what extent growth can be predictably and permanently modified by orthopedic treatment. Although there is consensus that there is an important genetic influence on the outcome of craniofacial growth, there is a wide range of views regarding the amount in which postnatal factors, particularly orthopedic treatment, influence this outcome. Views range from the belief that orthopedic alteration of jaw relationships is predictable and stable, to the contrasting opinion that facial growth is primarily determined genetically and cannot be significantly altered by orthopedic treatment. The reality is likely to be somewhere between these two extreme views. It has been proposed that the typical range of skeletal malocclusions include individuals with normal gene polymorphisms for signaling molecules and growth factors that attenuate the capacity of tissues and cells to reliably respond to orthopedic treatment.¹³²

The efficacy of craniofacial growth modification has been a controversial subject for more than a century. At the onset of the twentieth century there was universal confidence by the orthodontic profession that forces applied through the dentition to the growing face could effectively treat craniofacial skeletal discrepancies. After the 1920s there was a decline in this conviction by North American orthodontists. With the invention of the cephalostat, more precise skeletal assessment of treatment outcomes became possible during the 1950s. This

resulted in renewed faith in growth modification, with the demonstration of skeletal changes from the use of extraoral force applied with a cervical headgear.

In Europe there was less controversy regarding craniofacial growth modification efficacy throughout the first half of the twentieth century. European orthodontists relied primarily on removable “functional” appliances, designed to provide forces from facial muscles and soft tissue function, for facial orthopedic treatment. The separate philosophical paths taken by European and American orthodontists united in the 1960s, resulting in a more global acceptance of either extraoral (headgear) or intraoral (functional) appliances, or a combination of both to facilitate craniofacial orthopedic treatment. This acceptance gained support and enthusiasm from results of basic research conducted during the 1970s using animal models. Although this enthusiasm reached its peak in the 1980s, it was considerably moderated in the 1990s from clinical experiences and the results of retrospective clinical studies. There remains little argument that some craniofacial growth modification is feasible, but there continues to be controversy over the nature and extent of the skeletal change possible in individual patients as well as the optimal treatment timing and appliance type. In addition a reliable and accurate method of predicting the direction, timing, and magnitude of craniofacial growth for an individual has not been devised.

The aim of craniofacial growth modification is to alter the growth pattern by changing the relationships of the jaws. If the skeletal unit is too large, the aim of the orthopedic treatment is to attenuate or redirect its growth to improve its relationship relative to the opposing jaw. If the jaw is too small, the growth modification treatment is aimed at enhancing or redirecting its growth relative to the larger skeletal unit. Virtually all of the growth modification appliances to date have been “tooth-

borne” to some extent, so that the orthopedic forces applied to the skeletal units also create stress to the teeth that results in some dental movement. Although the goal of craniofacial growth modification is to limit the changes to the skeletal units with minimal movement of the teeth, the reality is that the treatment is a combination of skeletal and dentoalveolar changes.

There is growing evidence that the long-term success of many forms of growth modification requires that the treatment be continued until facial growth is nearly complete, making early treatment a less efficient way to treat many jaw discrepancies. The following discussion will summarize the facial orthopedic options we have for clinical application of our present understanding of craniofacial growth in the three planes of space.

Transverse Orthopedic Treatment Since transverse growth reaches completion earlier than anteroposterior or vertical craniofacial growth, it follows that transverse skeletal problems should be addressed early. The most common transverse skeletal problem is maxillary constriction, which can be treated in the preadolescent child, even as early as during the primary dentition. The most recent federal epidemiologic study, the National Health and Nutrition Estimates Survey (NHANES-III) conducted from 1989 through 1994, indicates the prevalence of posterior crossbite is about 5% of the US population.¹³³ Significant facial or mandibular asymmetry represents about 0.1% of the total population.¹³⁴ Although maxillary orthopedic expansion devices have been used since 1860, they fell out of favor for a few decades prior to the 1940s due to unsubstantiated concerns regarding their safety and effectiveness.¹³⁵ Orthopedic expansion of the maxilla can be achieved with a variety of toothborne appliances (Figure 53-17). These appliances apply moderate to high forces to the teeth that are transmitted as stresses to the

maxilla, primarily distracting the midpalatal sutures but also producing less pronounced stresses to the sphenoid and zygomatic bones and other adjacent structures.¹³⁶ Within days following initial expansion, new bone forms, eventually depositing both perpendicular and parallel to the edges of the expanded sutures.¹³⁷ Although a large amount of the skeletal

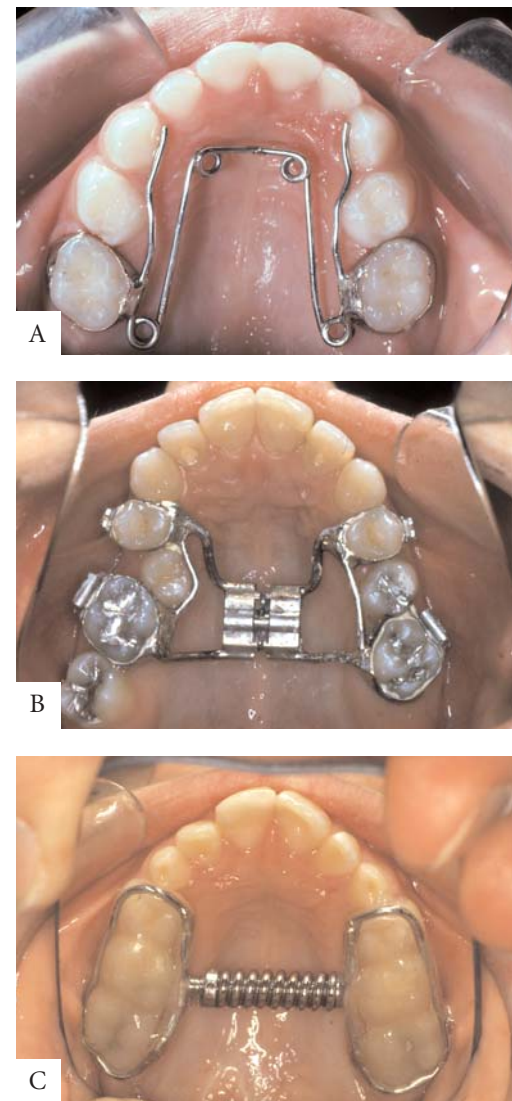

FIGURE 53-17 Types of maxillary orthopedic expansion appliances. A, Quad-helix: An effective skeletal expansion appliance in the primary dentition. B, Banded Hyrax: This traditional jackscrew also can be used as an activation component for an appliance bonded to the maxillary posterior teeth. C, Bonded Minne-expander: This spring-loaded component also can be used as an activation component for an appliance banded to the maxillary posterior teeth.

expansion relapses during retention, overall stability is good if the extent of sutural patency and magnitude of expansion are great enough. A potential additional benefit to improvement in interarch transverse compatibility is an increase in arch perimeter made possible by the maxillary orthopedic expansion.¹³⁸

Although complete fusion of the midpalatal suture usually does not occur until the third postnatal decade, the process leading to fusion is a gradual one, characterized by progressive sutural interdigitation and ossification.¹³⁹ For this reason more effective sutural separation, requiring less force and concomitant dental expansion, is possible in the younger child, especially prior to puberty, during a “phase 1” treatment in the mixed or early permanent dentition. Treatment prior to the pubertal growth velocity peak may result in greater long-term skeletal craniofacial transverse width.¹⁴⁰ Treatment may even be indicated as early as the primary dentition in the presence of a transverse functional shift. This compensatory functional problem can result in asymmetric condylar positioning that may lead to asymmetric mandibular growth and uneven remodeling of the glenoid fossae, possibly resulting in permanent facial asymmetry, even if the constricted maxillary arch is corrected at a later date.¹⁴¹ Maxillary constriction without a transverse functional shift does not carry the same urgency and is conveniently treated closer to the onset of puberty during the early permanent dentition.¹⁴²

Maxillary orthopedic expansion in late adolescent or postadolescent patients should be attempted with caution. Even if skeletal expansion is possible in these older patients, the extent of circum-maxillary sutural patency is limited enough to compromise stability of the treatment outcome. It is appropriate to confirm intermaxillary expansion with an occlusal radiograph in these patients, since the development of a midline diastema may only indicate bending of maxillary bones.

If the expansion is limited to lateral tipping of maxillary posterior teeth, buccal alveolar bone height reduction and gingival recession may occur. It usually is more prudent to consider surgically assisted palatal expansion for late adolescent or postadolescent patients to avoid periodontal compromises and instability.

The expansion appliance can be banded or bonded to the maxillary posterior teeth with a spring-loaded or nonspring-loaded palatal jackscrew that usually is activated by the patient 0.5 mm per day, delivering from 2 to more than 10 pounds of force (this may increase to cumulative loads of 20 pounds or more with multiple activations in the absence of adequate sutural separation). The conventional description for the expansion induced with this appliance is “rapid palatal expansion.” However, it is possible to affect slower expansion with less frequent activations, requiring more active treatment time, but less retention time to ensure sta-

bility.¹⁴³ It is possible to achieve skeletal expansion with simpler appliances such as a W-arch or Quad-helix, provided that the patient is in the primary or very early mixed dentition, when the maxillary sutures are more patent or when a cleft of the hard palate is present (Figure 53-18).

Since all of these expansion appliances are toothborne, unwanted dentoalveolar expansion is an inevitable consequence.^{144,145} An additional undesirable outcome is the long-term loss of about 30% of the skeletal expansion achieved during active treatment due to the rebound of stretched palatal tissues.¹⁴⁶ To compensate for these effects, maxillary expansion should be continued until adequate overexpansion is achieved, usually to the extent that the lingual cusps of the maxillary molars are opposing the buccal cusps of the mandibular molars (Figure 53-19). Once adequate expansion has been accomplished, at least 3 to 6 months of retention is necessary to permit new bone

FIGURE 53-18 Intraoral radiographs demonstrating maxillary skeletal expansion with a Quad-helix during the primary dentition. Note the distraction of the midpalatal suture. A, Before expansion. B, After initial expansion.

to fill in the spaces created by maxillary separation and to permit time for dissipation of reaction forces stored in the facial bones that promote relapse. The overexpansion permits the orthodontist to upright the posterior teeth in their alveolar housing without compromising the transverse occlusal correction following retention. Osseointegrated attachments may hold future promise for a means of expanding the maxilla without buccally tipping posterior teeth (Figure 53-20).¹⁴⁷

A less common transverse skeletal problem than maxillary constriction is asymmetric mandibular deficiency, usually caused from a previous trauma associated

FIGURE 53-20 Palatal distraction appliance. Reproduced with permission from Gerlach KL, Zahl C. Transversal palatal expansion using a palatal distractor. *J Orofac Orthop* 2003; 64:444.

with unilateral mandibular condylar fracture or hemifacial microsomia, a congenital facial asymmetry. In both of these conditions the affected side exhibits growth deficiency relative to the unaffected or normal side, resulting in a mandibular deviation toward the affected side. If left untreated in a growing individual, the alveolar processes compensate with limited eruption of the maxillary posterior teeth on the affected side and excessive eruption of the maxillary posterior teeth on the unaffected side, resulting in an occlusal cant that is higher on the affected side. It is best to start orthopedic treatment with these individuals prior to the pubertal growth spurt, as early as patient compliance will permit. The goal is to maximize the growth expression on the deficient side and minimize dentoalveolar compensation. The orthopedic appliance of choice is an asymmetric “hybrid” functional appliance that is constructed to posture the mandible forward on the affected side, bringing the chin to the midline.¹⁴⁸ Posterior dental eruption is attenuated on the unaffected side with a bite block and eruption is facilitated on the affected side with a buccal shield and the absence of interocclusal acrylic (Figure 53-21). Since untreated mandibular asymmetries of this nature invariably worsen with growth, orthopedic treatment is considered successful if the asymmetry remains stable or improves. Treatment should not continue if progressive asymmetry is apparent in spite of reliable appliance use by the patient.

Anteroposterior Orthopedic Treatment: Class II A Class II skeletal relationship can be the result of a retrusive and/or deficient mandible, a protrusive or vertically excessive maxilla, or a combination of these skeletal problems. The prevalence of this type of malocclusion is about 15 to 20% of the US population, with about 2% severe enough to be considered as handicapping.^{133,134} Prospective clinical studies have supported that early growth modification therapy may lead to an improve-

FIGURE 53-21 Asymmetric “hybrid” functional appliance: A, right lateral view; B, frontal view. On the left, unaffected side, posterior dental eruption is restricted with an interocclusal acrylic block. On the right, affected side, the mandible is postured forward and posterior dental eruption is encouraged with a buccal shield and absence of an interocclusal acrylic block. ment in the skeletal Class II malocclusion.^{149–151} It should be kept in mind that regardless of whether orthopedic treatment is attempted during active facial growth, approximately 10% of patients ultimately require orthognathic surgery to fully correct the Class II malocclusion.¹⁵⁰

The headgear has been used as a means of Class II orthopedic treatment in North America since the late nineteenth century (Figure 53-22). An orthopedic force ranging from 16 to more than 32 ounces is delivered using elastic traction from the headgear to a cervical or cranial attachment for 12 to 14 hours per day, usually for 9 to 12 months. Theoretically the force is transmitted in a posterior and

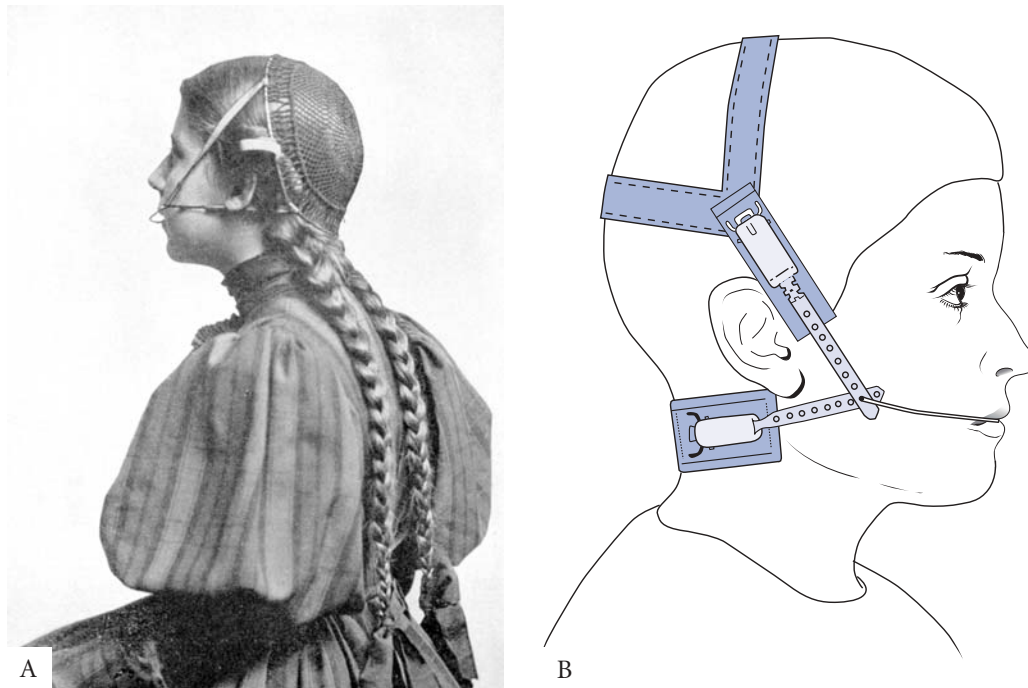

FIGURE 53-22 Headgear, past and present. An orthopedic force is directed posteriorly and superiorly to the maxilla, attenuating circum-maxillary sutural growth. superior direction via the teeth through the maxilla to compress the circum-maxillary sutures, limiting or redirecting maxillary growth. Since the introduction of standardized cephalometric radiographs, many clinical studies have demonstrated that maxillary growth can be altered with the use of the headgear.^{152–170} These clinical data have been supported by primate studies demonstrating that extraoral orthopedic force directed against the maxilla attenuates forward growth and alters bone apposition at the maxillary sutures.^{171–179} There are some studies that suggest that mandibular growth may be enhanced as well. Since the headgear is a toothborne appliance, there is some maxillary dental retraction that accompanies the skeletal change. Another dentoalveolar effect is the attenuation of maxillary molar eruption, resulting in anterior and superior mandibular rotation. There is some support for this being the only clinically rele-

vant skeletal effect.¹⁸⁰ A significant treatment effect usually requires that a headgear be worn 12 to 16 hours per day with a superior and posterior force of one pound or more per side. Human GH and other endocrine factors that promote growth and dental eruption are primarily released during the evening and night.^{181–183} It is fortuitous that this is the only time of day that one can reliably expect an adolescent to wear a headgear. Since it is a removable appliance, few adolescents after the peak of the pubertal growth spurt will reliably wear the appliance.

The alternative orthopedic method for treating a Class II skeletal relationship is the Class II functional appliance, which has been used since the early twentieth century in Europe and since the 1960s in North America. These appliances include the removable toothborne activator, bionator, and twin block, the removable and primarily tissueborne Fränkel (functional

regulator) appliance, or the fixed toothborne Herbst appliance (Figure 53-23). All of these appliances position the mandibular condyles downward and forward away from the glenoid fossae. Theoretically the distracted condylar positions reduce the normal compressive joint pressure on the growing condylar cartilage and the forward mandibular posturing alters muscle tension on the condyles, stimulating or accelerating the endochondral condylar growth more than would normally occur.¹⁸⁴ There is some support from animal studies that a histologic increase in condylar growth can be achieved.^{185–187} However, clinical studies have not confirmed that a greater absolute growth is the long-term treatment outcome.^{149,150} Some retrospective clinical studies have supported the assertion that clinically significant lengthening of the mandible can be achieved with functional appliances.^{188–198} Others have refuted this assertion.^{158,199–217} Much of the skeletal change demonstrated with a functional appliance may result from forces against the maxilla, similar to those applied with a headgear, that are created from the stretched facial muscles and soft tissues attempting to return the postured mandible back to its posterior and superior position.^{158,202,203,208,218–222} Because of the toothborne nature of this appliance, dentoalveolar changes accompany the skeletal changes, including maxillary dental retraction and mandibular dental protrusion.

Clinical studies have demonstrated few differences in treatment outcome when comparing the skeletal response between headgear and functional appliance treatment.^{168,193,223} However, there appears to be more of a maxillary effect with headgears.^{150,158,161,168} There is more of a mandibular effect with functional appliances.^{149,150,168,192,205} Most functional appliances need to be worn for the same daily duration as the headgear (exceptions are the Fränkel and Herbst appliances which

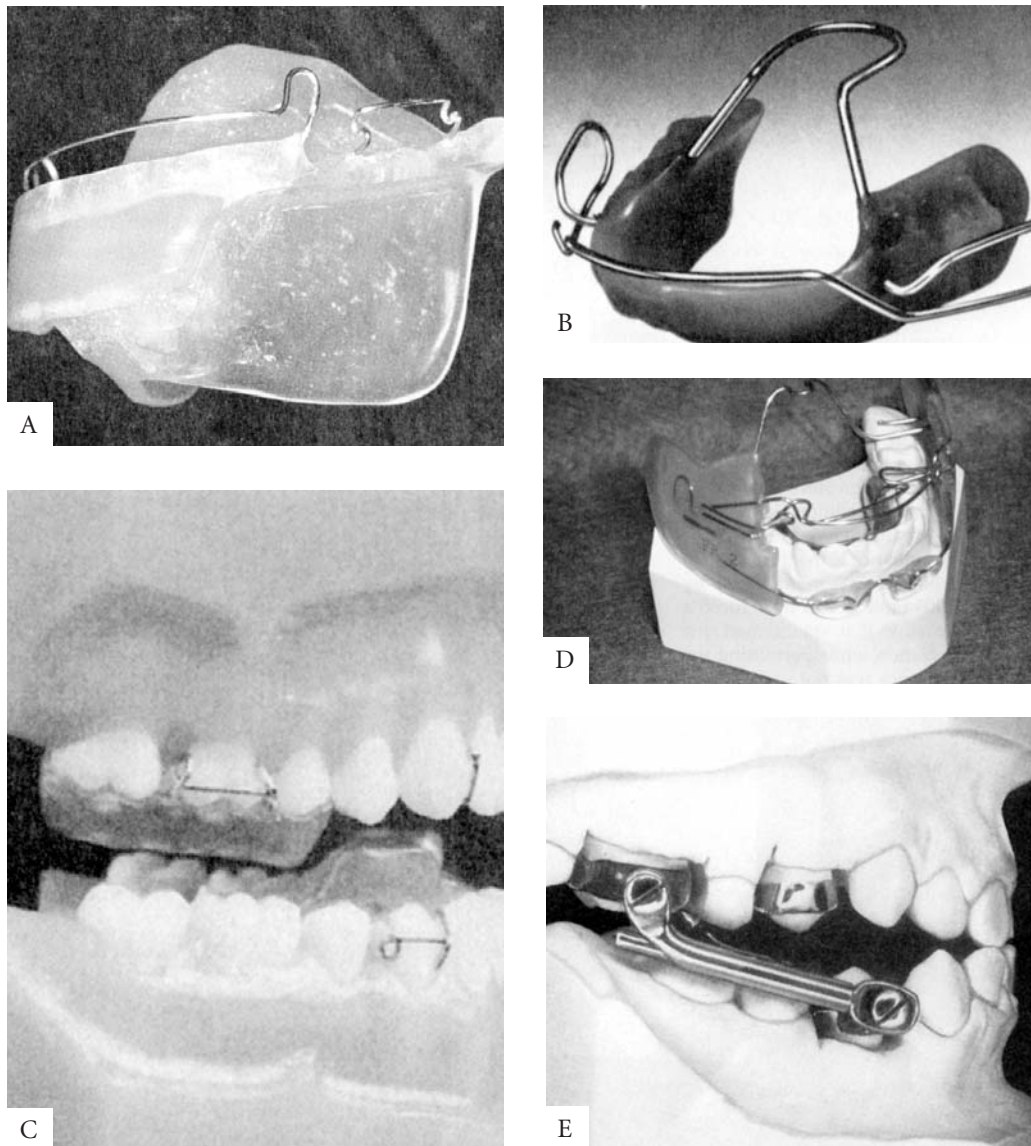

FIGURE 53-23 Class II functional appliances. All of these appliances position the mandible downward and forward, distracting the condyles from the glenoid fossae. This simultaneously creates posterior and superior forces to the maxilla from the facial muscles and soft tissues attempting to return the mandible to its normal position. A, Activator. B, Bionator. C, Twin block. D, Fränkel. E, Fixed Herbst. An alternative is to utilize occlusal acrylic and bond the maxillary portion of the appliance with a removable acrylic splint for the mandibular arch. are worn full-time) for a significant treatment effect. Much like the headgear, dependable wear is more realistic during the evening and at night when the most active facial growth and dental eruption usually occur. However, like the headgear, its removable nature prevents it from being

reliably worn by most adolescents after the peak of their pubertal growth spurt.

In the late 1960s, when European and American facial orthopedic philosophies were becoming more fully integrated, a method was introduced in Europe using a headgear in combination with a function-

al appliance (Figure 53-24).^{204,224–227} This approach was intended to provide greater cumulative skeletal growth effects than use of either appliance alone, but this has yet to be demonstrated by clinical studies.

Although there is greater general acceptance that treatment with a headgear or functional appliance may achieve an improved long-term treatment outcome, there continues to be controversy over the optimum treatment time in the growing child. It has already been demonstrated that orthopedic Class II treatment in the very young child, in the primary or early mixed dentition, results in substantial relapse and recurrence of the original facial skeletal pattern by late adolescence.²²⁸ However, there is great debate regarding the efficacy of orthopedic treatment during later mixed dentition as the first phase of a two-phase treatment versus delaying orthopedic treatment until definitive orthodontic treatment during puberty, after the eruption of the permanent dentition. Many orthodontists historically have preferred the earlier first phase since there is substantial potential growth remaining, compliance in wearing the orthopedic appliance often is greater, and the arch space for the remaining erupting dentition may be improved. The advocates for a delayed one-phase treatment have contended that comparable skeletal treatment effects can be achieved during definitive orthodontic treatment, without putting the patient through an unnecessary initial phase.^{229,230} Recent prospective randomized clinical trials have supported this position, demonstrating that early skeletal improvement achieved from these appliances seems to represent accelerated growth and can be used just as effectively later during pubertal growth.^{149–151} They also showed that there was substantial individual growth variability with no reliable predictors for a favorable growth response identified, and early treatment did not reduce the need for dental extraction or orthognathic

B

surgery during the definitive phase. These studies indicate that there is no adequate additional benefit in treatment outcome to justify the greater burden to the patient, their parents, and the orthodontist, as represented by an early phase that precedes the definitive phase of orthodontic treatment.

It can be concluded from past retrospective and more recent prospective clinical trials that headgear treatment tends to have more of a maxillary restrictive effect whereas functional appliances have more of a mandibular enhancing effect. Either approach can be satisfactory and should be selected on the basis of patient acceptance of the appliance and dentoalveolar side effects (there is more maxillary dental retrusion with headgear and more mandibular protrusion with a functional appliance). It appears that orthopedic treatment during the mixed dentition can only be justified where there is increased trauma risk (due to excessive overjet), sufficient esthetic concern by the patient, or a precocious adolescent growth spurt that substantially precedes dental development. Treatment at an earlier age has been further justified by the argument that there is lack of reliable means of

predicting mandibular growth and that improved cooperation usually is present with the younger patient.²³¹

Although improvement in skeletal discrepancy is expected, the Class II correction usually is due to a combined response of both the dentoalveolar and skeletal segments. Both headgear and Class II functional appliance use can be effective in limiting downward and forward eruption of the maxillary molars. However, the functional appliance tends to promote upward and forward eruption of mandibular molars, which may complement the correction in deep overbite cases but is counterproductive in patients with a long face. Since Class II orthopedic appliances are toothborne, there may be some unwanted dentoalveolar change, including retraction of maxillary anterior teeth and protraction of mandibular anterior teeth. This compensatory change may be undesirable if the skeletal discrepancy ultimately requires orthognathic surgery for correction. With the advent of osseointegrated attachments there may be the future possibility of preventing unwanted dentoalveolar change by attaching a force system directly to these

attachments rather than using toothborne attachments.

Anteroposterior Orthopedic Treatment: Class III A Class III skeletal relationship can be the result of a retrusive and/or deficient maxilla, a large and/or prognathic mandible, or most often, a combination of these skeletal problems. The prevalence of this type of malocclusion is about 3 to 5% of the US population, with about 0.3% severe enough to be considered as handicapping.^{133,134} Since the late nineteenth century, when headgear was being used for Class II skeletal problems, the chin cup was the appliance used for orthopedic treatment of skeletal Class III problems (Figure 53-25). Theoretically an orthopedic force is transmitted to the mandibular condyles, compressing the condylar cartilage and limiting endochondral growth in order to decrease the ultimate length of the mandible.²³² Primate studies suggest that mandibular growth can be limited with heavy full-time forces directed against the condyles.²³³ Full-time wear is unrealistic with humans and most clinical studies have demonstrated that mandibular growth is not restrained, but rather vertically redirected from chin cup wear, resulting in decreased chin prominence at the expense of increased face height.²³⁴⁻²³⁸ Studies also have suggested that the long-term stability of these changes is poor.^{239,240} Treatment with a chin cup may be an acceptable option for an individual with mandibular excess associated with decreased facial height but is contraindicated where there is a normal or excessive facial height, since the treatment outcome simply would be trading one deformity for another.

Class III functional appliances also have been developed, limiting eruption of mandibular posterior teeth and promoting eruption of maxillary posterior teeth. These functional appliances have few advocates due to their effectiveness being limited to dentoalveolar changes and their inability to promote forward maxillary growth or attenuate mandibular growth.²⁴¹

Jean Delaire, a French dentist, was responsible for developing the protraction headgear or facemask, the most effective orthopedic appliance for skeletal Class III problems since its introduction in the early 1970s (Figure 53-26).²⁴² Delaire recognized that the offending jaw in many of the skeletal Class III problems was the maxilla, so he departed from the historic focus on the mandible and directed treatment at the retrusive or deficient maxilla. The appliance creates tension in the circum-maxillary sutures with elastics from the maxillary dental arch to a frame that uses the forehead and chin to dissipate the force anteriorly. Primate studies have demonstrated adaptive responses of the sutures to the stress from the distraction forces produced by this appliance.¹³⁷

Depending on the developmental stage and size of the patient, a protractive force ranging from 2 to 4 pounds is applied to the facemask in an anterior and slightly inferior direction relative to the occlusal plane for 12 to 16 hours per day, usually for 6 to 9 months. Clinical studies have demonstrated clinically relevant

maxillary skeletal protraction downward and forward on average with this appliance, with some concomitant protraction of the maxillary teeth due to the tooth-borne nature of the intraoral part of the appliance.^{243–246} However, as with other forms of craniofacial orthopedic treatment, there is substantial variability and an unpredictable patient response to the appliance, ranging from no appreciable skeletal change to about 5 mm anterior maxillary movement.²⁴⁷ It is important to achieve overcorrection of the anterior crossbite and anterior overbite since there is some relapse following discontinuation of treatment.²⁴⁸ Additional effects of maxillary orthopedic protraction often include rotation of the maxilla downward in the posterior and upward in the anterior, downward and backward rotation of the mandible, and retraction of the mandibular incisors due to the reactive posterior force dissipated on the chin. These additional orthopedic and dentoalveolar changes that accompany maxillary skeletal protraction would be contraindicated for a Class III pattern with excessive vertical

development or where mandibular excess is the underlying cause of the problem.²⁴⁹

The timing of facemask therapy usually is recommended for patients in the primary to early mixed dentition (ie, ages 4 to 8), due to the increased patency of the maxillary sutures and compliance with appliance wear at this age.^{250,251} As the patient ages there is more interdigitation and ossification of the sutures, resulting in less skeletal and more dental response to the protraction forces. Nevertheless most clinical studies have found few differences between early and late treatment up until puberty.^{251–254}

The stability of maxillary orthopedic protraction with a facemask is variable and dependent on favorable facial growth following active treatment. However, it is common for the original facial growth pattern to resume after treatment, often resulting in relapse of the skeletal discrepancy. The best overall success rate at the end of adolescent growth cannot be expected to be more than 50%.²⁵⁵ One should expect that about 20% of these patients will ultimately require orthognathic surgery to fully correct the Class III malocclusion.²⁴⁸ The patients who relapse usually have mandibular growth during late adolescence that overwhelms the earlier correction. Long-term efficacy of facemask treatment has not been fully studied.

Class III orthopedic appliances, as with Class II devices, result in dentoalveolar movements that accompany the skeletal changes. Treatment with the facemask causes protraction of maxillary anterior teeth and retraction of mandibular anterior teeth. The development of osseointegrated attachments may make it possible to transmit the orthopedic protraction force to intraoral skeletal attachments that prevent undesirable dentoalveolar changes.²⁵⁶

Vertical Orthopedic Treatment Vertical maxillary excess presents with a maxilla that is inferiorly positioned, resulting in excessive vertical display of maxillary

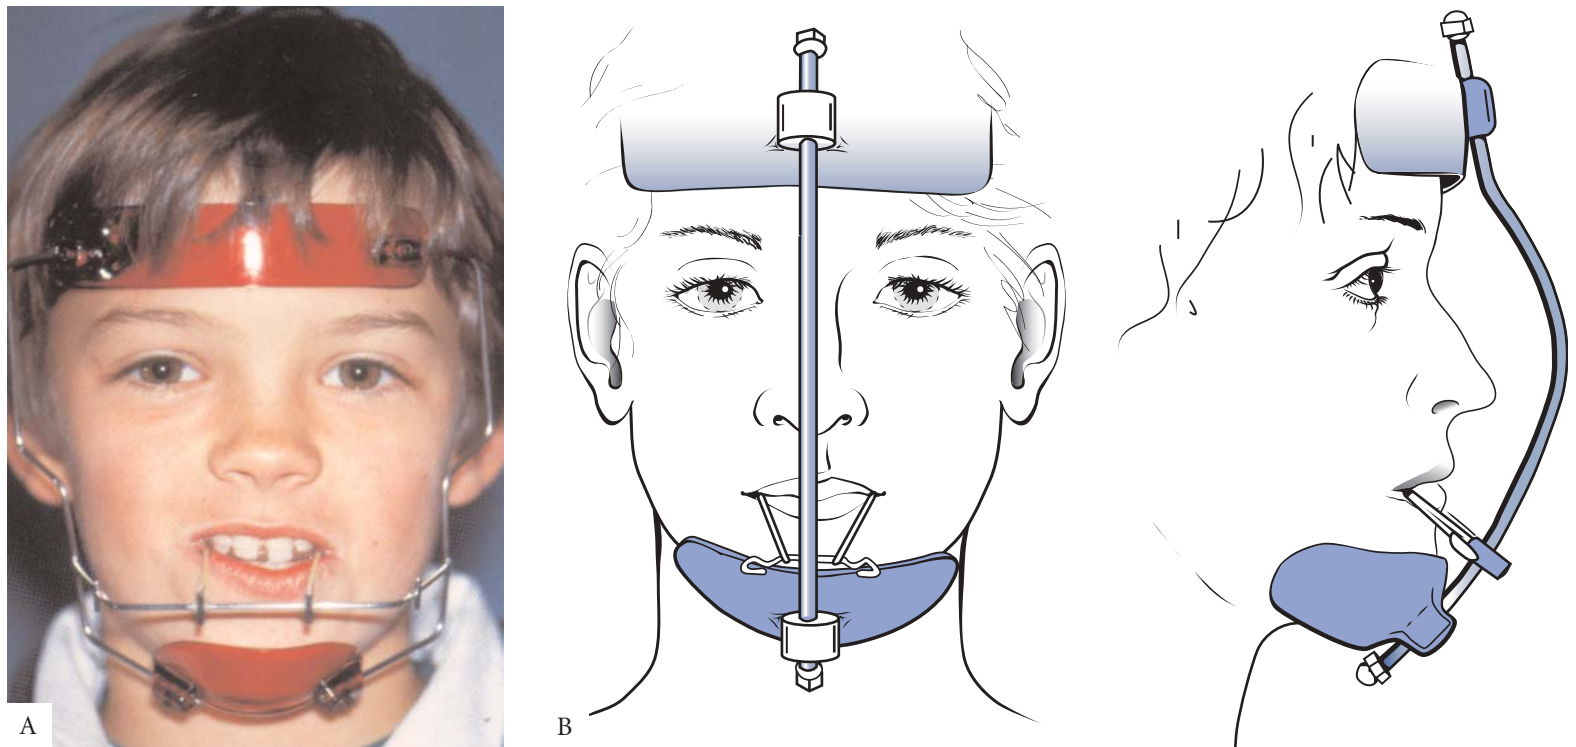

FIGURE 53-26 Class III protraction headgear or facemask. A protractive orthopedic force is directed downward and forward, with the force being dissipated on the forehead and chin, distracting the circum-maxillary sutures to augment anterior maxillary growth. A, Delaire design. Reproduced with permission from Proffit WR, Fields HW. *Contemporary orthodontics*. 3rd ed. St. Louis (MO): Mosby; 2000. p. 516. B, Petit design (frontal and lateral views). Adapted from McNamara JA, Brudon WL. *Orthodontics and dentofacial orthopedics*. Ann Arbor (MI): Needham Press, Inc.; 2001. p. 378.

incisors relative to the upper lip, and downward and backward rotation of the mandible, resulting in an increased mandibular plane angle and lower face height. The prevalence of vertical facial problems is less than 5% of the US population with about 0.3% considered as handicapping.^{133,134}

The orthodontist presently does not have very effective nonsurgical options to manage vertical skeletal problems. Orthopedic treatment strategy is directed at restraining vertical maxillary growth and posterior dental eruption in order to promote anterior and superior mandibular rotation. A high-pull headgear is used to apply a superior intrusive force of 2 to 4 pounds to inhibit eruption of maxillary posterior teeth and compress circum-maxillary sutures to limit the downward development of the maxilla. With exceptional daily (14 to 16 hours) and long-term (throughout adolescent growth)

wear, mandibular growth may be redirected in a more anterior than downward direction, improving a Class II skeletal discrepancy with vertical maxillary excess. However, this is counterproductive when treating vertical maxillary excess with a normal or prognathic mandible, since any decrease in vertical maxillary development would promote anterior mandibular rotation, thereby aggravating the Class III malocclusion. An alternative to the use of high-pull headgear is a removable orthopedic appliance that incorporates interocclusal acrylic bite blocks in order to stretch the facial musculature and soft tissue beyond the normal resting vertical dimension, creating a reactive intrusive force against the mandibular as well as maxillary teeth.^{257,258} As with the high-pull headgear option, exceptional daily and long-term wear is necessary to obtain any appreciable benefit. Repelling magnets have been embedded in the opposing

acrylic bite blocks to accentuate the intrusive force.^{259–261} Most of the treatment benefit from this method appears to be limitation of posterior vertical dentoalveolar development rather than any appreciable skeletal effect.^{261–263}

A significant treatment effect by either the headgear or interocclusal bite block is rare since it is dependent on the patient wearing the appliance at least 14 to 16 hours per day over a number of years. In fact significant clinical benefit from the use of interocclusal acrylic alone may require closer to 16 to 24 hours per day. As with the Class II orthopedic methods these two methods have been combined into one appliance with the hope that this approach may provide greater cumulative skeletal growth effects than use of either appliance alone.²⁶⁴ In combination with the interocclusal bite block the force transmitted by the headgear can be distributed over all of the teeth

contacting the acrylic, and the force vector can be directed further forward and more vertically, closer to the maxillary center of resistance (see Figure 53-24).

Use of either or both of these orthopedic appliances to treat vertical maxillary excess is particularly challenging since it is impossible to direct the force in a straight vertical manner. Both methods include some posteriorly directed force to the maxilla that is not appropriate unless the maxilla is protrusive as well as inferiorly positioned. It also is counterproductive in a patient with maxillary vertical excess combined with a Class III skeletal relationship. Just as the protraction headgear should not be used with this individual to address the anteroposterior skeletal problem, the high-pull headgear and/or interocclusal bite block are contraindicated in this same clinical situation to address the vertical excess.

No studies to date have been able to demonstrate long-term stability with any nonsurgical orthopedic methods for correcting vertical maxillary excess, with or without an anterior open bite.²⁶⁵ Achieving stability is particularly difficult due to the extended duration of vertical facial growth, often continuing well beyond adolescence.⁴⁰ For a successful outcome orthopedic treatment may have to be extended over a number of years, from the time of the mixed dentition through definitive orthodontic treatment in the permanent dentition, perhaps including a removable orthopedic appliance even during orthodontic retention. This extended treatment makes the vertical plane of space the most difficult to successfully manage by the orthodontist attempting facial growth modification. Osseointegrated attachments hold promise as a means of anchorage to potentially permit more effective treatment of skeletal vertical problems in the future.²⁶⁶

Conclusion Facial orthopedic treatment may be effective in resolving mild to mod-

erate skeletal discrepancies in some patients. An orthopedic phase should be attempted with a specific treatment time frame established in order to assess treatment progress toward successful correction. This time frame must be honored in order to prevent protracted treatment with excessive dental compensations that need to be reversed for surgical correction. The orthodontist attempting growth modification must be mindful of the duration and extent of treatment to prevent excessive length and morbidity of the orthodontic treatment. If significant skeletal improvement is not being achieved within 6 to 8 months of starting orthopedic treatment, the case needs to be reevaluated and the growth modification treatment likely abandoned as a treatment choice.

It has become clear that there is great variability in individual treatment response, even when factoring out wear compliance and duration of treatment. It has not been possible to identify the variables to explain why some patients respond well and some do not demonstrate any significant skeletal improvement with treatment regardless of their facial morphology or the severity of their skeletal discrepancy. It is anticipated that future research will reveal the variables that will enable the clinician to predict treatment response.

It also is expected that research will provide a greater understanding of the nature and extent of facial growth modification possible in individual patients as well as the type of appliance and timing of treatment to achieve the best outcome. The development of intraoral osseointegrated attachments holds promise for a future means of dissipating orthopedic forces to prevent unwanted dentoalveolar changes that presently occur with our toothborne appliances. Analogous attachments are presently undergoing clinical testing for surgically assisted orthopedic movements associated with distraction osteogenesis.^{267,268} Recent and future advances in developmental biology and genomics hold

great promise in increasing our understanding of the molecular and genetic mediators of craniofacial growth.¹³² This understanding will be crucial for us to make constructive modifications of our treatment methods to target these mediators in order to prevent or correct a craniofacial anomaly or developmental deformity.

Orthodontic Camouflage: Orthopedic Consequence versus Surgical Preparation

Orthodontic camouflage, rather than orthognathic surgery, may indeed be an appropriate treatment choice for some mild and moderate skeletal malocclusions in patients who are beyond the pubertal growth spurt. The treatment goal, however, must include a realistic outcome characterized by an acceptable dental and facial esthetic appearance with favorable dental function and occlusion. Since esthetic appearance is subjective in nature, it is essential to have the patient and parent perceptions dictate whether camouflage is a reasonable option.

Most mild and some moderate skeletal Class II malocclusions can be effectively camouflaged with extraction of two maxillary premolars and retraction of maxillary anterior teeth, leaving the posterior teeth in a Class II occlusion. However, these cases should mainly be limited to those that present without significant dental crowding, some protrusion of the maxillary incisors, and where there is not significant maxillary gingival display on smiling. If the maxillary incisors are normally or palatally inclined prior to treatment, orthodontic retraction of these teeth may result in an even poorer esthetic result than the original problem even if the occlusion is acceptable. The unesthetic appearance includes not just the incisor inclination but often an unattractive retrusive upper lip and increased gingival exposure during smiling as well. This is why the recent introduction of palatal implants as orthodontic anchorage, which

provide the opportunity for the orthodontist to retract maxillary incisors even further than was previously possible, is a mixed blessing.

It is more challenging to camouflage Class III than Class II skeletal malocclusions since considerable natural dentoalveolar camouflage (proclined maxillary incisors, lingually inclined mandibular incisors) is often already present prior to treatment. Additional maxillary incisor proclination may be unesthetic, and further lingual inclination of mandibular incisors usually accentuates an already prominent chin. For this reason extraction of mandibular premolars to permit more retraction of mandibular incisors to obtain positive overjet often compromises the esthetic outcome. If interarch tooth size compatibility can be maintained, extraction of one mandibular incisor rather than two premolars may provide an acceptable compromise.

Camouflage of an anterior open bite that is due to maxillary vertical excess has been notoriously unsuccessful in the past. Recently an orthodontic technique for stably extruding anterior teeth has been introduced.²⁶⁹ Unfortunately this only exacerbates the excessive vertical display of maxillary gingiva and anterior teeth.

Summary

The surgeon's understanding of craniofacial growth has an important impact on clinical treatment decisions to alter craniofacial morphology. This understanding is relevant to the appreciation of the role of orthopedic treatment in the prepubertal and pubertal patient to limit or preclude the need for corrective surgery at a later age. Clinically relevant modification of craniofacial growth is possible, but substantial advances will be necessary to elucidate how growth modification can be accomplished in a controlled and predictable manner to achieve an efficacious outcome. Optimal timing and stability of craniofacial surgery are dependent on a thorough appreciation of the sequence, timing, magnitude, and

differential expression of craniofacial growth. The recent dramatic advances in developmental genetics and molecular biology, highlighted by complete mapping of the human genome, usher in a new millennium that promises to bring an explosive increase to our understanding of the complex interactions of the genetic and environmental influences that determine human craniofacial morphogenesis, prenatal development, and postnatal growth. A thorough understanding of these genomic and epigenetic factors will be necessary to determine the best timing and method of clinical intervention to achieve the optimum treatment outcome.

Database Acquisition and Treatment Planning

Marc B. Ackerman, DMD

David M. Sarver, DMD, MS

Until the turn of the twenty-first century, treatment planning in orthognathic surgery was based primarily on a system of clinical observation, a static set of records (models, radiographs), with the major thrust of treatment being directed toward satisfying lateral cephalometric goals. These goals might include particular measurements (sella-nasion–A point and A point–nasion–B point differences) or analytical norms (Steiner, Ricketts), or even comparison of lateral head film tracings of persons with craniofacial skeletal dysplasia^{1–3} to templates having average skeletal proportions derived from longitudinal growth studies.⁴ The most significant shortcoming of this reliance on the lateral cephalogram as the primary determinant of treatment goal setting is that it did not take into account the resting and dynamic hard–soft tissue relationships, which are the most critical aspects in treatment planning in both orthodontics and orthognathic surgery. Furthermore, cephalometric analysis quantifies dento-skeletal relationships in angular and linear measures, which are not entirely representative of the multidimensional interrelationship of craniofacial parts. That is to say, the integumental soft tissue drape may sometimes be inconsistent with the underlying skeletal framework in a given patient.

Whereas the skeletal framework may be reasonably stable post-adolescence, the soft tissues are more subject to maturational and age-related changes. The cephalometric approach to treatment planning is now considered “Procrustean,” after the story based on Greek mythology. As the story goes, Procrustes was an innkeeper with only one bed. If a traveler was too tall for the bed, Procrustes would cut off the traveler’s feet so that he or she would fit the bed. A traveler who was too short would be stretched on a rack to likewise fit the bed in length. This charming story relates to this chapter in that by applying the same hard tissue cephalometric analysis to all patients, all of our patients end up being crammed into the same bed!

The contemporary approach to the surgical orthodontic treatment of dentofacial deformity will illustrate the use of dentofacial proportionality in the place of applying absolute linear or angular norms to the individual patient. Patient-specific treatment planning will be the focus of this chapter.

Contemporary Orthognathic Treatment Planning

The emphasis in this chapter on orthognathic diagnosis and treatment planning

is intended to lead us into a new era and methodology of patient analysis and treatment goal setting. In modern orthognathic surgery, treatment goals are determined through systematic clinical examination and quantification of the patient’s dentofacial characteristics. Therefore, the purpose of this chapter will be to introduce the reader to a method of systematic dentofacial analysis in all three dimensions with emphasis on both static and dynamic relationships, as well as both functional and esthetic objectives.

Problem-oriented treatment planning has served us very well in the past several decades, by focusing on the problems in need of correction, including the identification of solutions for each problem. The natural progression of problem-oriented treatment planning should now include the identification of favorable attributes as well as the problems. The reason for this next step is the realization that focusing solely on the problems and their solutions may result in a treatment plan which potentially has a negative effect on the positive attributes in that patient. A classic orthodontic example is where the extraction of maxillary premolars in the correction of a skeletal Class II malocclusion, while satisfying functional

and occlusal issues, may result in profile flattening and an unfortunate effect on facial appearance. In the orthognathic arena, a good example is the widening of the alar base secondary to maxillary advancement and/or impaction. The goal of orthognathic treatment is the optimization of negative attributes, while at the same time preserving those attributes that are deemed favorable (Figure 54-1).

This systematic approach to clinical examination of the patient is essential for the development of an optimization-oriented database. All clinically detectable deviations from the optimal range fall into the two broad categories of function and esthetics.

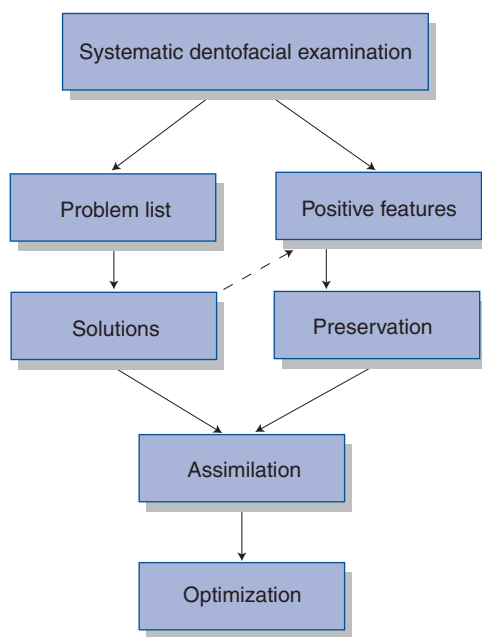

FIGURE 54-1 Contemporary treatment planning flow chart. After the clinical examination and databasing of the quantitative measurements, both problems and positive attributes are identified. Solutions for the problems are identified and the dotted arrow indicates that each potential solution can negatively impact a positive feature. Therefore, the advantage of measuring both problems and positive features permits the clinician to recognize the potential negative impact that any given solution has on the positive attributes. This “decision tree” leads to correction of the problems but also preservation of the positive attributes. The clinician then assimilates all of this information for optimization of treatment.

Function and Dentofacial Deformity

Patients with severe discrepancies in the size and position of their jaws and their teeth often have difficulty in oral function. Certain foods may be difficult to incise and chew. Speech may also be affected by jaw deformity. If the patient cannot bring the tongue and lips into the proper position, it may not be possible to produce a specific sound properly. Besides careful examination of the patient, it is doubtful that diagnostic tests of function that can be carried out in the dental or surgical office are useful. The relationship of temporomandibular (TM) joint problems to severe malocclusion and dentofacial deformities is complex but important. Although there is some evidence that patients with specific types of malocclusion are more susceptible to TM joint problems, the increased risk is relatively small.⁵ In general terms, patients with dentofacial deformity are similar to patients with normal facial proportions in the prevalence of TM joint problems.⁶

Appearance and Dentofacial Deformity

Appearance and dentofacial esthetics can be divided into three subcategories: macroesthetics, miniesthetics, and microesthetics (Figure 54-2). The specific concerns of the patient can be elucidated through open-ended doctor-patient communication and then integrated into the diagnostic decision tree. The surgeon and orthodontist should be sensitive to the patient’s esthetic desires, balancing them against cultural and familial standards. The physical burden of treatment is borne by the patient and must be weighed when determining the extent of surgical intervention. For example, when deciding whether treatment should involve orthodontics alone, orthodontics and orthognathic surgery, or acceptable orthodontic camouflage, the patient should understand the risk-benefit ratio of any given treatment sequence.

Data Collection

Primary data collection begins at the clinical examination and is supplemented with static and dynamic recordings of the patient in three spatial dimensions. Record taking should replicate the functional and esthetic presentation of the patient. Findings from the clinical examination should either be confirmed or challenged by data obtained from the records. The analysis of the clinical database will generate a diagnostic summary and optimized problem list. An emerging soft-tissue paradigm in surgical orthodontic treatment planning has refocused analysis on facial proportionality and balance versus reliance on normative data derived from cephalometrics.⁷ The art of surgical orthodontics rests in the ability to envisage the patient’s desired three-dimensional soft tissue outcome and then retroengineer the dental and skeletal hard tissues to produce such a change. The concept of retroengineering will be explained later in this chapter under technological applications to orthognathic treatment planning.

In today’s clinical environment there are three methods of data collection. The first and most commonly used method includes still photography, study models, and cephalometric radiographs. The second is the use of databasing programs to document direct clinical measurement of the patient’s resting and dynamic relationships. The third involves the use of digital video to record the dynamics of facial movement. This methodology as it currently exists does not dynamically quantify movement. Expect to see greater recognition of the value of this technology, which should lead to research into the quantification of dynamic facial movements.

Conventional Records

Standard orthodontic records have not changed significantly in many years, but contemporary records in surgical orthodontic treatment are changing rapidly.

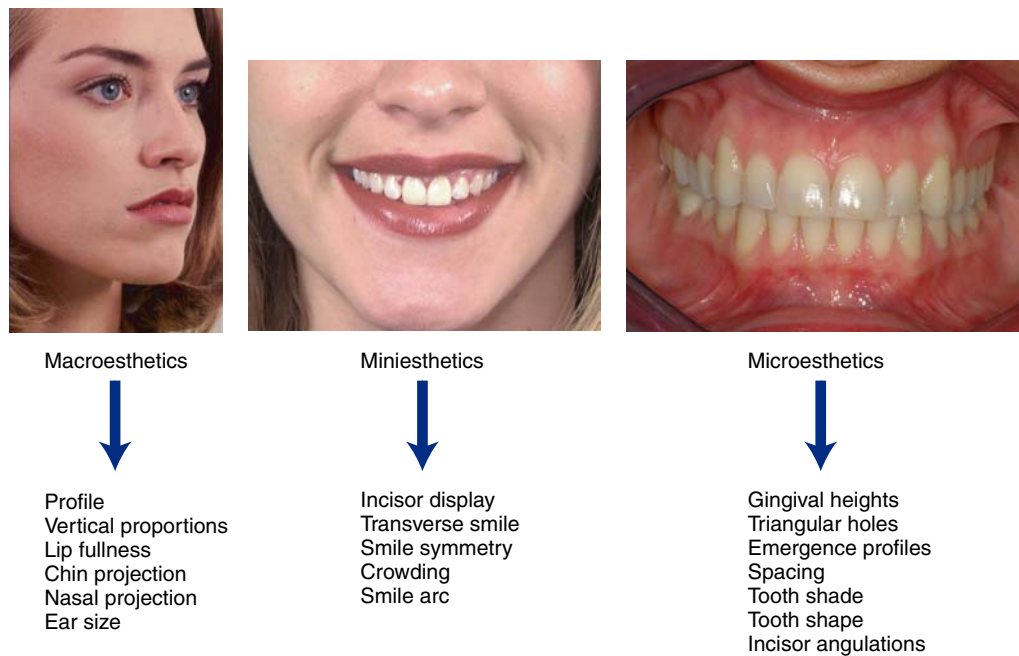

FIGURE 54-2 Recommended subcategories of appearance and esthetics.

Surgical orthodontics demands treating all dimensions of patients. In clinical practice, standard records include film or digital photographs, radiographs, and study models (whether plaster, mounted or unmounted, or electronic models). The facial images, which are universally considered standard records, include frontal at rest, frontal smile, and profile at rest images. Whereas these orientations do provide an adequate amount of diagnostic information, they do not contain all of the information needed for three-dimensional visualization and quantification. Orthognathic surgery requires expansion of the database compared to conventional orthodontic treatment.

The suggested records can be divided into two groups—static and dynamic. The accepted facial photographic recordings should include frontal smile close-up, oblique facial smile, oblique smile close-up, and profile smile.⁸

Direct Measurement as a Biometric Tool

The goal of the clinical examination is to quantitatively assess soft and hard tissue attributes of the dentofacial complex, and

record what elements are satisfactory and which are in need of optimization. Clinical examination procedures vary greatly among practitioners. Measurement should be thorough, systematic, and consistent, thus minimizing the chance that something of importance will be overlooked. We want to avoid the situation where the clinician performs a cursory examination, jotting down brief notes as to abnormalities that are observed without recording any other descriptive data. This practice is often justified by the assumption that most diagnostic decisions can be made from the records after the patient leaves. This is a poor diagnostic technique for several reasons.

First, static records cannot reflect the dynamic relationships that are important in the overall functional assessment of the patient. For example, the simple idea of the relationship of the upper incisor at rest and on smile is not reflected on radiographs or models and is poorly evaluated in photographs. Second, information that may have not looked important enough to write down during a cursory examination may be important later, and thus would be unavailable because it was not recorded.

Third, a thorough and comprehensive examination record that includes normal observations is an accurate medicolegal document. It is hard for an unhappy patient to charge negligence when it is clear that the information was obtained and used. The more thorough and well documented the record is, the more valuable it is if problems arise.

Contemporary clinical examination uses a computer-databasing program to facilitate data entry, and these data are then merged into reports and treatment planning screens or forms.⁹ Each clinical characteristic in the examination has a pop-up menu containing all of the possible descriptions for that particular trait (Figure 54-3). By using a computer interface, the surgeon or orthodontist saves valuable time in both the clinical examination and diagnostic and treatment planning work-up. The information is then stored for recall and analysis, and can even have predefined parameters that identify problematic measurements automatically.

As an example of how this interface facilitates the examination of dynamic hard–soft tissue relationships, we suggest that the following frontal measurements be performed systematically in evaluation of anterior dental display, both at rest and at smile:

- **Philtrum height:** The philtrum height is measured in millimeters from subnasale (the base of the nose at the midline) to the most inferior portion of the upper lip on the vermilion tip beneath the philtral columns. The absolute linear measurement is not particularly important, but what is significant is its relationship to the upper incisor, and the commissures of the mouth. In the adolescent, it is common to find the philtrum height to be shorter than the commissure height, and the difference can be explained in the differential in lip growth with maturation.

FIGURE 54-3 A computer-databasing program facilitates data entry, and these data are then merged into reports and treatment planning screens or forms. Each clinical characteristic in the examination has a pop-up menu containing all of the possible descriptions for that particular trait.

- Commissure height: The commissure height is measured from a line constructed from the alar bases through subspinale, then from the commissures perpendicular to this line.
- Interlabial gap: The interlabial gap is the distance in millimeters between the upper and lower lips, when lip incompetence is present.
- Amount of incisor show at rest: The amount of upper incisor show at rest is

a critical esthetic parameter because one of the inevitable characteristics of an aging tooth-lip relationship is diminished upper incisor show at rest and on smile. For example, an adult patient who displays 3 mm of gingival display on smile and 3 mm of upper incisor at rest should only carefully consider maxillary incisor intrusion or maxillary impaction to reduce gingival display, since reduction in gingival dis-

play also results in diminished incisor show at rest and during conversation (a characteristic of the aging face).

- Amount of incisor display on smile: On smile, patients will either show their entire upper incisor, or only a percentage of the incisor. Measurement of the percentage of incisor display, when combined with the crown height measured next, leads the clinician to decide how much tooth movement is required to attain the appropriate smile for that patient.
- Crown height: The vertical height of the maxillary central incisors in the adult is measured in millimeters and is normally between 9 and 12 mm, with an average of 10.6 mm in males and 9.6 mm in females. The age of the patient is a factor in crown height because of the rate of apical migration in the adolescent.
- Gingival display: There is variability in what is esthetically acceptable for the amount of gingival display on smile, but it is important to always remember the relationship between gingival display and the amount of incisor shown at rest. In broad terms, it is better for a patient to be treated less aggressively in reducing smile gumminess when considering that the aging process will result in a natural diminishment of this characteristic. A gummy smile is often more esthetic than a smile with diminished tooth display.
- Smile arc: The smile arc should be defined as the relationship of the curvature of the incisal edges of the maxillary incisors and canines to the curvature of the lower lip in the posed social smile.^{10,11} The ideal smile arc has the maxillary incisal edge curvature parallel to the curvature of the lower lip upon smile, and the term *consonant* is used to describe this parallel relationship. A *nonconsonant* or flat smile arc is characterized by the

maxillary incisal curvature being flatter than the curvature of the lower lip on smile. The smile arc relationship is not as quantitatively measurable as the other attributes, so the qualitative observation of consonant, flat, or reverse smile arcs is generally cited.

Is it important to measure these above-described characteristics in orthognathic cases? The following case illustrates the significance of resting and dynamic soft tissue measurement, and how surgical or orthodontic treatment planning is determined by direct measurement as much as it is by cephalometric analysis. The role of cephalometrics will be discussed later in this chapter, and the emphasis will be less on static comparisons to norms and more on its coordination with the soft tissue overlay of the face and the use of predictive algorithms to arrive at final macrotreatment decisions.

The patient in Figure 54-4 was a 16-year-old male who presented for an opinion relative to his chief complaint of excessive gingival display on smile, or a “gummy smile” (see Figure 54-4A). He had finished orthodontic treatment about 1 year earlier, and when his mother asked the

orthodontist if something could be done, the orthodontist felt that the only way to improve that smile characteristic was to consider surgical maxillary superior repositioning via Le Fort I osteotomy. A referral to the oral and maxillofacial surgeon was recommended, and maxillary impaction was recommended, but the surgeon felt that he wanted to wait until the patient had reached full physical maturity. The patient’s mother felt further investigation was warranted.

The examination revealed a well-treated orthodontic case with excellent occlusion, and the macrorelations were also quite normal in terms of profile and facial proportion. The anterior tooth-lip relationships were as follows:

- Resting relationships (see Figure 54-4B)
 - Philtrum height: 25 mm
 - Commissure height: 25 mm
 - Maxillary incisor at rest: 2 mm
- Dynamic relationships (see Figure 54-4C)
 - Percentage of maxillary incisor display on smile: 100%
 - Maxillary incisor crown height: 8 mm
 - Gingival display on smile: 4 mm
 - Smile arc: consonant

It is instructive to outline the etiologies of excessive gingival display on smile and characteristics seen with each in order to demonstrate the decision-making process in problem-oriented treatment planning with optimization.

- Vertical maxillary excess: Characterized by a disproportionately long lower facial height, lip incompetence, excessive incisor display at rest, and excessive gingival display on smile
- Short philtrum: The philtrum height shorter than the commissure, excessive incisor display at rest, and a reverse resting upper lip line
- Excessive smile curtain: Excessive animation of the upper lip on smile, displaying more tooth and gingiva than desired
- Short crown height: If the anterior incisor height is short, excessive gingival display may result

In this case, vertical maxillary excess was ruled out because facial proportionality was normal, no lip incompetence was present, and only 2 mm of upper incisor showed at rest. The second possibility, a short philtrum, was ruled out since the philtrum and commissure heights were

FIGURE 54-4 A–D, Case illustration of direct measurement of lip-tooth-gingival relationships.

the same, and no reverse upper lip resting characteristics were noted. The third possibility, excessive curtain, was eliminated because the vermilion was adequate on smile and the margins of the commissure and philtrum even on posed smile. The fourth possibility, short crown height, was significant since the maxillary incisors measured to be only 8 mm in height.

Therapeutic options to decrease gingival display included maxillary impaction, orthodontic intrusion of maxillary incisors, or periodontal crown lengthening.

- Maxillary impaction: A 4 mm superior repositioning of the maxilla would decrease the gumminess of the smile, but would result in a -2 mm upper incisor show at rest, greatly hastening the aging characteristics of the face and smile.
- Orthodontic intrusion of the maxillary anterior teeth: This would likewise result in reduction of incisor display at rest but would also flatten the already consonant smile arc.
- Periodontal crown lengthening: The increase in anterior crown height decreases the gumminess of the smile (appropriate because the teeth are short), and optimizes treatment by *not* decreasing incisor display at rest and by maintaining the consonant smile arc.

After discussing all these options with the family, the family decided to proceed with the third and recommended option of crown lengthening, with an excellent outcome (see Figure 54-4D).

In summary, this case demonstrates the new direction in dentofacial treatment planning, even though the final result was not an orthognathic treatment plan. This case was selected to make the point that through careful observation and measurement, the appropriate treatment plan was delivered.

Digital Videography

Dynamic recording of patient's facial motion is accomplished with the use of

digital videography.¹² This technology may be used to document and evaluate such characteristics as range of mandibular motion on opening and laterotrusion movements, deviations on opening, smile, and speech. Digital video and computer technology have primarily been used to record anterior tooth display during speech and smiling. Digital videos can be recorded in a standardized fashion with the camera at a fixed distance from the subject. We recommend that these images be taken in a standard format with emphasis on natural head position, so that future analysis and research possibilities may be maximized. We also recommend that video be taken in the frontal, oblique, and lateral dimensions. Clinically, an example of where this technology is most relevant is the patient with an asymmetric smile. The question that arises is whether or not the patient has a dental asymmetry, skeletal asymmetry, or asymmetric movement of the lip curtain during animation. The single smile photograph cannot corroborate the clinical impression gained during the data collection process. The video clip may be reviewed and evaluated during all planning phases of treatment as well as for comparison of the orthognathic treatment effects (Figure 54-5).

Systematic Clinical Examination of Dentofacial Deformity

We have previously discussed the importance of clinical observation and direct measurement of the interaction of hard and soft tissues in planning appropriate combined orthodontic and orthognathic treatments of dentofacial deformity. In this section, we will describe the components of the examination from the macro-, mini-, and microperspectives.

Macroesthetic Examination: Frontal View

The facial areas for macroesthetic examination, as investigated from the frontal view, can be summarized as follows:

- Vertical proportions
 - Facial heights:
 - Lower third
- Transverse proportions
 - Rule of fifths
 - Middle fifth
 - Inner canthi
 - Alar base
 - Medial two-fifths
 - Outer canthi
 - Gonial angles of mandible
 - Outer two-fifths
 - Ear deformity
 - Ear projection
 - Nasal anatomy
 - Alar base
 - Columella
 - Nasal tip
 - Dorsum
- Transverse symmetry
 - Nasal tip to midsagittal plane
 - Maxillary dental midline to midsagittal plane
 - Mandibular dental midline to symphysis
 - Mandibular asymmetry with or without functional shift
 - Maxillomandibular asymmetry
 - Chin asymmetry

The starting point for the macroesthetic examination is the frontal perspective. Transverse and vertical relationships comprise the major components of the frontal examination and analysis. As emphasized in our introduction, the *proportional* relationship of height and width is far more important than absolute values in establishing overall facial type. Faces can be broadly categorized as either mesocephalic, brachycephalic, or dolichocephalic (Figure 54-6).¹³ The differentiation between these facial types has to do with the general proportionality of facial breadth to facial height, with brachycephalic faces being broader and shorter in comparison to the longer and more narrow dolichocephalic faces. Generally, the most attractive faces tend to have common

FIGURE 54-5 The video clip may be reviewed and evaluated during all planning phases of treatment as well as for comparison of the orthognathic treatment effects.

proportions and relationships that generally differ from normative values.¹⁴

Vertical Facial Proportions The ideal face is vertically divided into equal thirds by horizontal lines adjacent to the hairline, the nasal base, and menton (Figure 54-7A). Surgical orthodontic treatment is in a large part limited to the lower facial third. Measurement of the upper face is often hindered by the variability in identification of broad landmarks such as the location of the hairline and radix.

We will begin our clinical examination with the evaluation of lower facial height. In the ideal lower third of the

face, the upper lip makes up the upper third, and the lower lip and chin compose the lower two-thirds (Figure 54-7B). Disproportion of the vertical facial thirds may be a result of many dental and skeletal factors, and these proportional relationships may help us define the contributing factors related to vertical dentofacial deformities.

In the following sections, we present case illustrations of orthognathic changes in vertical proportionality.

Short Vertical Proportions The patient in Figure 54-8 presented for correction of her Class II deep bite secondary to her

mandibular deficiency. Her anterior vertical relationships were characterized by a short lower facial third relative to her upper thirds (see Figure 54-8A and B). In addition, the lower third was comprised of a 45:55 vertical relation of the upper lip to lower lip and chin height. Recalling that the ideal proportions of the lower face are one-third upper lip and two-thirds lower lip and chin, the treatment plan was clearly a result of the direct clinical examination rather than any cephalometric standard. Other important clinical measurements entered into the decision process. Differential diagnosis for a short lower facial height included the following:

FIGURE 54-6 A, The mesocephalic facial type is characterized by equal vertical facial thirds. B, The brachycephalic facial type appears square with a diminished lower third. C, The dolichocephalic facial type appears ovoid with an increased lower third.

- Vertical maxillary deficiencies, which are then characterized by the following characteristics:
 - Short lower facial third
 - Diminished maxillary incisor display at rest
 - Diminished incisor display on smile
- Diminished chin height, ascertained through the proportionality in the lower face rather than a linear cephalometric value
- Posterior dental collapse secondary to the loss of posterior dental support

case, our patient displayed 3 mm of maxillary incisor at rest, and all of her maxillary incisor on smile (see Figure 54-8C), which was inconsistent with vertical maxillary

deficiency. Since the chin height was short, the final diagnosis was mandibular deficiency with short chin height. Therefore, the recommended treatment plan was

The functional goal of mandibular advancement to correct the Class II dentoskeletal relationship was obvious, but an esthetic adjunctive consideration was a vertical genioplasty to optimize the macroesthetics of her vertical facial thirds. The final diagnosis depended not only on the vertical facial proportionality but on the measurement of the resting tooth-lip relationships as well in order to more clearly define the etiology of the lower facial height. In this

FIGURE 54-7 A, The ideal face is vertically divided into equal thirds by horizontal lines adjacent to the hairline, the nasal base, and menton. B, In the ideal lower third of the face, the upper lip makes up the upper third, and the lower lip and chin compose the lower two-thirds.

FIGURE 54-8 A, This patient was referred for correction of her Class II deep bite secondary to her mandibular deficiency. B, Evaluation of her anterior vertical relationships was characterized by a short lower facial third relative to her upper thirds. The lower third was comprised of a 45:55 vertical relationship of the upper lip to lower lip and chin height. The ideal proportions of the lower face are one-third upper lip and two-thirds lower lip and chin; thus the treatment plan was derived from the direct clinical examination of this patient rather than any cephalometric standard. C, Our patient displayed 3 mm of maxillary incisor at rest, and all of her maxillary incisors on smile, inconsistent with vertical maxillary deficiency. D, The treatment plan was orthodontic preparation for mandibular advancement and vertical genioplasty. E, The post-treatment frontal view demonstrating balance of the vertical facial thirds. F, The vertical incisor position at smile was maintained, while the lower facial third was vertically augmented. G, The profile view shows improved mandibular projection relative to the upper face, improved chin-neck angle, and improved chin-neck length.

orthodontic preparation for mandibular advancement and vertical genioplasty (see Figure 54-8D) to increase the lower facial height (see Figure 54-8E–G).

Long Vertical Proportions Long lower facial height is due to one of two possibilities: (1) vertical maxillary excess (VME) or (2) excessive chin height. The clinical keys that may be associated with VME are

gummy smile, open bite, lip incompetence, and steep mandibular plane as evidenced by gonial angle form. Excessive chin height is measured from the lower vermilion to the soft tissue menton. The clinical keys that may be associated with excessive chin height are lower facial third disproportionate from the one-third upper lip to two-thirds low lip and chin ratio, and the absence of VME characteristics.

The patient in Figure 54-9A was referred for correction of an anterior open bite and a gummy smile. Our systematic examination revealed the following problem list and characteristics:

- Frontal proportions at rest
 1. Long lower facial third
 2. Disproportion of chin height with the upper lip occupying 25% of the

lower facial third and the lower lip and chin occupying 75% of the lower third of the face

3. Lip incompetence of 5 mm
4. 8 mm of maxillary incisor display at rest
5. Midsymphysis to right 3 mm with no functional shift
6. Lip strain on closure (Figure 54-9B)

Clinical assessment of the frontal resting macroesthetic evaluation: This patient had most of the macrocharacteristics of vertical maxillary excess with a long lower facial height and excessive incisor display at rest. Excessive chin height was also a contributor to the lower facial height disproportion, as is evidenced by the upper lip and chin height clinical proportions.

- Frontal proportions on smile (Figure 54-9C)
 1. 100% of maxillary incisor displayed on smile
 2. Excessive gingival display on smile with 3 mm gingival display at the right cuspid and 5 mm at the left with a transverse cant to the palatal plane
 3. Transverse cant to the maxilla with the left side down 2 mm more than the left

Clinical assessment of the frontal dynamic (smiling) macroesthetic evaluation: A gummy smile was present but with normal incisor crown height. This would exclude cosmetic periodontal crown lengthening as the primary therapeutic choice for improvement of the gummy smile. The asymmetry of the maxilla is in compensation for the mandibular asymmetry, and results in a canted frontal occlusal plane and smile line.

- Oblique at-rest facial observation (Figure 54-9D)
 1. Excessive lower facial height
 2. Lip strain and excessive chin height

3. Flat labiomental sulcus
4. Nasal form judged to be quite adequate

Clinical assessment of the oblique macroesthetic evaluation: The flattened labiomental sulcus was secondary to the excessive lower facial height, lip incompetence, and chin deficiency.

- Oblique smiling facial observation (Figure 54-9E)
 1. No noticeable anteroposterior cant to the maxillary occlusal plane
 2. The smile arc was consonant
 3. The excessive gingival display was also evident on the oblique smile

Clinical assessment from the oblique smiling macroesthetic evaluation: Since the smile arc was consonant, alteration of the palatal plane would not have been indicated either through surgery or orthodontic incisor repositioning.

- Profile evaluation (Figure 54-9F)
 1. Long lower facial third
 2. Long chin height
 3. Flat labiomental sulcus
 4. Lip strain on closure

Clinical assessment of the profile macroesthetic evaluation: As would be expected from the frontal and oblique characteristics, the lateral profile reflected the overall skeletal and dental characteristics of vertical maxillary excess, but the chin deficiency that became evident on the oblique view was clearly demonstrated on the profile view.

The functional problem of the anterior open bite in this nongrowing patient necessitated superior repositioning of the maxilla to correct the functional complaint (Figure 54-9G–K). The exact surgical movements were directed by the clinical examination and measurements. Because the patient had the clinical diag-

nosis of vertical maxillary excess, maxillary impaction was indicated, but some discretionary decisions were needed for appropriate position of the maxilla from the esthetic standpoint. From the frontal dimension, the left side of the maxilla was impacted 2 mm more than the right in order to level the smile line. The differential degree of impaction reflected the degree of the maxillary compensation for the mandibular asymmetry.

Transverse Facial Proportions The assessment of the transverse components of facial width is best described by the rule of fifths.⁹ This method describes the ideal transverse relationships of the face. The face is divided sagittally into five equal parts from helix to helix of the outer ears (Figure 54-10). Each of the segments should be one eye distance in width. Each transverse fifth should be individually examined and then assessed as a complete group.

The middle fifth of the face is delineated by the inner canthus of the eyes. A vertical line from the inner canthus should be coincident with the alar base of the nose. Variation in this facial fifth could be due to transverse deficiencies or excesses in either the inner canthi or alar base. For example, hypertelorism in craniofacial syndromes can create disproportionate transverse facial esthetics.

A vertical line from the outer canthus of the eyes frames the medial three-fifths of the face, which should be coincident with the gonial angles of the mandible. Although disproportion may be very subtle, it is worth noting since our treatments can positively change the shape or relative proportion of the gonial angles.

The outer two-fifths of the face is measured from the lateral canthus to lateral helix of the ear, which represents the width of the ears. Unless this abnormality is part of the chief complaint, prominent ears are often a difficult feature to discuss with the patient because laypeople only recognize its effect on the face in severe cases. However,

FIGURE 54-9 A, This patient was referred for correction of an anterior open bite and a gummy smile. B, Lip strain on closure. C, Frontal proportions on smile with 100% of maxillary incisor displayed. There was excessive gingival display on smile with 3 mm gingival display at the right cuspid and 5 mm at the left with a transverse cant to the palatal plane. Transverse cant to the maxilla with the left side down 2 mm more than the right. D, Oblique at-rest facial observation with excessive lower facial height, lip strain and excessive chin height, and a flat labiomental sulcus. The nasal form was judged to be quite adequate. E, Oblique smiling facial observation with no noticeable anteroposterior cant to the maxillary occlusal plane. The smile arc was consonant. The excessive gingival display was also evident on the oblique smile. F, Profile evaluation with emphasis on a long lower facial third, long chin height, a flat labiomental sulcus, and lip strain on closure. G–K, The functional problem of the anterior open bite in this nongrowing patient necessitated superior repositioning of the maxilla to correct the functional complaint. The exact surgical movements were obtained from the clinical examination and measurements (see text).

FIGURE 54-10 The face is divided sagittally into five equal parts from helix to helix of the outer ears. The middle fifth of the face is delineated by the inner canthus of the eyes, the inner corner of the eye containing the lacrimal duct. A line from the inner canthus should be coincident with the ala of the base of the nose. A vertical line from the outer canthus of the eyes frames the medial two-fifths of the face, which should be coincident with the gonial angles of the mandible. The outer two-fifths of the face is measured from the lateral canthus to the lateral helix, which represents the width of the ears. Another significant frontal relationship is the midpupillary distance, which should be transversely aligned with the commissures of the mouth.

studies clearly indicate that large ears are judged by laypeople to be one of the most unesthetic features, particularly in males. Otoplastic surgical procedures are relatively atraumatic and can dramatically improve facial appearance. In orthognathic cases in which this disproportion is noted by the clinician, we feel that failure to mention this feature violates informed consent. Therefore, otoplasty should be presented as a treatment option, whether received positively or not. These procedures can be performed on adolescents and adults as is illustrated in Figure 54-11A and B.

Another significant frontal relationship is the midpupillary distance, which

FIGURE 54-11 A, An otoplastic surgical procedure was recommended for this patient's prominent ears. B, The facial transverse fifths were improved, resulting in a dramatic facial improvement.

should be transversely aligned with the commissures of the mouth.¹⁵ Although this is considered the ideal transverse facial proportionality, there is little that can be done therapeutically to correct this disproportion, except in craniofacial synostosis such as Apert syndrome.

Nasal anatomy in the transverse plane should also be assessed through proportionality. The width of the alar base should be approximately the same as the intercanthal distance, which should be the same as the width of an eye. If the intercanthal distance is smaller than an eye width, it is better to keep the nose slightly wider than the intercanthal distance. The width of the alar base is heavily influenced by inherited ethnic characteristics.

Asymmetry of the face is a somewhat natural occurrence. Systematic examination of the patient's facial symmetry should be directly measured in the frontal plane. The following measures compose this portion of the clinical examination.

Nasal Tip to Midsagittal Plane Having the patient elevate the head slightly and then visualizing the nasal tip in relation to the

midsagittal plane provides the best view to evaluate the position of the nasal tip (Figure 54-12). Any deviation of the nasal tip should be noted in relation to the maxillary midline. The clinician should not make the mistake of treating the maxillary midline to a distorted nose. An attempt to obtain the etiology of nasal tip asymmetry is recommended. The

FIGURE 54-12 The "gull in flight" contour of the base of the nose.

patient should be questioned as to any previous history of nasal trauma or nasal surgery for a deviated septum. Patients may then be advised appropriately as to whether this deviation is severe enough to consider correction.

Maxillary Dental Midline to Midsagittal Plane The maxillary dental midline should be recorded relative to the midsagittal plane. A discrepancy could be due to either dental factors or skeletal maxillary rotation. Maxillary rotation is a rarely occurring clinical finding and is usually accompanied by posterior dental crossbite. The dental features of maxillary midline discrepancies will be discussed in both the miniesthetic and microesthetic perspectives.

Mandibular Dental Midline to Midsymphysis The mandibular dental midline to midsymphysis relationship is best visualized by standing behind the patient and then viewing the lower arch from above (Figure 54-13). The patient should open his or her mouth in order for the clinician to view the lower arch and its relationship to the body of the mandible and symphysis. Lower dental midline discrepancies are usually due to tooth related issues such as dental crowding with shifted incisors, premature exfoliation of primary teeth and subsequent space closure in pre-adolescents, congenitally missing teeth, or

FIGURE 54-13 If the lower dental midline is not coincident with the midsymphysis, it usually indicates a dental shift. However, chin asymmetry should also be considered.

an extracted unilateral tooth. If the lower dental midline is not coincident with the midsymphysis, it usually indicates a dental shift. However, chin asymmetry should also be considered.

Mandibular Asymmetry with or without Functional Shift Mandibular asymmetry is suspected when the midsymphysis is not coincident with the midsagittal plane. An important diagnostic factor is whether a lateral functional shift is present secondary to a functional shift of the mandible due to crossbite. When the patient is manipulated into centric relation, a bilateral, end-to-end crossbite usually is present, and as the patient moves the teeth into full occlusion, the patient must choose a side to move his or her mandible into maximum intercuspation. This lateral shift is indicative not of true mandibular asymmetry but of transverse maxillary deficiency and a resultant functional shift of the mandible.

True mandibular asymmetry is suspected when, in closure into centric relation, no lateral functional shift occurs. The truly asymmetric mandible may be due to an inherited asymmetric facial growth pattern or a result of localized or systemic factors. A thorough history of traumatic injuries and a review of systems of the patient will help ascertain potential etiologies of true mandibular asymmetry.

Chin Asymmetry Facial asymmetry in some cases may be limited to the chin only. If the systematic evaluation of facial symmetry has dental and skeletal midlines and vertical relationships of the maxilla normal and lower facial asymmetry is noted, then the asymmetry may be isolated to the chin. Measurement of the midsymphysis to the midsagittal plane is a logical indicator of chin asymmetry, but the parasymphyseal heights should also be measured when chin asymmetry is suspected (Figure 54-14). The frontal view is recommended, but a view from

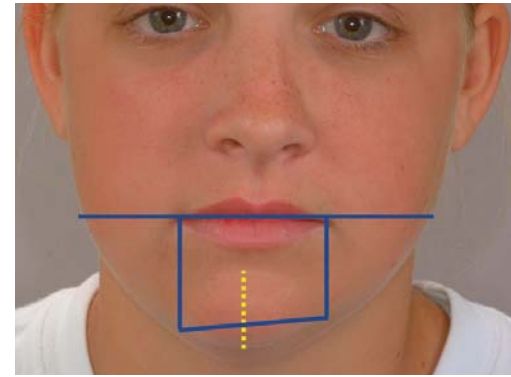

FIGURE 54-14 Measurement of the midsymphysis to the midsagittal plane is a logical indicator of chin asymmetry, but the parasymphyseal heights should also be measured when chin asymmetry is suspected.

the superior facial aspect (much like the evaluation of the mandibular dental midline) with the mouth closed also affords the clinician excellent visualization of the chin to the body of the mandible and the midsymphysis.

Maxillomandibular Asymmetry Mandibular asymmetry is often accompanied by maxillary compensation, which is reflected clinically by a transverse cant of the maxilla. This means that evaluation of mandibular deformity should now include the possibility of maxillomandibular deformity. Transverse tilting of the maxilla may be detectable cephalometrically but is most evident during the macroesthetic examination (Figure 54-15). Clinically, one notes this, for example, as *right maxilla 4 mm more superior than left*. The transverse cant of the maxilla

FIGURE 54-15 Transverse tilting of the maxilla may be detectable cephalometrically but is most evident during the macroesthetic examination.

is often determined by the relative difference in gingival show present at the level of the canine moving posterior at smile. Differentiation between the macro- and miniesthetic factors that are related to the transverse cant of the maxilla will be discussed later.

Macroesthetic Examination: Oblique View

The facial areas for macroesthetic examination, as investigated from the oblique view, can be summarized as follows:

- Midfacial
 - Orbital position
 - Nasal form
 - Cheek/zygomatic form
- Lower facial
 - Lip form
 - Philtrum
 - Vermilion
 - Mandibular form
 - Chin projection

The oblique view (Figure 54-16A) in the macroesthetic examination affords the surgeon and orthodontist another perspective for evaluating the facial thirds. With

regard to the upper face, the clinician may view the relative projection of the orbital rim and malar eminence. Orbital and malar retrusion is often seen in craniofacial syndromes. Cheek projection is evaluated in the area of the zygomaticus and malar scaffold. Skin laxity and atrophy of the malar fat pad in this area may actually be a characteristic of aging and therefore seen in the older orthognathic population.¹⁶ This area can be described as deficient, balanced, or prominent. Nasal anatomy, which was described in the frontal examination, may also be characterized in this dimension.

Lip anatomy is also examined in the oblique and lateral views. The philtral area and vermilion of the maxillary lip should be clearly demarcated. The height of the philtrum should be noted as short, balanced, or excessive. Vermilion display should be termed as excessive, balanced, or thin.

The relative projection of the maxilla and mandible can be assessed in the oblique view. Midface deficiency can result in increased nasolabial folding, relaxed upper lip support, and altered columella and nasal tip support.

One of the greatest values of the oblique view is visualization of the body and gonial angle of the mandible as well as the cervicomental area. The patient in Figure 54-16A illustrates a desirable definition of the chin-neck anatomy. The patient in Figure 54-16B has a dolichofacial skeletal pattern with a steeper mandibular plane, not as esthetically pleasing as the previous illustration. The patient in Figure 54-16C demonstrates a brachyfacial pattern with an obtuse cervicomental angle secondary to submental fat deposition.

A characterization of mandibular form is also very important. The oblique view also demonstrates the effects of animation on the appearance of lip and chin projection. The patient in Figure 54-17A and B shows a moderate anterior divergence and facial concavity at rest, but during the smile, animation reveals an increased chin projection with excessive concavity.

FIGURE 54-16 A, Desirable definition of the chin-neck anatomy. B, A dolichofacial skeletal pattern with a steeper mandibular plane, not as esthetic as the previous illustration. C, A brachyfacial pattern with an obtuse cervicomental angle secondary to submental fat deposition.

FIGURE 54-17 A, The amount of facial concavity and chin projection at rest is within acceptable limits. B, When this patient animates, an excessive amount of chin projection and facial concavity is revealed.

Macroesthetic Examination: Profile View

The facial areas for macroesthetic examination, as investigated from the profile view, can be summarized as follows:

- Lower facial
 - Maxillomandibular projection or facial divergence
 - Lip form
 - Size
 - Projection
 - Labiomental sulcus
 - Chin projection

The last view in the macroesthetic examination is the profile perspective. Natural head position is essential for accurate evaluation of profile characteristics. The patient should be instructed to look straight ahead and, if possible, into his or her own image in an appropriately placed mirror. The visual axis is what determines “natural head position.” This axis very often, but not always, approximates the Frankfort horizontal plane. The classic vertical facial thirds should also be applied in profile view. An assessment of lower facial deficiency or excess should be noted.

The nasolabial angle describes the inclination of the columella in relation to the upper lip. The nasolabial angle should be in the range of 90 to 120° (Figure 54-18A).¹⁷ The nasolabial angle is determined by several factors: (1) the anteroposterior

position of the maxilla to some degree; (2) the anteroposterior position of the maxillary incisors; (3) vertical position or rotation of the nasal tip, which can result in a more obtuse or acute nasolabial angle; and (4) soft tissue thickness of the maxillary lip that contributes the nasolabial angle, where a thin upper lip favors a flatter angle and a thicker lip favors an acute angle.

The characterization of the lower face in profile (Figure 54-18B) is measured by the relative degree of lip projection, the labiomental sulcus, the chin-neck length, and the chin-neck angle. Maxillary and mandibular sagittal position can be described by means of facial divergence. The lower third of the face is evaluated in reference to the anterior soft tissue point at the glabella. Based on the position of the maxilla and mandible relative to this point, a patient’s profile will be described as straight, convex, or concave, and either anteriorly or posteriorly divergent.

Lip projection is a function of maxillo-mandibular protrusion or retrusion, dental protrusion or retrusion, and/or lip thickness. The description of lip projection

FIGURE 54-18 A, The facial profile view. Superiorly, the radix of the nose is characterized by an unbroken curve that begins in the superior orbital ridge and continues along the lateral nasal wall. The nasal dorsum is made up of both bony and cartilaginous tissues. The nasal tip is described as the most anterior point of the nose, and the supratip is just cephalic to the tip. The columella is the portion of the nose between the base of the nose (subspinale) and the nasal tip. B, The characterization of the lower face in profile is measured by the relative degree of lip projection, the labiomental sulcus, the chin-neck length, and the chin-neck angle.

should include pertinent information from any of the above sources. For example, a patient with lower lip protrusion may be maxillary (midface) deficient with dentoalveolar compensation including flared incisors and a thin maxillary vermilion display, or simply may have a thick lower lip that appears protrusive.

The labiomental sulcus is defined as the fold of soft tissue between the lower lip and the chin and may vary greatly in form and depth. The clinical variables that can affect the labiomental sulcus include (1) lower incisor position, where upright lower incisors tend to result in a shallow labiomental sulcus because of lack of lower lip projection, whereas excessive lower incisor proclination deepens the labiomental sulcus; and (2) vertical height of the lower facial third, which has a direct bearing on chin position and the labiomental sulcus. Diminished lower facial height will usually result in a deeper labiomental sulcus (just as in the overclosed full denture patient), whereas a patient with a long lower facial third has a tendency toward a flat labiomental sulcus.

Chin projection is determined by the amount of anteroposterior bony projection of the anterior, inferior border of the mandible, and the amount of soft tissue that overlays that bony projection. The amount of profile chin projection is measured by the distance from pogonion (or Pg, the most anterior point on the bony chin) to soft tissue pogonion' (or Pg', the most anterior point on the soft tissue profile of the chin) and is not particularly alterable by surgical means. In the adolescent, the amount of chin is directly correlated to the amount of mandibular growth that occurs because the chin point itself is borne on the mandible as it grows anteriorly.

The angle between the lower lip, chin, and R point (the deepest point along the chin-neck contour) should be approximately 90°. An obtuse angle often indicates (1) chin deficiency, (2) lower lip procumbency, (3) excessive submental fat, (4),

retropositioned mandible, and (5) low hyoid bone position.

Another important measure in this area is the chin-neck length and chin-neck angle. The angle, also termed the *cervicomental angle*, has been studied extensively in plastic surgery and orthognathic literature.¹⁸ Studies report that a wide range of normal neck morphology exists, and that the cervicomental angle may vary between 105° and 120°, with gender being a major consideration. Age of the patient must be considered with regard to this area. Soft tissue “sag” due to the loss of skin elasticity during aging is a major cause of change in the cervicomental region. Weight gain is another important factor in the morphology of this area.

Miniesthetic Examination: Frontal View

The facial areas for miniesthetic examination, as investigated from the frontal view, can be summarized as follows:

- Vertical characteristics of the smile
 - Lip-tooth-gingival relationships
 - Gingival display on smile
 - Excessive gingival display on smile
 - Vertical maxillary excess
 - Short philtrum height
 - Excessive curtain
 - Short clinical crown height
 - Upright maxillary incisors
 - Inadequate gingival display on smile
 - Vertical maxillary deficiency
 - Diminished curtain
 - Short clinical crown height
 - Flared maxillary incisors
- Transverse characteristics of the smile
 - Arch form
 - Buccal corridor
 - Cant of the transverse occlusal plane

Vertical Characteristics Lip-Tooth-Gingival Relationships A key feature of vertical facial esthetic characteristics is the

relationship between the incisal edges of the maxillary incisors relative to the lower lip as well as the relationship between the gingival margins of the maxillary incisors relative to the upper lip. The gingival margins of the cuspids should be coincident with the upper lip, and the lateral incisors positioned slightly inferior to the adjacent teeth. It is generally accepted that the gingival margins should be coincident with the upper lip in the social smile. However, this is very much a function of the age of the patient, since children show more teeth at rest and gingival display on smile than do adults.¹⁹

Excessive Gingival Display on Smile

The vertical characteristics of facial miniesthetics impact the relative amount of gingival display at rest and during animation. Gingival display is the amount of “gumminess” of the smile. Measuring the amount of gingival display on smile easily quantitates a “gummy” smile. The decision as to whether the amount of gingival display is an esthetic problem in which treatment is desirable is a personal choice. Orthodontists and oral and maxillofacial surgeons tend to see the “gummy” smile as an unesthetic characteristic, while laypersons attach importance only in the more extreme cases. The use of computerized graphic simulation of the frontal view of the smile is useful in counseling a patient and showing potential treatment changes. The individual is then able to guide the clinician and express opinions about what should and should not be corrected. Computer imaging not only provides the patient with a visual template for treatment but it also provides the clinician with a testing ground for treatment options. The patient in Figure 54-19A exhibits excessive gingival display on smile, secondary to vertical maxillary excess. The diagnosis of vertical maxillary excess is confirmed by the facial characteristics of a long lower facial third, lip incompetence,

FIGURE 54-19 A, This patient exhibits excessive gingival display on smile, secondary to vertical maxillary excess. B, The actual post-treatment outcome.

excessive incisor display at rest, and excessive gingival display on smile. Superior repositioning of the maxilla was performed with excellent facial proportions and smile esthetics (Figure 54-19B).

The patient in Figure 54-20A also exhibited excessive gingival display, but has normal vertical facial proportions. Her incisor crown height, however, is only 8 mm. The etiology of her “gummy” smile is not an orthognathic problem or an orthodontic problem but a cosmetic or periodontal problem. This diagnosis was confirmed and further visualized through computerized image modification (Figure 54-20B and C), simulating the crown-lengthening procedure. Orthodontic intrusion of maxillary incisors would have reduced gingival display but would also have adversely affected the smile arc with concomitant flattening. This case example emphasizes differential diagnosis of gingival display issues and it also emphasizes the optimization of unesthetic facial traits while preserving those positive facial esthetic attributes.

Transverse Characteristics The three transverse characteristics of facial esthetics in the frontal dimension are (1) arch form,

(2) buccal corridor, and (3) the transverse cant of the maxillary occlusal plane.

Arch form plays a pivotal role in the transverse dimension. Recently, much atten-

tion has been focused on using broad square arch forms in orthodontic treatment and orthognathic surgical treatment. In cases in which the arch forms are narrow or collapsed, the smile may also appear narrow and therefore present inadequate transverse smile characteristics. An important consideration in widening a narrow arch form, particularly in the adult, is the axial inclination of the buccal segments. Cases in which the posterior teeth are already flared laterally are not good candidates for dental expansion. Upright premolars and molars allow for a more bodily transverse expansion of the buccal segments in both adolescent and adult patients, but are particularly important in the adult where sutural expansion is less likely. Orthodontic expansion and widening of a collapsed arch form can dramatically improve the appearance of facial esthetics and smile by decreasing the size of the buccal corridors and improving the *transverse smile dimension* (Figure 54-21A and B). The transverse smile dimension

FIGURE 54-20 A, This patient exhibits excessive gingival display, but has normal vertical facial proportions. Her incisor crown height, however, is only 8 mm. The etiology of her “gummy” smile is not an orthognathic problem or an orthodontic problem but a cosmetic or periodontal problem. B and C, This diagnosis was confirmed and further visualized through computerized image modification, simulating the crown-lengthening procedure.

FIGURE 54-21 A, The transverse smile dimension in this patient was characterized by narrow arch form and excessive buccal corridor. In this adult, the axial inclinations of the molars and premolars were favorable for orthodontic expansion. B, The transverse smile dimension after orthodontic treatment.

(and the buccal corridor) is related to the lateral projection of the premolars and the molars into the buccal corridors. The wider the arch form is in the premolar area, the greater would be the portion of the buccal corridor filled.

As alluded to in the previous cases above, arch expansion can have undesirable effects. Expansion of the arch form may fill out the transverse dimension of the smile, but two undesirable side effects may result and careful observation should be made to avoid these side effects wherever possible. First, the buccal corridor can be obliterated and create a “denture”-like smile. Second, when the anterior sweep of the maxillary arch is broadened, the smile arc may be flattened. Although it may not be possible to avoid these undesirable aspects of expansion, the clinician must make a judgment in concert with the patient as to what “trade-offs” are acceptable in the pursuit of the ideal facial esthetic outcome.

The last transverse characteristic of facial esthetics is the transverse cant of the maxillary occlusal plane. Transverse cant of the maxilla can be due to differential eruption and placement of the anterior teeth, and skeletal asymmetry of the skull base and/or mandible resulting in a compensatory cant to the maxilla. Intraoral images or even mounted dental casts do not adequately reflect the relationship of

the maxilla to the smile. Only frontal smile visualization permits the orthodontist to visualize any tooth-related asymmetry transversely.

Smile asymmetry may also be due to soft tissue considerations such as an asymmetric smile curtain. In the asymmetric smile curtain, there is a differential elevation of the upper lip during smile, which gives the illusion of transverse cant to the maxilla. This smile characteristic emphasizes the importance of direct clinical examination in treatment planning the smile, since this soft tissue animation is not visible in a frontal radiograph or reflected in study models. It is not well documented in static photographic images, and is documented best in digital video clips.

Miniesthetic Examination: Oblique View

Miniesthetic examination from the oblique view involves two main areas:

- Orientation of the palatal and occlusal planes
- Smile arc

The oblique view of the smile reveals characteristics of the smile that are not obtainable on the frontal view and certainly not obtainable through any cephalometric analysis. The palatal plane may be canted anteroposteriorly in a number of

orientations. In the most desirable orientation, the occlusal plane is consonant with the curvature of the lower lip on smile (see discussion of *smile arc* below). Deviations from this orientation include a downward cant of the posterior maxilla, upward cant of the anterior maxilla, or variations of both.²⁰ In the initial examination and diagnostic phase of treatment, it is important to visualize the occlusal plane in its relationship to the lower lip.

The *smile arc* should be defined as the relationship of the curvature of the incisal edges of the maxillary incisors, canines, premolars, and molars to the curvature of the lower lip in the posed social smile. The ideal smile arc has the maxillary incisal edge curvature parallel to the curvature of the lower lip upon smile, and the term *consonant* is used to describe this parallel relationship. A *nonconsonant* or flat smile arc is characterized by the maxillary incisal curvature being flatter than the curvature of the lower lip on smile. Early definitions of the smile arc were limited to the curvature of the canines and the incisors to the lower lip on smile because smile evaluation was made on direct frontal view. The visualization of the complete smile arc afforded by the oblique view expands the definition of the smile arc to include the molars and the premolars (Figure 54-22).

Miniesthetic Examination: Profile View

The facial areas for miniesthetic examination, as investigated from the profile view, can be summarized as follows:

- Overjet
- Incisor angulation
 - Upright maxillary incisors
 - Flared maxillary incisors
 - Retroclined mandibular incisors

The two miniesthetic characteristics visualized in the sagittal dimension are overjet and incisor angulation (Figure 54-23). Excessively positive overjet is one of the most

FIGURE 54-22 The smile arc is best visualized in the oblique view, and should be defined as the relationship of the curvature of the incisal edges of the maxillary incisors, canines, premolars, and molars to the curvature of the lower lip in the posed social smile. The 45° view permits visualization of vermilion display, lip fullness, and turgor not readily seen in another view.

recognizable dental traits to the layperson. Adolescents tend to label unflattering names such as “Andy Gump” and “Bucky Beaver” onto children unfortunate enough to have inherited this dentoskeletal pattern. How overjet is orthodontically corrected involves

FIGURE 54-23 The two miniesthetic characteristics visualized in the sagittal dimension are overjet and incisor angulation.

macroelements such as jaw patterns and soft tissue elements such as nasal projection. Excessive positive overjet is not as readily perceived in the frontal dimension as it is in the sagittal dimension. Many Class II patterns have very esthetic smiles frontally, but not when the patient’s smile is observed from the side. In Class III patterns, the same phenomenon may be true, in that the smile looks esthetic on frontal smile, but on the oblique or sagittal view, the overall appearance reflects the underlying skeletal pattern and dental compensation. The patient and parents have to decide with the clinician whether this is an acceptable outcome.

The amount of anterior maxillary projection also has great influence on the transverse smile dimension in the frontal view. When the maxilla is retrusive, the wider portion of the dental arch is positioned more posteriorly relative to the anterior oral commissure. This creates the illusion of greater buccal corridor in the frontal dimension. Overall, the sagittal cant of the maxillary occlusal plane in natural head position can influence the smile arc in the frontal dimension, affecting vertical characteristics. A negative cant of this plane will diminish the apposition of the incisal edges of the maxillary anterior teeth to the superior vermilion border of the lower lip at smile.

Dental Examination

The dental component of the clinical examination is the evaluation of any standing periodontal or cariogenic disease process and the assessment of the patient’s occlusion. The areas for dental examination can be summarized as follows:

- Alignment
 - Crowding
 - Spacing
 - Missing or supernumerary teeth
- Anteroposterior
 - Angle classification
 - Overjet
 - Compensation

- Bite depth
 - Anterior
 - Posterior
 - Compensation
- Transverse
 - Compensation
- Functional occlusal issues
 - Missing teeth and sequelae
 - Occlusal interferences and para-function

Intra-arch and interarch relationships are described in the categories of dental alignment, anteroposterior occlusion, and bite depth. Clinically, the patient’s occlusion should be examined both in a static and dynamic sense.

The maxillary and mandibular dental arches are described as either well aligned, crowded, or spaced. The extent of crowding or spacing is usually noted in millimeters. Individual teeth are described by virtue of their spatial position and degree of rotation. Therefore, an incisor could be described as severely rotated and in linguoversion. Any congenitally missing, lost, or supernumerary teeth are noted. A description of teeth that have been severely worn or damaged due to trauma should be included.

In terms of the static occlusion, Angle’s classification of the patient should be recorded. The Angle Class I relationship is such that the mesiobuccal cusp of the maxillary first molar should rest in the buccal groove of the mandibular first molar. The Angle Class II relationship exhibits a more anterior position of the mesiobuccal cusp of the maxillary first molar and the Angle Class III relationship exhibits a more posterior position of the mesiobuccal cusp of the maxillary first molar. The degree of incisor overjet that accompanies an anteroposterior discrepancy should also be noted.

Concepts of Incisor Compensation
Incisor compensation in the sagittal view is very important in planning the presurgical

orthodontics, yet not fully recognized by both orthodontists and surgeons alike. In most cases of skeletal dysplasia, whether in the range of surgical or nonsurgical treatment, dental compensation is a common feature. The forms and expression of this compensation are as complex as the myriad of dentoskeletal problems that exist, but there are common patterns frequently encountered. In the diagnosis and proper treatment of these cases, the primary responsibility of the orthodontist is to recognize these compensations and eliminate or *decompensate* them. The range of which compensations are problematic is not concrete, so the surgeon and the orthodontist must decide how much compensation is acceptable and what is to be done for decompensation. Although we tend to think of these compensations as an anteroposterior consideration (incisor angulation problems), dental compensation can occur in all planes of space.

Class II and Class III Problems The classic pattern of compensation in Class II skeletal patterns is the proclination of the mandibular incisors and retroclination of the maxillary incisors. Conversely,

Class III skeletal dysplasias often feature retroclination of the mandibular incisors and proclination of the maxillary incisors. The orthodontist must recognize these compensations and decide what degree of compensation is acceptable and what requires substantive treatment. For example, if lower incisor flare in the Class II patient is only moderate, what is the value of removing two mandibular premolars to upright the incisors? These decompensation decisions affect the treatment outcome in three basic ways: (1) inadequate incisor positioning can compromise buccal interdigitation; (2) incisor positioning can substantially affect the esthetic outcome; and (3) in certain types of functional problems such as obstructive sleep apnea syndrome, esthetic considerations have a lower priority compared to correction of the functional problem.

The effect of incisor angulation on buccal occlusal relationships was advanced and best expressed by Andrews.²¹ In presurgical preparation for mandibular advancement, maxillary incisors that are not properly flared or mandibular incisors that are left overly

flared may result in the following: (1) insufficient overjet to provide for adequate advancement of the mandible from the esthetic standpoint, and (2) the inability to achieve desired Class I buccal segments because the advanced nature of the lower incisor edge does not permit interdigitation of the buccal segments (Figure 54-24A and B). The appropriate amount of incisor angulation can be determined either through cephalometric investigation or by simply holding study models in a simulated Class I molar relationship.

Vertical Characteristics and Compensations *Bite Depth* The vertical component of the dental examination describes bite depth. A patient's anterior bite depth is the amount of maxillary incisor overbite relative to the mandibular incisors. Therefore, a patient can be described as having an anterior open bite, satisfactory bite (25 to 50% overbite), or an anterior deep bite. The posterior bite depth is usually characterized as being open, satisfactory, or collapsed. The latter is seen when the patient is missing unilateral or bilateral posterior dental units.

FIGURE 54-24 A, Inadequate decompensation in Class II correction makes Class I buccal segments not attainable because the flared lower incisors do not permit interdigitation of the posterior segments. B, Inadequate decompensation in Class III correction makes Class I buccal segments not attainable because the upright lower incisors or flared maxillary incisors do not permit interdigitation of the posterior segments.

Curve of Spee Dental compensation in the vertical plane has to do with aberrations in the curve of Spee. The curve of Spee is measured by the arc extending from the cusp tips of the incisors posteriorly to the cusp tips of the molars in a sagittal view. Clinically, the study model can be placed on a flat surface and the cusp tips relative to that flat plane will give a rough estimate of the maxillary and mandibular curve of Spee. This is an important diagnostic feature of model analysis in recognizing potential pitfalls that may be encountered during orthodontic preparation for orthognathic surgery. For example, in a patient in whom the anterior segment is significantly superior (greater than 2 mm) to the posterior segment, failure to recognize this occlusal plane differential may result in orthodontic flattening prior to surgery and postsurgical relapse, resulting in anterior open bite.²²

Transverse Compensations The Class II patient often has narrowing of the maxilla in response to the narrower portion of the mandible being placed in the broader portion of the maxillary arch. In the Class III patient, the maxillary posterior segments are often flared buccally in compensation for the wider portion of the mandible being placed into the narrower aspect of the maxilla. By holding the study models in a simulated Class I relationship, these compensations can be easily recognized (Figure 54-25).

Functional Occlusal Issues The last portion of the dental examination relates to dynamics of occlusal function. The clinician should ascertain whether the patient exhibits a discrepancy between maximum intercuspal position and retruded contact position in the anteroposterior dimension. In general, small differences exist in the vast majority of patients. Only large slides should be recorded. If the patient's dentition is mutilated the clinician should note the resultant occlusal compensa-

tions. Any supererupted teeth will create lateral and anteroposterior interferences. A history of bruxism or other parafunctional habits will affect orthodontic appliances and will impact on the type of retention used post-treatment.

Microesthetic Examination

The microesthetic portion of the clinical examination focuses on the morphology of tooth-to-tooth contacts and the surrounding intraoral tissues, summarized as follows:

- Dentogingival relationships
Tooth form/tooth contact/gingival architecture

As a structural unit, the dentogingival complex is defined by the relationship of the teeth to the alveolar bone and surrounding gingival and masticatory mucosa. The factors that influence the appearance of the dentogingival complex are the patient's periodontal status and past history of disease, the proximal and occlusal contacts of the teeth, the shape of the individual teeth, and the type of gingival architecture.

An assessment of the patient's current periodontal status is exceedingly important from an orthodontic and surgical point of view. The clinician should take an accurate dental history in order to ascertain whether the patient has had any periodontal disease and related treatment. Clinically, the teeth should be examined for plaque accumulation and any supragingival calculus. Patients who cannot maintain a satisfactory level of oral hygiene are at risk for gingival inflammation, attachment loss, and caries during presurgical orthodontic treatment. Periapical radiographs combined with a panoramic radiograph will reveal alveolar architecture and any evidence of horizontal or vertical bone loss. Suspected periodontal defects should be probed and the depths recorded. The extent of attachment loss and degree of tooth mobility will influence tooth movement.

FIGURE 54-25 Transverse problems are first diagnosed by holding the study models together in a simulated Class I relationship. The most commonly found transverse problem is that the maxilla is narrower than the mandible in cases similar to that of this patient who was being evaluated for Class II correction by mandibular advancement.

Surgical treatment planning of the segmental Le Fort I osteotomy should consider gingival architecture in relation to maxillary segmentation. If the incisions are made mesial to the maxillary canines, the patient may lose the interdental papilla in between this tooth and the maxillary lateral incisor. By positioning the incisions distal to the maxillary canines, an obliterated papilla can be more easily camouflaged due to the convexity of the canine.

Computerized Cephalometric Prediction

For computer image prediction, a digital model of the cephalometric tracing must be entered into computer memory. It is important that the radiograph be obtained in natural head position, with the teeth lightly together and in retruded contact position and the lips relaxed. The details of the digital model vary among the several currently available software programs but the similarities are more impressive than the differences. The more points in the digital model, the greater the anatomic fidelity of that model. On the other hand, the more points that are digitized, the more time it takes to perform the digitization process.

A lateral image of the patient's profile, matching the cephalograms as closely as

possible in head position and lip posture, must be captured and entered into the computer program (either directly via digital photography or by scanning a slide). Ideally, the radiograph and profile image would be taken simultaneously, although the hardware arrangement to do this does not yet exist.

The patient in Figure 54-26A presented for correction of a severe Class II dentofacial deformity. After clinical examination and diagnostic records, digital image integration and algorithmic projections are used for consultation with the patient.

After the records are gathered, the next step in the treatment planning is to superimpose the profile image and radiograph, with the hard and soft tissues matched to each other as closely as possible. Most programs use the profile as the major method of image coordination. Once the images are coordinated, any cephalometric analysis can be displayed, although in contemporary surgical planning, the goal of treatment is not what the analysis indicates.

At that point, a “treatment screen” (Figure 54-26B) provides the clinician with “handles” (the blue squares) by which selected sections of hard tissue can be moved (eg, the mandible, the maxilla, or maxillary incisor segment); the procedures similar to the use of templates and manual prediction. In this case illustration, surgical mandibular advancement is being contemplated. Dental compensation is present in the form of flared mandibular incisors, and decompensation is recommended to decompensate the dentition in order to increase the overjet, thus maximizing the magnitude of mandibular advancement. Simulation of lower first premolar extraction and lower incisor retraction is made on the treatment screen; the software applies its imbedded algorithms for profile prediction and creates a new line drawing of the profile (Figure 54-26C) reflecting the expected profile change after incisor decompensation. The algorithms may be ratios based on regressive equations and multiple correla-

tions. They are not the same in all programs: the quality of the algorithms is the major determinant of how well or poorly the predicted profile matches the actual change produced by the treatment. The quantitative table on the right of Figure 54-26C provides to the clinician the measurements of the movements made on screen calibrated to actual movements required clinically to achieve the projected change.

After decompensation movements are simulated, the mandible is advanced on the treatment screen to ideal overjet, and the software then “warps” the original profile image to fit the prediction line drawing, producing an image that conveys much more visual information to the clinician and patient than the line drawing (Figure 54-26D). As treatment is being planned, the amount of change is suggested until, within the limits of possible surgical change, it looks best; it is advantageous to include the patient in this process of adjusting the amount of change to provide an optimal outcome. In this case, a comparison image is generated so the patient may visualize the profile outcome expected with mandibular advancement (Figure 54-26E). The profile was judged to be improved but was still clearly chin deficient. Simulation of chin advancement is then performed (Figure 54-26F), not by using any cephalometric norm or predetermined value, but by simply using the facial outline as a guide. In other words, the chin is moved horizontally and vertically until it meets the approval of the patient. The projected final profile image is depicted in Figure 54-26G. The quantitative table reflects the exact movements in millimeters so that the surgeon and orthodontist have a precise plan for the amount of change needed to produce the desired result seen in Figure 54-26H. Presurgical planning using this methodology should eliminate “on-the-table” estimates of whether or not the patient needs “a bit more chin.” It is ludicrous to make esthetic treatment decisions with the patient under general anesthesia,

horizontal, fully draped, paralyzed, and with a nasal tube in place.

An important consideration is the accuracy of the computer prediction process. Although it is far from perfect (some computer programs are more accurate than others), it is good enough to be clinically useful.²³⁻²⁷ Chin predictions are usually quite accurate and those of the upper lip are reasonably good, whereas predictions of the lower lip can be problematic. As the data on which algorithms are based become more extensive, as different algorithms are applied when vertical and anterior changes occur, and as multiple regression equations replace simple ratios, accuracy can be expected to improve.²⁸

It could be said that in this era of informed consent and bioethical decision-making, the patient should be actively involved in the process of computer prediction and treatment planning. Cultural and familial traits may be important to the patient. Surgeons and orthodontists tend to want to “optimize” all patients to the prevailing esthetic norm, which diminishes any ethnic variation in dentofacial appearance.

Synthesis of an Optimized Problem List

The data derived from the systematic clinical examination and analysis of patient records are synthesized into a diagnostic optimized problem list. Essentially there are two branches in the problem-solving tree: esthetics and function. Thus, the diagnostic problem list should be subdivided into the categories of macroesthetic problems, miniesthetic problems, microesthetic problems, and functional problems. All recognizable problems that are relevant to the patient’s chief complaint should be rank-ordered. Lastly, each problem should be evaluated in terms of its therapeutic modifiability.

Conceptually and operatively, the orthodontist and surgeon have to visualize the desired solution to the specific problem and then assess whether the given solution will negatively impact some other dentofacial

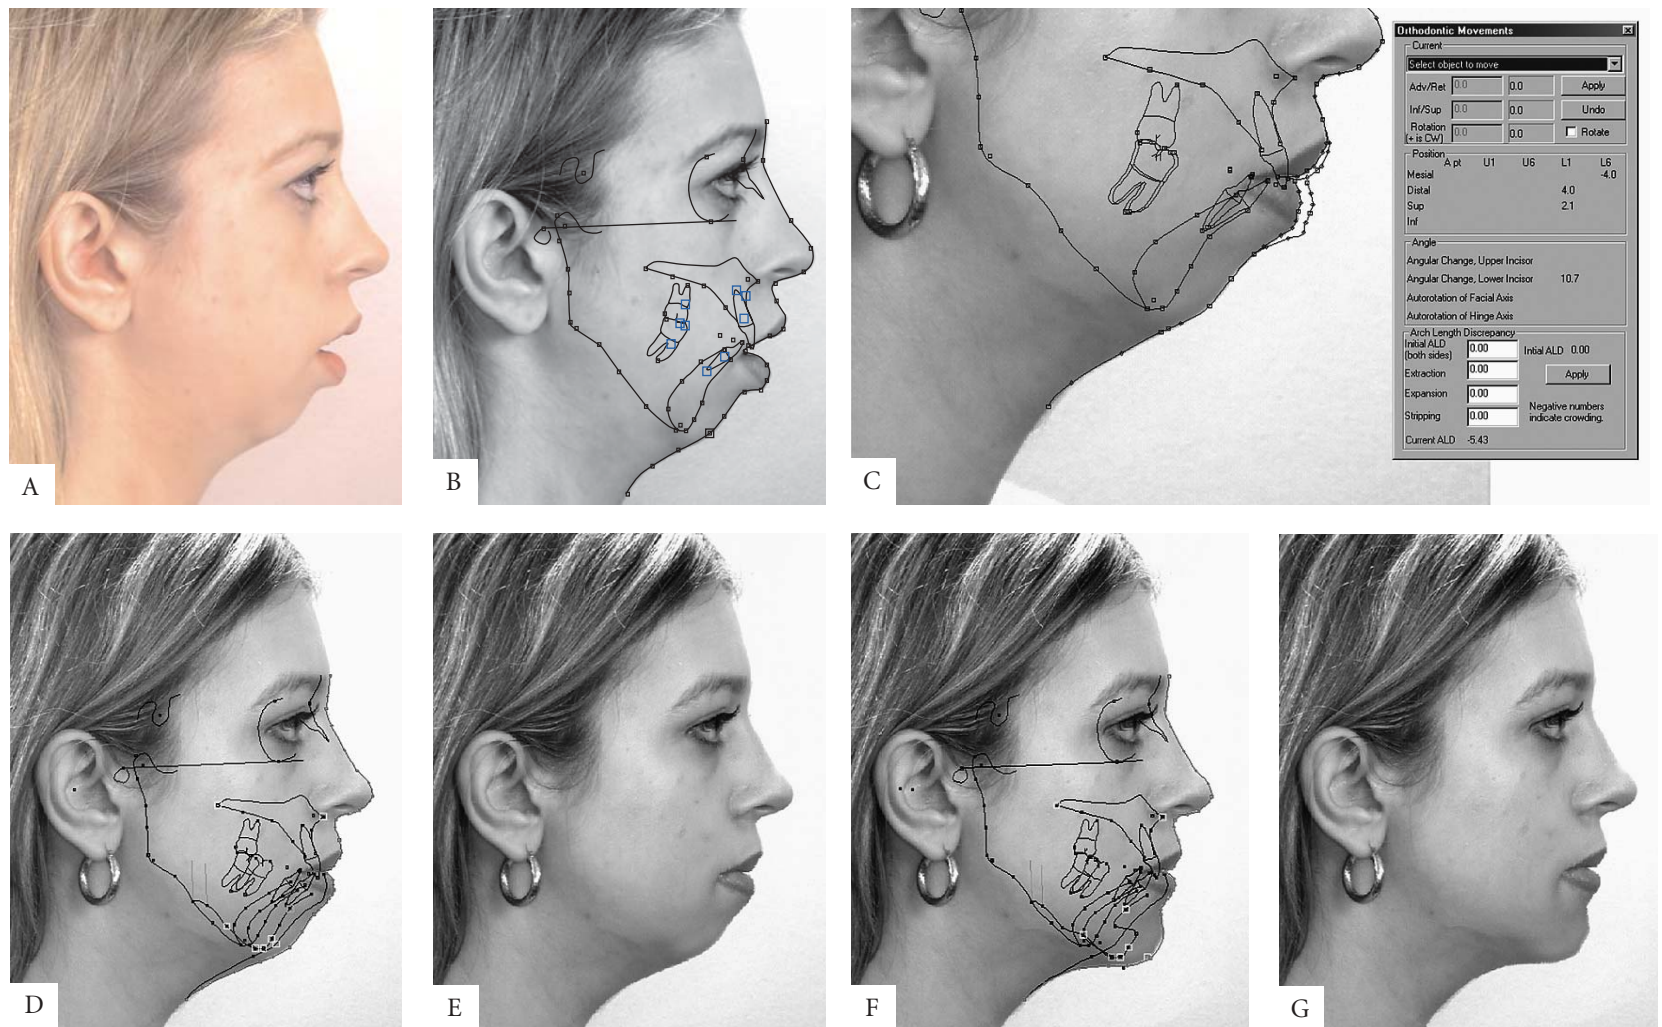

FIGURE 54-26 A, This patient presented for correction of a severe Class II dentofacial deformity. B, A “treatment screen” provides the clinician with “handles” (the blue squares) by which selected sections of hard tissue can be moved (eg, the mandible, the maxilla, or the maxillary incisor segment); the procedures are similar to the use of templates and manual prediction. C, Simulation of lower first premolar extraction and lower incisor retraction is made on the treatment screen. The software applies its imbedded algorithms for profile prediction and creates a new line drawing of the profile reflecting the expected profile change after incisor decompensation. D, After decompensation movements are simulated, the mandible is advanced on the treatment screen to ideal overjet, and the software then “warps” the original profile image to fit the prediction line drawing, producing an image that conveys much more visual information to the clinician and patient than the line drawing. E, In this case, a comparison image is generated so that the patient may visualize the profile outcome expected with mandibular advancement. F, Simulation of chin advancement is then performed, not by using any cephalometric norms or predetermined value, but by simply using the facial outline as a guide. G, The projected final profile image. H, The actual treatment result.

feature at the same time. The concept of facial optimization involves the preservation of as many positive elements as possible, while harmonizing those elements that fall short of the esthetic and functional needs of the patient. The problems that

might exceed the limitations of treatment or perhaps have a poor therapeutic prognosis should be described. Informed consent and bioethical treatment of the surgical patient requires that the clinician explain the risk/benefit considerations of the pro-

posed treatment strategy. The goal of the systematized clinical examination and optimized problem-oriented diagnosis is to record and analyze the data in such a way that the required treatment becomes implicit in the description of the problem.

Orthodontics for Orthognathic Surgery

Larry M. Wolford, DMD

C. Moody Alexander, DDS, MS

Joao Roberto Goncalves, DDS, PhD

Moderate to severe occlusal discrepancies and dentofacial deformities in late adolescents and adults usually require combined orthodontic treatment and orthognathic surgery to obtain optimal, stable, functional, and esthetic results. The basic goals of orthodontics and orthognathic surgery are to (1) satisfy the patients' concerns, (2) establish optimal functional outcomes, and (3) provide good esthetic results. To accomplish this the orthodontist and the oral and maxillofacial (OMF) surgeon must be able to correctly diagnose existing dental and skeletal deformities, establish an appropriate treatment plan, and properly execute the recommended treatment. The orthodontist is limited, to a great extent, by growth, and although the orthodontist can move teeth and, to some degree, the alveolar bone, he or she does not have any appreciable effect on the basal bone of the jaws. The orthodontist's role is to align the teeth relative to the maxillary and mandibular jaws. The OMF surgeon is responsible for surgically repositioning the jaw(s) and associated structures.

It is very important to listen to and understand the patients concerns. Empa-

thetic listening from the first appointment and throughout the treatment will build trust, improve communication, and help provide a quality end result for all parties involved. Comprehensive analysis of the patient and the complete orthodontic records (cephalograms, pantomograms, photographs, dental models) are important for diagnosis and development of the presurgical orthodontic goals. Although detailed analysis of the patient's facial and jaw structures from a clinical and radiographic perspective are vitally important, the focus of this chapter will be the teeth and orthodontic considerations in preparation for orthognathic surgery. Other important factors in diagnosis, treatment planning, and outcomes, such as patient concerns, psychosocial factors, masticatory dysfunction, airway problems, speech difficulties, temporomandibular joint (TMJ) pathologies, and comprehensive orthognathic surgery work-up are discussed elsewhere in this book.

The normal values provided in this chapter are not absolutes for every patient because of individual size, morphologic variances, and racial and ethnic differ-

ences. They are provided as a guide to help the clinician evaluate his or her patient.

Establishing an all-inclusive diagnosis is paramount to developing a comprehensive treatment plan. The orthodontist must determine the orthodontic goals based on the pretreatment findings and on the projected treatment outcome. This chapter will first present orthodontic diagnostic information, followed by orthodontic treatment considerations.

Clinical and Dental Model Diagnosis

From an orthodontic standpoint, in evaluating the occlusion and dental factors, the clinical and dental model analyses correlated with the cephalometric analysis provide the most information for diagnosis and treatment planning. There are 12 basic evaluations that are helpful for these determinations.

1. Arch length: This assessment correlates the mesiodistal widths of the teeth relative to the amount of alveolar bone available and aids in identifying the presence of crowding or

FIGURE 55-1 Arch length assessment correlates the mesiodistal widths of the teeth relative to the amount of alveolar bone available and aids in identifying the presence of crowding or spacing. The curved wire illustrates ideal cuspid and incisor tip position relative to the basal bone.

spacing. This helps determine if teeth need to be extracted or if spaces need to be either created or closed (Figure 55-1). Clinical and dental model assessment correlated to cephalometric analysis will aid in determining arch length requirements. Generally Class II patients will tend to have more crowding in the mandibular arch and less in the maxillary arch, whereas Class III patients may have spacing in the mandibular

arch but a tendency for crowding in the maxillary arch.

2. Tooth-size analysis: This analysis relates the mesiodistal width of the maxillary teeth compared with the mandibular teeth. A tooth-size discrepancy (TSD) causes incompatibility of the dental alignment and can occur in the anterior teeth, premolars, and molars. Approximately 40% of patients with dentofacial deformities will have an anterior TSD affecting the anterior six teeth of the maxillary and mandibular arches (the mandibular arch is commonly too large compared with the maxillary arch), usually due to small maxillary lateral incisors. In such cases proper tooth alignment with all spaces closed often precludes the establishment of a good Class I cuspid-molar relationship with treatment. Instead, a Class II end-on cuspid-molar occlusal relationship may result. Occasionally the maxillary anterior six teeth may be too large for the mandibular anterior teeth, creating an excessive anterior overjet when in a Class I cuspid relationship. Determination of a TSD pretreatment will provide the opportunity to correct the TSD during the presurgical orthodon-

tic phase of treatment. Explaining to the patient, before treatment, that small maxillary lateral incisors may need restorative bonding to maximize the quality esthetic and functional outcome is important, so that the patient is aware from the onset of the time and financial commitment necessary for treatment. The normal mesiodistal widths of each of the permanent teeth are recorded in Tables 55-1 and 55-2. Variations from the norm may create difficulties in the teeth fitting properly.

Bolton's analysis is a method to correlate the widths of the maxillary and mandibular anterior six teeth. Needle-point calipers can be used to measure each individual tooth, and successive holes punched into a tablet for each of the anterior six teeth for each arch. Then a measurement from the first to last holes will give the summation of mesiodistal widths of the anterior six teeth for each arch (Figures 55-2 and 55-3). The summation of the mesiodistal widths of the maxillary anterior six teeth measured at the contact level, divided into the combined width of the mandibular anterior six teeth, yields a value called

Table 55-1 Maxillary Mesiodistal Teeth Diameters

	Central Incisor*	Lateral Incisor*	Cuspids*	First Bicuspid*	Second Bicuspid*	First Molars*	Second Molars*
Males	8.9 (0.59)	6.9 (0.64)	8.0 (0.42)	6.8 (0.47)	6.7 (0.37)	10.6 (0.56)	9.5 (0.71)
Females	8.7 (0.57)	6.8 (0.64)	7.5 (0.36)	6.6 (0.46)	6.5 (0.46)	10.2 (0.58)	8.8 (0.73)

FIGURE 55-2 Bolton's analysis. Needle-point calipers are used to measure each tooth at a contact-point level to aid in tooth-size analysis.

the intermaxillary (Bolton's) index. The average index (percentage) is 77.5 ± 3.5 .¹ A simple conversion of this factor would be to measure the width of the mandibular anterior six teeth and then multiply that sum by 1.3. This results in a calculated ideal maxillary arch width. The difference between the calculated and the actual maxillary arch width values determines the TSD (see Figure 55-3). This evaluation is very helpful in determining presurgical orthodontic and surgical goals. TSDs can also occur in the premolar and molar areas (normally the same maxillary and mandibular teeth are similar in size) where the mandibular teeth may be significantly larger than the maxillary teeth.

The Bolton's analysis is not perfect and functions only as a guide in assessing the tooth-size compatibility of the anterior teeth because it does not take into consideration the labiolingual thickness of the incisors, the axial inclination of the teeth, or the thickness and prominence of the marginal ridges. A thin labiolingual dimension of the maxillary incisors may compensate for small TSDs, but thicker than normal dimensions or prominent marginal ridges may preclude a Class I cuspid relationship

FIGURE 55-3 Bolton's analysis. Successive holes are punched into a tablet for each of the anterior six teeth for each arch. Then measuring from the first hole to the last hole will give the summation of the mesiodistal widths of the anterior six teeth in each arch. Multiplying the summation of the mandibular anterior six teeth (LA) by 1.3 yields the calculated arch width for the maxillary anterior six teeth (UA). Subtracting the actual maxillary anterior arch width from the calculated width yields the tooth-size discrepancy.

even though the Bolton's index is normal. An accurate dental model orthodontic wax set-up may achieve a more accurate assessment.

FIGURE 55-4 Cephalometric analysis. Normal maxillary depth angle is $90^\circ \pm 3^\circ$ and mandibular depth is $88^\circ \pm 3^\circ$. Normal occlusal plane angulation is $8^\circ \pm 4^\circ$. Normal maxillary incisor angulation to the nasion point A (NA) line is $22^\circ \pm 2^\circ$ with the labial surface of the incisor being $4 \text{ mm} \pm 2 \text{ mm}$ anterior to the NA line. Normal mandibular incisor angulation to the nasion point B (NB) line is $20^\circ \pm 2^\circ$ with the labial surface of the incisor being $4 \text{ mm} \pm 2 \text{ mm}$ anterior to the NB line.

3. Incisor angulation: This refers to the angulation of the maxillary and mandibular incisors relative to their respective basal bones. The dental models are correlated to the cephalometric analysis and the ideal axial inclination of the incisors determined (Figure 55-4). The incisor angulation analysis contributes to the determination of whether extractions are necessary, spaces need to be created or eliminated, and what mechanics are required to align and level the arches or segments of the arches. The key is to get the incisors in proper position and angulation over basal bone.
4. Arch width analysis: This refers to the evaluation of the intra-arch transverse widths between the maxillary and mandibular arches. The average maxillary and mandibular arch widths for adults are listed in Tables 55-3 and 55-4 (data from University of Michigan Caucasian study).² These averages are only guides and do not account for

patient size, or racial or ethnic differences. However, from a practical standpoint a good way to analyze the arch width is to relate the models to the occlusal position that is to be achieved with the surgical correction and then assess the transverse relationship. For example, if a patient has a Class II occlusion, position the models in a Class I cuspid-molar relation and evaluate the transverse width relationship. Likewise, a patient with a Class III occlusion is evaluated by positioning the models into a Class I cuspid-molar relationship. When a Class II relationship is shifted to a Class I relationship, the maxilla may be narrow and require expansion. In some cases it may be indicated to evaluate the transverse relationship by placing the models into a Class II molar position to determine if a Class I cuspid and Class II molar relationship (this would require maxillary bicuspid extractions) would be best for that particular patient; this may be beneficial when there is significant crowding in the maxillary arch and no crowding in the mandibular arch. Transverse discrepancies will influence the presurgical orthodontics and dictate the surgical procedures required.

- Curve of Spee: This evaluates the vertical position of the anterior teeth compared with the posterior teeth. This assessment can be determined by placing the occlusion of the maxillary dental model on a flat plane; the incisors should be about 1 mm above the flat plane (Figure 55-5A). Placing the occlusion of the mandibular dental model on a flat plane should see the mandibular incisors elevated 1 mm above the midbuccal teeth. A significant accentuated curve of Spee in the maxilla is usually associated with an anterior open bite and a reverse curve associated with an anterior deep bite. An accentuated curve of Spee in the mandible (Figure 55-5B) is commonly associated with an anterior deep bite. Accentuated or reverse curves of Spee will influence whether the curve in each arch requires correction, and if so, whether the correction will be achieved by orthodontics, with or without extractions, opening spaces, or by surgical intervention.
- Cuspid-molar position: This identifies the angle classification and dental interrelationships. It is usually

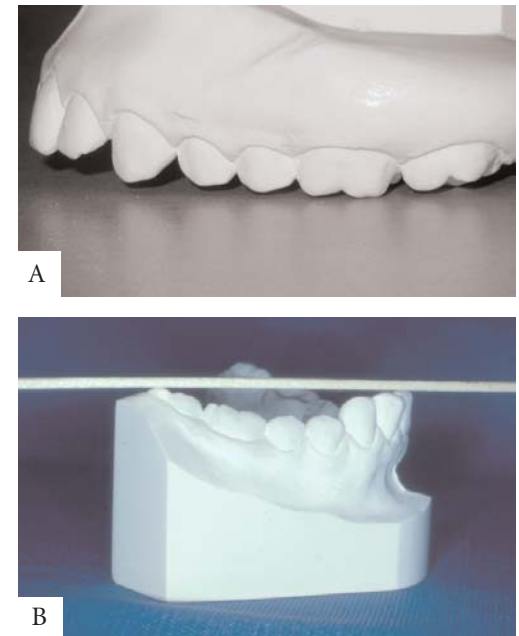

FIGURE 55-5 A, This maxillary arch demonstrates an increased curve of Spee. B, An accentuated (increased) curve of Spee is seen in the mandibular arch.

preferable to have a Class I cuspid-molar relationship as an outcome result; however, a Class II molar relationship is acceptable. A Class III molar relationship is less desirable because the mandibular first molar functions against the maxillary second bicuspid, but it may be indicated in some cases.

Table 55-3 Maxillary Arch Width*

7. **Tooth arch symmetry:** This compares the left to right side symmetry within each arch. There may be a significant asymmetry within the arch, such as a cuspid on one side being more anteriorly positioned in the arch than the cuspid on the opposite side (Figure 55-6). This problem often occurs with a unilateral missing tooth. Also, vertical asymmetries can occur with individual teeth, sections of the dentoalveolus, or the entire dental arches, creating a cant in the transverse occlusal plane. Correcting these types of conditions may require special orthodontic mechanics, unilateral extraction or opening-up space, asymmetric extractions, and/or surgical procedures.
8. **Curve of Wilson (buccal tooth tipping):** This evaluates the mediolateral position of the occlusal surfaces of the maxillary (Figure 55-7) and mandibular posterior teeth. If the occlusal surfaces of the maxillary or mandibular posterior teeth are tipped too far buccally, it may be difficult to achieve a proper occlusal interdigitation relationship. In the presence of a transverse maxillary deficiency with preexisting increased curve of Wilson and posterior crossbites, it is very difficult, if not impossible, to correct the problem orthodontically, orthopedically, or even with surgically assisted rapid

FIGURE 55-6 *Tooth arch symmetry.* This model demonstrates that the cuspid on one side of the arch is significantly more anteriorly positioned in the arch compared with the cuspid on the opposite side.

palatal expansion (SARPE). The curve of Wilson will usually get much worse with these mechanics. In these types of cases surgical expansion by multiple maxillary osteotomies may be indicated to decrease the curve of Wilson.

When the mandibular posterior teeth are tipped buccally, it is often related to macroglossia or habitual tongue posturing. Orthodontic lingual tipping of the posterior teeth is very difficult when macroglossia is present and will likely be unstable. A reduction glossectomy may be indicated before orthodontics in order to permit a more stable orthodontic result.

9. **Missing, broken down, or restored teeth:** These must be identified since they may influence treatment design. If a tooth is nonrestorable and requires extraction, it must be determined if the extraction space requires orthodontic closure or the space maintained for later dental reconstruction. In some cases it may be helpful to maintain the condemned tooth to improve stability during surgical alignment of the jaws or segments thereof, with removal postsurgery. Crowns on previously restored teeth may need to be redone post-orthodontics and -orthognathic surgery, since the crown anatomy may need to be changed for proper occlusion with the new dental relationships. Determination of salvageable teeth and restorative requirements are integral components in the planning and treatment of patients.
10. **Ankylosed teeth:** If undiagnosed, ankylosed teeth can have devastating effects on the presurgical orthodontics. Tooth ankylosis, the fusion of alveolar bone and cementum, results from damage to the periodontal ligament (PDL).

An ankylosed tooth may be identified by failure to move with orthodon-

FIGURE 55-7 *Curve of Wilson.* This evaluates the mediolateral position of the occlusal surfaces of the maxillary and mandibular posterior teeth.

tic forces (Figure 55-8), failure of a tooth to erupt, submerged or incomplete tooth eruption (Figure 55-9), or lack of eruption of a tooth compared with adjacent teeth and alveolar bone growth. The most sensitive diagnostic test is percussion, where the ankylosed tooth has a high, clear, solid metallic sound. A normal tooth has a dull sound, being protected by the PDL. However, an erupted tooth with an impacted tooth directly against it will also have a solid sound to percussion. Normal multirrooted teeth present a more solid sound than single-rooted teeth. Therefore, percussion testing should be compared with similar teeth (ie, test bicuspid against bicuspid, molars against molars, using both sides of the arch). An ankylosed tooth lacks

FIGURE 55-8 *This dental model shows a palatally displaced tooth, unresponsive to orthodontic mechanics, indicating probable ankylosis.*

FIGURE 55-9 This pantomogram demonstrates incomplete eruption of a primary tooth without a permanent successor, indicating ankylosis.

mobility. Over 90% of ankylosed teeth are deciduous; most often the second molar followed by the first molar.³ Ankylosed primary teeth are not susceptible to resorption by the follicle of the underlying permanent tooth and may result in its impaction.³

Ankylosed teeth can cause significant problems with jaw growth and development. Early ankylosis results in noneruption or partial eruption, resulting in incomplete development of the alveolar process.⁴ Permanent teeth may be displaced from normal eruption pathways with resulting loss of alveolar bone height. The failure of an ankylosed tooth to erupt may allow adjacent teeth to drift and permit super-eruption of the tooth in the opposing arch. Ankylosed teeth do not respond to orthodontic forces and can create significant orthodontic problems when malaligned and tied into the orthodontic arch wire (Figure 55-10).⁵ The ankylosed tooth functions as an anchor and in active uncontrolled orthodontics, will move adjacent teeth to align with its position, with subsequent development of an occlusal and possibly facial deformity.

11. Periodontal evaluation: This is very important, since preexisting periodontal pathologies could be exacerbated during orthodontic and orthognathic surgical treatments.⁶ Factors that can adversely affect the health and outcome of the periodontal tissues as well as the orthodontics and orthognathic surgery include smoking, excessive consumption of alcohol or caffeine, habitual patterns such as bruxism and clenching, preexisting connective tissue/autoimmune diseases, diabetes, malnutrition, and other diseases that could affect the local tissue blood supply perfusion, and healing. Any pretreatment of acute or chronic periodontal disease should be addressed prior to the orthodontics and surgery. The lack of attached gingiva around the teeth (most commonly seen in the mandibular anterior arch) can cause gingival retraction, loss of bone, and loosening of teeth if orthodontics is initiated and the mandibular incisors are tipped forward (Figure 55-11). Gingival grafting may be indicated prior to orthodontics to provide

attached gingiva so as to prevent these problems. Good communication between the periodontist, orthodontist, and OMF surgeon is of utmost importance.

Orthodontics can help prepare interdental osteotomy sites by tipping the roots of the adjacent teeth away from each other to increase the interosseous space between the roots. There have been a number of studies demonstrating that interdental osteotomies have a minimal effect on the periodontium when they are properly performed.⁷⁻¹¹ Having healthy stable dental tissues to work with during the orthodontics and surgery will maximize the periodontal outcome as well as the overall outcome. The failure to recognize preexisting periodontal pathology, identify risk factors, poor performance of surgery, and/or lack of attention to detail could result in significant periodontal problems as well as other problems that could compromise the final result.

12. Tongue assessment: An enlarged tongue (macroglossia) can cause dentoskeletal

FIGURE 55-10 This illustration depicts a partially submerged ankylosed maxillary cuspid (A). If tied into an active straight arch wire (B), the adjacent teeth will be orthodontically moved toward the ankylosed tooth, resulting in the development of a significant malocclusion.

FIGURE 55-11 *Periodontal concerns.* This patient had lack of attached gingiva prior to initiation of orthodontics and was left untreated, causing severe gingival retraction and loss of supporting bone. Gingival grafting should have been performed prior to initiation of orthodontics.

FIGURE 55-12 *Macroglossia.* Some of the clinical features associated with macroglossia include anterior open bite, diastemata between the teeth, accentuated curve of Spee maxillary arch, and reverse curve of Spee mandibular arch.

deformities, instability of orthodontic and orthognathic surgical treatments, and create masticatory, speech, and airway management problems. There are a number of congenital and acquired causes of true macroglossia, including muscular hypertrophy, glandular hyperplasia, hemangioma, lymphangioma, Down syndrome, and Beckwith-Wiedemann syndrome. Acquired factors include acromegaly, myxedema, amyloidosis, tertiary syphilis, cysts or tumors, and neurologic injury.¹² There are specific clinical and cephalometric features that may help the clinician identify the presence or absence of macroglossia, although not all of these features are always present. Specific clinical features include the following (Figure 55-12):

- Grossly enlarged, wide, broad, and flat tongue
- Open bite (anterior or posterior)
- Mandibular prognathism
- Class III malocclusion with or without anterior and posterior crossbite
- Chronic posturing of the tongue between the teeth at rest (rule out habitual posturing of a normal-sized tongue)
- Increased curve of Wilson of maxillary posterior teeth

- Reverse curve of Wilson of mandibular posterior teeth
- Accentuated curve of Spee in the maxillary arch
- Reverse curve of Spee in the mandibular arch
- Increased transverse width of maxillary and mandibular arches
- Diastemata with increased incisor angulation in the mandibular and/or maxillary arches

FIGURE 55-13 *Macroglossia.* Cephalometric analysis shows mandibular dentoalveolar protrusion and overangulation of the mandibular anterior teeth. The tongue fills the oral cavity (dotted line) and the oropharyngeal airway is decreased (normal distance from posterior aspect of tongue to posterior pharyngeal wall is 11 mm).

- Crenations (scalloping) on the tongue
- Glossitis (due to excessive mouth breathing)
- Speech articulation disorders
- Asymmetry in the maxillary or mandibular arches associated with an asymmetric tongue
- Difficulty eating and swallowing (severe cases)
- Instability in orthodontic mechanics or orthognathic surgical procedures that in normal circumstances would be stable
- Airway difficulties, such as sleep apnea, secondary to oral or oropharyngeal obstruction
- Drooling

Cephalometric radiographic features commonly seen with macroglossia (Figure 55-13) include the following:

- Tongue filling the oral cavity and extruding through an anterior open bite
- Mandibular dentoalveolar protrusion or bimaxillary dentoalveolar protrusion

- Overangulation of the maxillary and mandibular anterior teeth
- Disproportionately excessive mandibular growth
- Decreased oropharyngeal airway
- Increased gonial angle
- Increased mandibular plane angle
- Increased mandibular occlusal plane angle

Most open bite cases are not related to macroglossia. In fact it has been established that closing open bites with orthognathic surgery will allow a normal tongue (which is a very adaptable organ) to readjust to the altered volume of the oral cavity, with little tendency toward relapse.^{13,14} However, if true macroglossia is present with the open bite, then instability of the orthodontics and orthognathic surgery will likely occur, with a tendency for the open bite to return. Pseudomacroglossia is a condition where the tongue may be normal in size, but it appears large relative to its anatomic interrelationships. This can be created by (1) habitual posturing of the tongue; (2) hypertrophied tonsils and adenoid tissue displacing the tongue forward; (3) low palatal vault, decreasing the oral cavity volume; (4) transverse, vertical, or antero-posterior deficiency of the maxillary and/or mandibular arches decreasing oral cavity volume; and (5) tumors that displace the tongue. Pseudomacroglossia must be distinguished from true macroglossia because the methods of management are different.

Diagnostic List

Before a treatment plan can be properly developed, a diagnostic list of the existing problems is established based on patient concerns, and clinical, radiographic, dental model, and other indicated evaluations. This will include all findings relative to musculoskeletal and dental imbalances, occlusal problems, esthetic concerns, TMJ and/or myofascial pain problems, missing

teeth, crowns, bridges, endodontically treated teeth (these teeth are sometimes ankylosed), periodontal problems, other functional disorders, as well as any other medical factors that may affect treatment outcomes. The treatment plan is formulated from the diagnostic problem list.

Presurgical Orthodontic Goals

The basic presurgical orthodontic goals are as follows:

- Align and position teeth over basal bone
- Avoid excessive intrusion or extrusion of teeth
- Decompensate teeth
- Avoid unstable expansion of the dental arches
- Avoid class II and class III mechanics (unless required for dental decompensation correction in the arches)
- Perform stable and predictable orthodontics

Relative to the position of the maxillary and mandibular incisors, the ideal presurgical orthodontic goals are as follows:

1. Position the long axis of the maxillary central incisors approximately 22° to the nasion point A (NA) line, with the labial surface of the incisors 4 mm anterior to the NA line relative to a normally positioned maxilla and normal occlusal plane angle (see Figure 55-4)
2. Position the long axis of the mandibular central incisors 20° to the nasion point B (NB) line with the labial surface of the incisors 4 mm anterior to that line relative to a normally positioned mandible and normal occlusal plane angle (see Figure 55-4)
3. Satisfy arch length requirements (crowding or spacing)

We have found that using the ideal position of the maxillary and mandibular incisors to the NA and NB lines, respectively (see Figure 55-4), is the most convenient and practical method to establish the presurgical orthodontic goals for the

incisors. However, these presurgical orthodontic goals may be different if the occlusal plane angle is to be altered surgically. Removal of dental compensations is helpful before surgery so that maximum skeletal correction can be achieved. An exact orthodontic treatment plan, including the specific mechanics and anchorage requirements necessary to position the teeth to satisfy the presurgical orthodontic goals, must be developed and executed.

Initial Surgical Treatment Objective

The surgical treatment objective (STO), also known as a prediction tracing, is a two-dimensional visual projection of the changes in osseous, dental, and soft tissues as a result of orthodontics and orthognathic surgical correction of the dentofacial and occlusal deformity. The purpose of the STO is threefold: (1) establish presurgical orthodontic goals, (2) develop an accurate surgical objective that will achieve the best functional and esthetic result, and (3) create a facial profile objective which can be used as a visual aid in consultation with the patient and family members. A prediction tracing of the anticipated presurgical orthodontic dental movements is created by placing an acetate sheet on the original cephalometric tracing and retracing the teeth into the position they will be placed with the presurgical orthodontics, based on the goals and available mechanics (Figure 55-14A). The initial STO is then constructed with the teeth in their presurgical orthodontic final position.

The STO has significant importance in two phases of treatment planning: (1) the initial STO is prepared before treatment to determine the orthodontic and surgical goals; and (2) the final STO is prepared after the presurgical orthodontics are completed but prior to surgery to determine the exact vertical and antero-posterior skeletal and soft tissue movements to be achieved (Figure 55-14B). The

FIGURE 55-14 A, Presurgical orthodontics. The orthodontic movements are traced on the acetate paper overlying the original lateral cephalometric tracing with the teeth in their predetermined, simulated positions. The solid lines, are the original position of the teeth. The dashed lines are the new position of the teeth following simulated extraction of four first bicuspids and orthodontic closure of the spaces. B, Surgical treatment objective (STO). This is an example of a completed final STO which shows the predicted outcome of the presurgical orthodontics and the anticipated surgical treatment. The arrows and numbers indicate the direction and millimeters of movement.

STO is invaluable to the orthodontist and surgeon in establishing treatment objectives and projected results, acting as the *treatment plan blueprint*.

Definitive Interdisciplinary Treatment Plan

The definitive treatment plan is formulated based on the patient's concerns, clinical evaluation, radiographic analysis, dental model evaluation, initial STO, and other relevant evaluations. The general sequencing of the treatment that may be involved is described below.

Dental and Periodontal Treatment

Any indicated periodontal or general dental care related to maintaining teeth or improving dental health should be performed prior to orthodontics and surgical intervention. The objective is to

maintain as many teeth as possible and stabilize the periodontium. Temporary crowns and bridges should be placed where necessary for the orthodontic and surgical phases of the treatment. Permanent crowns, inlays, and bridges should be constructed and inserted after the surgery and orthodontics have been completed. This gives the restorative dentist the opportunity to provide escapement grooves, cuspid protection, and incisal guidance for optimum function and esthetics. Initial periodontal management may include scaling and curettage, eliminating pockets, as well as gingival grafting to provide adequate attached gingiva. Occasionally, in patients with several missing teeth, osseointegrated implant placement prior to orthodontics and orthognathic surgery may provide anchorage for orthodontics and additional dental units

to help in repositioning the jaw structures at surgery.

Presurgical Orthodontics

The orthodontist is responsible for positioning the teeth to the most desirable position over basal bone in preparation for surgery. The development of prescription brackets and straight wire orthodontic techniques has helped simplify orthodontics. Most prescription bracket systems are designed to tip the cuspid roots distally, creating some space between the roots of the lateral incisors and cuspids. In cases requiring segmentalization of the maxilla, this interdental space may be adequate through which to perform interdental osteotomies, but if inadequate, additional room can be created by tipping the lateral incisor roots mesially and the cuspids more distally. Bonded brackets are clean and eliminate interdental spacing problems

created by circumferential bands. Bonded brackets with the currently available resins are quite adequate for orthognathic surgery procedures. However, inaccurate placement of the brackets on the teeth can result in undesired rotations, vertical discrepancies between teeth, malalignment of marginal ridges and labial surfaces of adjacent teeth, and unfavorable root positions. Careful placement of brackets is paramount in helping to achieve high-quality results.

Nickel-titanium or similarly shaped memory arch wires can be advantageous for many orthognathic cases to aid in presurgical orthodontic dental alignment goals. However, there are cases where shape memory wires could be detrimental, such as in an anterior open bite with an accentuated maxillary curve of Spee. The use of nickel-titanium wires or any type of straight wire in these cases can create unstable results such as extrusion of teeth and buccal tipping of the molars as a result of reciprocal forces. Stainless steel wires with compensating bends (Figure 55-15A) or sectional wires (Figure 55-15B) may be a better-controlled mechanical force in these types of cases. The type of arch wire and how long each is left in place is critical and must be carefully monitored by the orthodontist.

FIGURE 55-15 A, Compensating steps (arrow) have been placed in the orthodontic arch wire so that the anterior teeth are aligned at an elevated level compared with the posterior teeth to eliminate extrusion or intrusion of teeth that may otherwise result in unstable orthodontic movements. B, Sectioning the arch wire (arrow) is another approach to aligning teeth at separate independent levels to avoid extrusion or intrusion of teeth as seen in this maxilla. However, the use of sectional wires may decrease positional control of the teeth adjacent to the ends of the cut wire.

To follow are basic presurgical orthodontic factors that commonly must be addressed in preparing patients for orthognathic surgery.

It is important to avoid interarch class II mechanics (ie, class II elastics, growth appliances, TMJ “disk recapturing” splints, Herbst’s appliances) unless they are specifically required during the presurgical orthodontics (ie, to correct arch asymmetry, decompensate mandibular arch with lingually inclined mandibular incisors). Long-term class II mechanics positions the mandibular condyle downward and forward in the fossa and may allow hypertrophy (thickening) of the TMJ bilaminar tissues (Figure 55-16). This same situation can occur in patients with a “Sunday” bite. In these situations, following surgical mandibular advancement, the bilaminar tissue will slowly thin out over time causing a slow relapse of the mandible toward a Class II relationship. In addition posturing the mandible forward for an extended time could result in foreshortening of the anterior articular disk attachments, increasing the risk of TMJ articular disk displacement postsurgery.

If a patient has been treated with long-term class II mechanics or has a “Sunday” bite, it may be an advantage to use light class III mechanics for a few months presurgery

FIGURE 55-16 Use of long-term class II mechanics, anterior repositioning splints, growth devices, or “Sunday” bite relationships can cause hypertrophy of the bilaminar tissue, positioning the condyle downward and forward in the fossa. Postsurgery, particularly with mandibular advancements, this tissue will slowly thin out, and the condyles will move posteriorly in the fossa causing a shift of the mandible and occlusion toward a Class II position.

to eliminate the hypertrophied bilaminar tissue and to decompensate for any unstable orthodontics that may have been created. If the TMJ articular disk does become displaced, it would be better to have that occur before surgery because the articular disk can be surgically repositioned and stabilized with high predictability at the same time as the orthognathic surgery.^{15–18} Attempts to recapture a TMJ displaced disk with splint therapy prior to surgery could be detrimental to the patient relative to outcome stability and pain. In most cases nonsurgical “recapturing” the disk procedures have proved clinically unsuccessful.

Treatment Options for Specific Orthodontic Problems

This section presents specific dental malrelationships and the orthodontic and surgical treatment options for consideration. Comprehensive assessment of the patient and developing treatment objectives will aid in selecting the appropriate treatment.

Adjustment for Tooth-Size Discrepancy

Usually TSDs occur because of small maxillary lateral incisors, making the combined

mesiodistal width of the maxillary anterior six teeth too small to fit properly around the mandibular anterior six teeth, so that when the teeth are properly aligned, an end-on Class II cuspid relationship will result (Figure 55-17). If the Bolton's analysis indicates a significant TSD, presurgical orthodontic adjustments can usually correct the discrepancy and aid in providing a solid Class I cuspid relationship at surgery and in the final outcome. TSDs can also occur in the bicuspid and molars, with the maxillary teeth usually being too small compared with the mandibular teeth. The following are treatment options that can be used to correct TSDs.

Slenderizing Teeth (Interproximal Tooth Size Reduction) This technique reduces the mesiodistal dimension of the involved teeth. Since most TSDs involve larger mandibular anterior teeth compared to the maxillary anterior teeth, slenderizing the mandibular anterior teeth can address the issue (Figure 55-18). Approximately 10 to 12% of the mesiodistal width can be safely removed from each tooth with 50% of the interproximal enamel remaining. Up to 3 mm of reduction can usually be safely achieved in the mandibular anterior

FIGURE 55-17 This patient has well-aligned and leveled teeth in each arch. Maxillary lateral incisors are small creating a tooth-size discrepancy (TSD). Note that with the best possible fit, the patient has an end-on Class II occlusal relationship secondary to the TSD.

FIGURE 55-18 Mandibular anterior teeth can be slenderized using (A) diamond strip or (B) thin cylindrical diamond bur to reduce the width of the teeth at the contact level. Spacing generated can then be closed with orthodontics.

six teeth. Slenderizing the mandibular anterior teeth is an advantageous procedure, where the maximum width of the incisors is toward the incisor edge, particularly in the presence of crowding and/or overangulation of the mandibular incisors. It is not advantageous if the mandibular anterior teeth are decreased in angulation (lingual inclination), since closing the resultant spaces will further decrease the incisor angulation and may adversely affect esthetics and stability. This technique is not indicated when the contact points are positioned toward the gingiva, as this could result in tissue strangulation with loss of papilla and interdental bone, creating significant periodontal issues. In the rare case where the maxillary teeth are too large for the mandibular teeth, the maxillary teeth can be slenderized, but this is best used when the maxillary teeth are crowded and/or overangulated, and the individual crowns are wider than normal (see Table 55-1).

When TSDs occurs in the bicuspid and/or molar area, slenderizing the mandibular teeth will usually correct the problem, unless the slenderizing will cause excessive retraction of the mandibular anterior teeth. If this appears to be a potential outcome, then careful closure of the spacing by loosening (slipping) posterior anchorage (using mechanics that will

move the posterior teeth forward instead of the anterior teeth backward) may solve the problem. This approach may include class II mechanics to provide forward forces on the posterior teeth or moving one tooth at a time on each side. Dental implants placed adjacent to or posterior to the molars could provide stable anchorage to aid in applying the mechanics necessary to push the posterior teeth forward.

Creating Space In the Arch This can enlarge the circumference of the involved arch. Since TSDs are often related to small maxillary lateral incisors, opening space around the maxillary lateral incisors may be a logical approach. A simple technique involves placement of coil springs between the cuspids and lateral incisors and if needed between the lateral incisors and central incisors to open spaces (Figure 55-19). At the end of treatment the lateral incisors can be built up by bonding, veneers, or crowns. This technique can also be used in the mandibular arch when the mandibular anterior teeth are too small compared to the maxillary anterior teeth. In either arch this technique is most applicable when the teeth are decreased in angulation, since opening space will increase the axial inclination of the incisors. It may not be indicated when the maxillary or mandibular incisors are overangulated or crowded, as

FIGURE 55-19 *Placing coil springs between the maxillary cuspids and lateral incisors as well as the lateral incisors and central incisors can open up spacing around the lateral incisors to correct a tooth-size discrepancy. Post-treatment, the lateral incisors can be built up by bonding, veneers, or crowns.*

the resultant increased angulation may be unstable and cause untoward periodontal changes. However, if there is significant crowding or overangulation of the incisors requiring extraction of bicuspids, during closure of the bicuspid spacing by retraction of the anterior teeth, space could be created around the lateral incisors.

When maxillary incisors are already overangulated, it is not feasible to open spaces during the presurgical orthodontics. In this situation performing interdental osteotomies between the maxillary cuspids and lateral incisors will permit opening space at surgery and the incisors can also be uprighted to decrease their axial angulation. A maximum 3 mm of spacing (1.5 mm on each side) can usually be acquired with this approach.

When the TSD occurs in the bicuspid or molar area, space can be opened around the maxillary bicuspids and/or molars to compensate for the tooth mass deficiency. Bonding, veneers, or crowns can then be placed to eliminate the created space.

Altering Axial Inclination of Incisors This technique can affect the labial circumference of the anterior teeth. Increased axial inclination slightly increases the arch length, and decreased axial inclination slightly decreases it. Application of this technique would result in

increasing the maxillary incisors' angulation above normal and decreasing the mandibular incisors' angulation below normal. This technique can accommodate small TSD differences, but may place the teeth in a compromised position relative to stability and esthetics.

Surgery can alter the axial inclination of the anterior teeth. In the maxillary arch, interdental osteotomies between the lateral incisors and cuspids, and in the mandibular arch anterior subapical osteotomies, will provide a means to alter axial inclination of the incisors.

Altering Mesiodistal Angulation of Maxillary Incisors Tipping the roots of the maxillary central incisors distally away from each other alters the position of the contact points, making the intercontact distance on each tooth slightly wider. This can only be used for small differences. However, it then usually requires recontouring of the distal aspect of the incisor edges and could cause a soft tissue void between the mesial contact points and gingival tissues ("the black triangle"), creating much concern for the patient. This technique is rarely recommended.

Extraction of Mandibular Incisor This technique should only be used for large TSDs (5 mm or more) and only if there is significant crowding and/or significant overangulation of the mandibular incisors. Removing a mandibular incisor usually creates a significant space (the width of the tooth), and closure of that space may significantly decrease the axial inclination of the mandibular incisors. In addition it may cause a decreased transverse width between the cuspids resulting in relative narrowing of both maxillary and mandibular arches. Extraction of a mandibular incisor may produce an increased overjet. If the patient has a good maxillary arch but mandibular crowding and overangulation, large TSD, and an end-on or slight Class III anterior

occlusion, the single mandibular incisor extraction may be the treatment of choice. An alternative in cases with large tooth-size discrepancies would be to slenderize the mandibular anterior teeth and create spacing around the maxillary lateral incisors.

A surgical alternative for a large TSD, when the teeth are not crowded and have good axial angulation, would be to extract the mandibular incisor and perform a vertical osteotomy through the mandible at the extraction site and rotate the segments together to eliminate the extraction space (Figure 55-20). This would prevent further decreased angulation of the incisors with subsequent orthodontics but may narrow the anterior aspect of the mandible.

Correct Overangulated (Proclined) and/or Crowded Maxillary Anterior Teeth

Overangulated and/or crowded maxillary anterior teeth are most commonly seen in patients with maxillary deficiency (hypoplasia). The following treatment methods can be used to correct this type of situation.

Slenderizing and Retraction This technique involves removal of tooth structure at the contact points and is applicable when there is a rare reverse TSD with the maxillary anterior teeth too large for the mandibular anterior teeth. Usually up to 3 mm of tooth structure can be safely removed from the contact area of the maxillary anterior six teeth with a margin of 50% of enamel remaining at the contact areas. However, this could make the maxillary incisors slightly smaller in size unless they are significantly oversized to begin with.

Extraction and Retraction First or second bicuspids can be extracted depending on the amount of crowding, the anchorage requirements, and the amount of retraction of the incisors necessary.

FIGURE 55-20 In the case of a tooth-size discrepancy (TSD) ≥ 5 mm, in the presence of well-aligned teeth in proper angulation, the TSD can be managed by removing a mandibular central incisor and performing a vertical midline osteotomy (A) with closure of that space (B) and stabilization with a bone plate.

Every 1 mm of incisor retraction will require 1 mm of space on each side of the arch. Therefore, if the orthodontic goal is to retract the maxillary incisors by 3 mm, then 6 mm of maxillary arch space will be required to accomplish this. Extracting first bicusps will result in greater incisor retraction, whereas six multirooted posterior dental units (compared to six single-rooted anterior dental units) provide greater posterior anchorage. Extracting second bicusps will result in less incisor retraction, whereas four posterior dental units (compared to eight anterior units) provide less posterior anchorage so that the posterior teeth will move forward a greater amount compared with first bicuspid extractions. The occlusal plane angle will also affect the posterior anchorage. Low occlusal plane angle cases will have greater posterior anchorage stability, even with second bicuspid extraction, than will high occlusal plane angle cases. High occlusal plane angle cases will have less posterior anchorage stability, even with first bicuspid extraction, than low occlusal plane angle cases. These factors are probably

related to bite force influences. The amount of crowding may also influence which teeth to extract.

Distalizing Posterior Teeth This objective can be accomplished using pendulum-type appliances, headgear, class II mechanics, or osseointegrated implants (ie, implants posterior to molars, zygomatic implants, palatal implants, or buccal cortex implants). Distalizing maxillary posterior teeth can be augmented with class II mechanics but should only be used short-term and discontinued several months prior to surgery to minimize postsurgical skeletal relapse potential that can occur with the use of long-term class II mechanics and the subsequent adverse effects on the TMJs. Another option is to distalize one tooth at a time on each side of the arch, beginning with the second molars (2 teeth moved against 12 anchor teeth). Another feasible approach is to use osseointegrated anchors to distalize the maxillary arch, with implants placed in either the zygoma buttress, posterior to second molars, or attached to the buccal cortex. The implants can be left submerged after orthodontic treatment is completed, or could require additional surgery for removal if not removed during the orthognathic surgery.

Anterior Maxillary Segmental Osteotomies This technique permits uprighting of the anterior teeth but will cause the apical base of the segment to shift forward relative to the incisor edges unless teeth are extracted to reposition the incisal edges of the anterior teeth posteriorly. Careful assessment of the profile esthetics is necessary to determine if the patient can esthetically benefit from this change. The interdental osteotomies should be done between the lateral incisors and cuspids as this offers the best control in uprighting the segments (Figure 55-21) and also allows opening of space between the lateral incisors (up to 3 mm with 1.5 mm per side) that can be used for correction of crowding or TSD.

Maxillary Expansion by Orthodontics, Orthopedics (Rapid Palatal Expansion), and Surgically Assisted Rapid Palatal Expansion These techniques will increase arch length and may allow retraction of the anterior teeth. However, they will also increase the curve of Wilson as the transverse width of the maxillary arch increases because the teeth will expand three times as much as the palate expands (Figure 55-22). In addition, with SARPE, the palate moves inferiorly. The expanded arches may not be as orthodontically stable, requiring long-term or permanent retention.

Correct Overangulated (Proclined) and/or Crowded Mandibular Anterior Teeth

Overangulated and/or crowded mandibular teeth occur most often with mandibular deficiency (hypoplasia). The following

FIGURE 55-21 An anterior maxillary segmental osteotomy can be used to upright the maxillary incisors. However, the dentoalveolus at the apical base will rotate anteriorly if no teeth are extracted. Since this may affect the position of the nose and upper lip, careful evaluation of facial esthetics is necessary to determine if this approach is appropriate. Dashed line represents the original position of the anterior maxilla, and the solid line represents the uprighted segment.

treatment options can be used to correct these types of conditions.

Slenderizing and Retraction This technique involves removal of tooth structure at the contact points and is most applicable when there is a TSD with the mandibular anterior teeth being too large for the maxillary anterior teeth. Up to 3 mm of tooth structure can be safely removed from the contact areas of the mandibular anterior six teeth with a margin of 50% of enamel remaining at the contact areas. Subsequent retraction will decrease the axial inclination of the incisors providing that no major crowding is present.

Extraction and Retraction First or second bicuspid can be extracted depending on the degree of angulation, amount of crowding, the anchorage requirements, and the amount of retraction of the incisors necessary. Every 1 mm of incisor

retraction will require 1 mm of space on each side of the arch. Therefore, if the orthodontic goal is to retract the mandibular incisors by 3 mm, then 6 mm of mandibular arch space will be required to accomplish this. Extracting first bicuspid will result in greater incisor retraction, whereas six multirooted posterior dental units (compared with six single-rooted anterior dental units) provide greater posterior anchorage. Extracting the second bicuspid will result in less incisor retraction, whereas four posterior dental units (compared with eight anterior units) provide less posterior anchorage, so that the posterior teeth will move forward a greater amount compared with first bicuspid extractions. The occlusal plane angle will also affect the posterior anchorage. Low occlusal plane angle cases will have greater posterior anchorage stability, even with second bicuspid extraction, than will high occlusal plane angle cases. High occlusal

plane angle cases will have less posterior anchorage stability even with first bicuspid extraction than low angle cases. These factors are probably related to bite force influences. The amount of crowding may also influence which teeth to extract. If there is a large TSD (≥ 5 mm), then extraction of a mandibular incisor could be considered.

Distalize Posterior Teeth The mechanics to accomplish this include intra-arch, inter-arch, extraoral, or implant mechanics. Class III mechanics (ie, elastics, headgear) can be used to distalize the mandibular teeth, but may increase loading on the TMJs and could initiate TMJ problems. Another option is to distalize one tooth at a time on each side of the arch, beginning with the second molars (2 teeth moved against 12 anchor teeth). However, this technique takes a lot of time. The placement of dental implants posterior to the molar teeth or in the posterior buccal cortex could facilitate retraction without appreciably increasing the load to the TMJs.

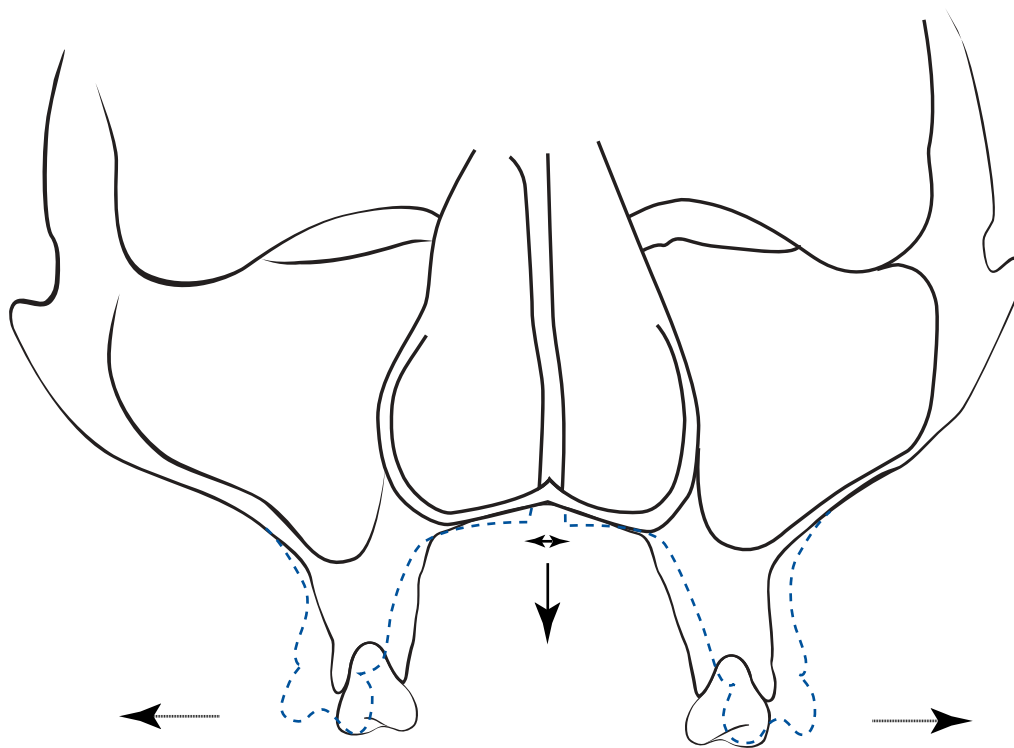

FIGURE 55-22 Maxillary expansion by orthodontics, orthopedics, or surgically assisted rapid palatal expansion (SARPE) will cause an increase of the curve of Wilson. Even with SARPE, the occlusal surface will expand three times as much as the palate will expand, thus increasing the curve of Wilson. The palate will also move inferiorly.

Anterior Mandibular Subapical Osteotomies This technique permits uprighting of the anterior teeth, but will cause the apical base of the segment to shift forward relative to the chin (Figure 55-23), unless teeth are extracted at the time of surgery to reposition the incisal edges of the anterior teeth posteriorly.

Bilateral Mandibular Body Osteotomies This technique will permit uprighting of the anterior teeth and forward rotation of the chin (Figure 55-24), unless teeth are extracted. Without extraction, bilateral body bone grafting will be required to provide bony continuity between the segments and facilitate healing. This technique would only be indicated if the chin is anteroposteriorly deficient before surgery.

Mandibular Symphysis Distraction Osteogenesis This technique, usually performed with a midline vertical osteotomy, will allow expansion of the dentoalveolus and widening of the mandibular arch,

providing room to retract and/or align the teeth. This is an excellent treatment method to gain space for major arch length discrepancies. However, it is done as a prerequisite surgery to achieve the orthodontic goals prior to the major orthognathic surgery. Orthodontic preparation may be necessary prior to performing the midline vertical osteotomy. The roots of the central incisors (or the adjacent teeth, wherever the osteotomy is to be performed) must be tipped away from each other to make room for the interdental osteotomy. This can be accomplished by placing the mesial aspect of the bracket higher than the distal aspect on each of the central incisors. Placing a short segment straight arch wire will then tip the roots distally, creating space to safely perform the vertical interdental osteotomy (Figure 55-25). If a tooth-borne distraction device is used, orthodontic treatment on any other teeth should *not* be initiated until adequate healing of the distraction area has occurred (approximately 4 months from initiation of the distraction). Otherwise it may result in developing dental mobility and orthodontic instability, with the teeth expanding more than the basal bone. This can result in transverse dental

FIGURE 55-23 The anterior mandibular sub-apical osteotomy can be used to upright the mandibular anterior teeth, causing the apical base of the segment to shift forward relative to the chin, if teeth (bicuspid) are not extracted at the time of surgery. This may or may not be a desired outcome. A chin augmentation may be required to achieve optimal esthetics.

FIGURE 55-24 Bilateral body osteotomies can be used to upright the mandibular anterior teeth, but the chin will rotate forward unless teeth are extracted. A gap created in the mandibular body area will require grafting unless teeth are extracted (first bicuspid) to allow the mandibular anterior teeth to move posteriorly, thus decreasing the forward movement of the chin.

relapse postdistraction with less expansion of the dental arch than desired. Bone-borne devices are not affected by predistraction orthodontics.

Correct Underangulated (Retroclined) Maxillary Incisors

Underangulated maxillary incisors are most commonly seen in Class II Division 2 malocclusions or with missing teeth in the arch. The following approaches can be used to correct this type of condition.

Correct Crowding Crowding of the maxillary anterior teeth can accompany vertically inclined teeth. Therefore, correcting the crowding will increase the incisor angulation.

Open Space In Class I and Class II patients underangulated incisors may be present because of previous extractions (ie, bicuspid), congenitally missing teeth, previous trauma resulting in loss of teeth, or small maxillary anterior teeth (ie, small maxillary lateral incisors). Opening space in the bicuspid areas, if the problem exists there, can correct this problem and provide additional dental units for a more complete occlusal

result. The use of coil springs usually works well for this situation. If the problem is in the lateral incisor area, opening space can help correct the TSD as well as increase the incisor angulation (Figure 55-26).

Interarch Mechanics The use of class III mechanics (ie, elastics) can increase maxillary incisor angulation. However, the class III mechanics can be detrimental by overloading the TMJs.

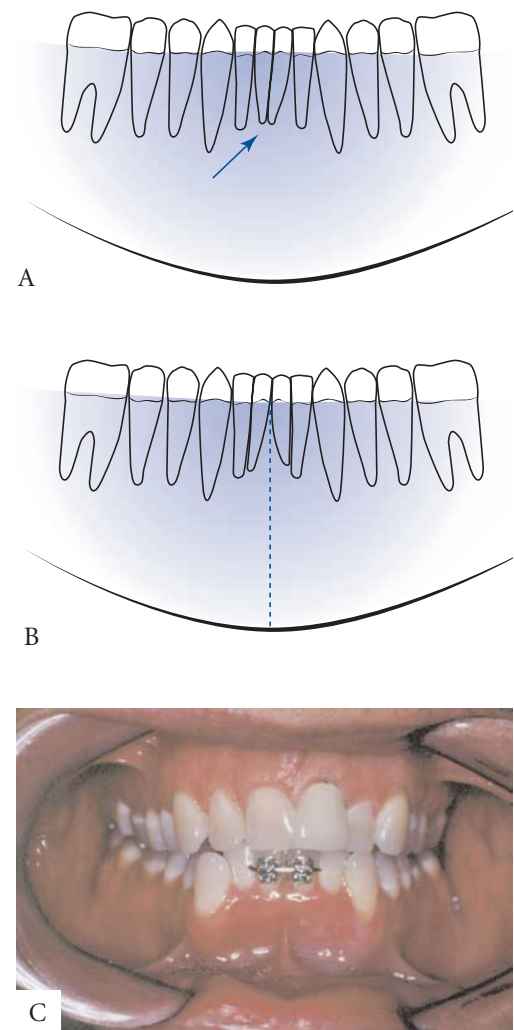

FIGURE 55-25 Mandibular symphysis distraction osteogenesis. A, Often the incisor roots are very close together. B, Space must be created between the roots of teeth adjacent to the intended vertical osteotomy. C, Placing brackets on only the central incisors with the mesial aspect of the brackets higher than the distal aspect on each tooth and placing a short straight wire segment, will tip the roots distally away from each other, creating space to perform the vertical interdental osteotomy.

Interdental Osteotomies An anterior maxillary subapical osteotomy or segmentalized Le Fort I osteotomy will permit rotation of the anterior teeth to increase their angulation. However, significant room must be created between the roots of the adjacent teeth (lateral incisors and cuspids) at the osteotomy areas. Since bone removal between the teeth may be required, there is an increased risk of damage to the adjacent teeth. If the maxilla requires surgical expansion, then segmentalization between the lateral incisors and cuspids will allow the anterior segment to rotate posteriorly between the expanded posterior segments with fewer requirements for bone removal, if required at all.

Correct Underangulated (Retroclined) Mandibular Incisors

Underangulated mandibular incisors are more commonly seen in patients with prognathic mandibles or with missing teeth. The following treatment methods can be used to correct this condition.

Correct Crowding Crowding of the mandibular anterior teeth often accompa-

nies vertically inclined teeth. Therefore, correcting the crowding will increase the incisor angulation.

Open Space In Class I and Class II patients underangulated incisors may be present because of previous extractions, congenitally missing teeth, previous trauma resulting in loss of teeth, or small mandibular teeth. In Class III patients underangulated incisors may be present due to an excessive amount of alveolar bone compared with the size of the teeth. If bicuspid are missing, opening space in the bicuspid areas can correct this problem and provide additional dental units for a more complete occlusal result. The use of coil springs usually works well for this situation (see Figure 55-26).

Occasionally a mandibular incisor may be missing for various reasons. Viable options include opening appropriate space around the remaining three incisors and building up the crowns by bonding, veneers, or crowns. This technique works best if there is a TSD that is less than the width of the missing tooth. However, the maxillary dental midline will be in the center of a mandibular incisor. Another option would be to open space in the area

of the missing tooth and then replace it with a dental implant or bridge. This technique may work best when there is no TSD with a full-size dental replacement.

Interarch Mechanics The use of class II mechanics (ie, elastics, Herbst's appliance) can increase mandibular incisor angulation. However, long-term class II mechanics can be detrimental to outcome stability and results, because of the potential unto-ward effects on the TMJs.

Interdental Osteotomies An anterior subapical osteotomy or bilateral anterior body osteotomies will permit rotation of the anterior teeth to increase their angulation. However, significant room must be created between the roots of the teeth adjacent to the osteotomy areas. Since bone removal between the teeth may be required, there is an increased risk of damage to the adjacent teeth.

Correct Excess Curve of Spee: Maxillary Arch

This condition is most often seen with anterior open-bite situations and high occlusal plane facial types. Careful assessment of the curve of Spee is important because using only orthodontic mechanics to correct this condition may not be very stable. An increased curve of Spee usually makes it difficult to get the occlusion to fit together. The condition can be addressed by the following treatment options.

Extruding Anterior Teeth Conventional orthodontics with straight wire techniques will tend to extrude the anterior teeth, and as a byproduct will tip the molars buccally, increasing the curve of Wilson. These dental changes may be unstable and fraught with relapse potential.

Intruding Midbuccal Teeth This is a very difficult technique, unless high-pull head-gear or osseointegrated implants are used to provide intrusive forces. This would

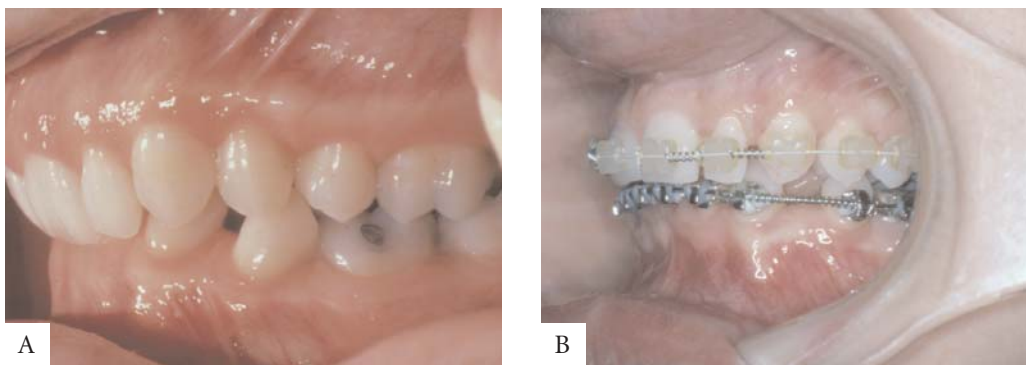

FIGURE 55-26 Coil springs to open space. In some cases, “retroclined” incisors are a result of Division 2 malocclusion, crowding, missing dental units, or small teeth. If there is no significant crowding, spacing can be created by the use of coil springs that will tip the incisors forward. A, Small maxillary lateral incisors and missing mandibular bicuspid. B, The use of coiled springs is demonstrated to open up interdental spaces around the maxillary lateral incisor (to correct for an anterior tooth-size discrepancy) and in the mandibular first bicuspid area (to replace a missing dental unit and increase the angulation of the anterior teeth). The spaces around the maxillary lateral incisor can be eliminated by bonding, veneer, or crown. In the mandibular arch, the space can be eliminated by surgical osteotomy versus replacement of the missing dental unit by crown-and-bridge or osseointegrated implant and crown.

require significant patient compliance and is not a commonly applied procedure.

Extraction and Retraction Extraction of maxillary first or second bicuspid with retraction will usually decrease the curve of Spee, providing the incisors are overangulated to begin with.

Orthodontic, Orthopedic, or Surgically Assisted Rapid Palatal Expansion with Retraction Expansion of the maxillary arch by any of these techniques will increase the arch length and allow some retraction of the anterior teeth. In late adolescence or adulthood, SARPE may provide better stability than the other two techniques. However, note that the curve of Wilson will increase because the expansion at the occlusal level compared with the palate will be a 3:1 ratio.¹⁹

Surgical Correction The maxilla can be orthodontically aligned in segments by aligning the four incisors at a different level, compared with the posterior teeth, to avoid extrusion, intrusion, and buccal tipping of teeth. Placing compensating vertical steps between the lateral incisors and cuspids (see Figure 55-15A) will accomplish alignment at different levels. For some cases the vertical positional difference may occur between the cuspids and bicuspid, or could occur asymmetrically on one side of the arch compared with the other side. The step in the arch would then be made between the appropriate teeth. Another technique to use involves cutting the arch wire into two or more segments and aligning groups of teeth in individual units (see Figure 55-15B). However, it may be more difficult to control rotations and root position, particularly of the teeth adjacent to the ends of the segmented wires, compared with using a continuous wire with compensating vertical steps. The arch can then be leveled surgically with a three-piece maxilla performing osteotomies between the lateral

incisors and cuspids. The three-piece Le Fort I osteotomy, with interdental osteotomies performed between the lateral incisors and cuspids, will permit repositioning of the anterior segment independent of the posterior segments (Figure 55-27). The anterior segment can be reoriented vertically and anteroposteriorly, and the axial inclination of the incisors can be changed to correct the curve of Spee and achieve the best interdigitation of the segments.

Correct Accentuated Curve of Spee: Mandibular Arch

An accentuated curve of Spee in the mandibular arch most often occurs in anterior deep-bite relationships.

Intruding Mandibular Anterior Teeth Intrusion mechanics can predictably inferiorly position mandibular anterior teeth approximately 2 mm. Beyond 2 mm the vertical relapse approaches 60%. With accentuated curves of Spee the contact area of the teeth will be at a different level

where the teeth are more narrow, below the normal contact level. Therefore, for every 1 mm of leveling of the mandibular arch, the mandibular incisor edges will move forward 0.6 mm to 1 mm as the contact points align. Any crowding of the arch will further contribute to flaring of the incisors. Intruding teeth will decrease the anterior mandibular vertical height and must also be taken into consideration so that the anterior mandibular height is not excessively shortened.

Extruding Midbuccal Teeth Extrusion of midbuccal teeth may be more stable than intrusion of anterior teeth. However, this technique is difficult to perform without special considerations. If the patient's malocclusion has the bicuspid and first molars in occlusion, extrusion will be virtually impossible. However, constructing a splint that will open the bite and engage only the mandibular anterior teeth and second molars, with the bicuspid and first molars out of contact with the splint, will permit extrusion

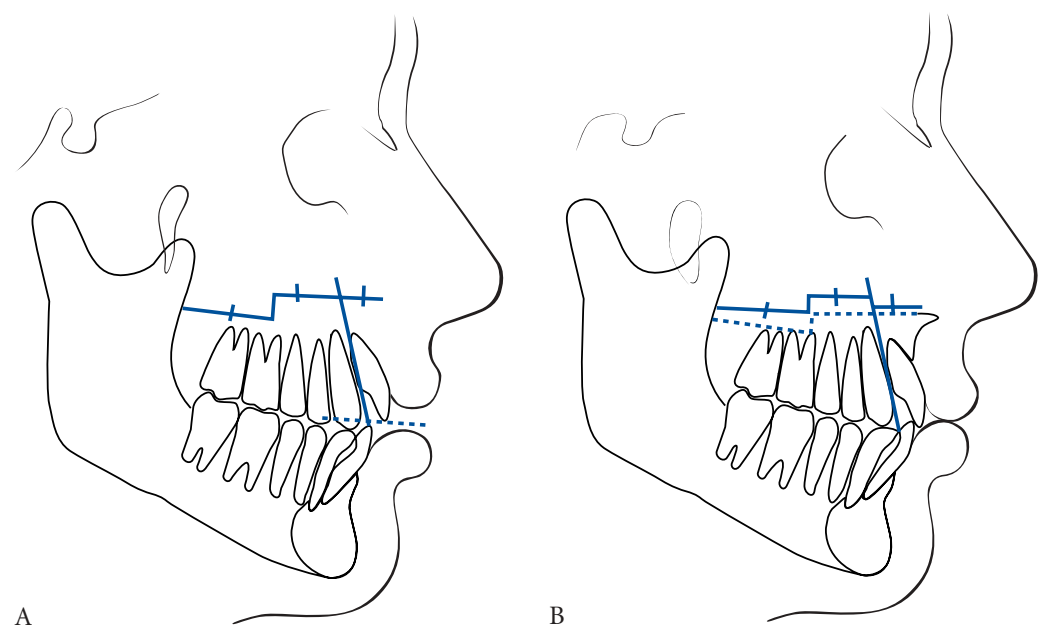

FIGURE 55-27 Surgery for correcting an excessive curve of Spee. A, Aligning the maxilla in segments with the incisors at an elevated level compared with the posterior teeth will permit interdental osteotomies to be performed. B, Surgical leveling of the occlusal plane from a predictability and stability standpoint is superior to orthodontic means alone, particularly when no extractions are performed.

of the midbuccal teeth. Another alternative would be to correct the accentuated curve of Spee after the mandible and occlusion are surgically repositioned, placing the incisors and molars into proper contact, and then extrude the midbuccal teeth postsurgery. With this approach the molars may tip distally and the arch may widen somewhat.

Interdental Osteotomies An anterior subapical osteotomy (Figure 55-28) or bilateral anterior body osteotomies (Figure 55-29) will permit downward repositioning of the anterior teeth, with very stable results when the surgery is properly performed. If the anterior vertical height of the mandible is excessive, then the subapical osteotomy would be indicated since it will shorten the anterior mandibular height by the amount that the incisors are lowered. Bilateral anterior body osteotomies would be indicated when the vertical height of the anterior mandible is normal or less, so that the anterior height remains unaltered while the curve of Spee is corrected.

Correct Reverse Curve of Spee: Maxillary Arch

Reverse curves of Spee are more commonly seen in Division 2 malocclusions and in vertical maxillary deficiencies with an anterior deep bite. The maxillary incisors are commonly in a decreased axial inclination. Crowding may or may not be present.

Correct Crowding or Division 2 Relations Eliminating crowding and Division 2 dental positions will tip the incisors forward, increasing the incisor axial angulation and decreasing the reverse curve of Spee. These movements will usually fill out the upper lip, but may decrease the maxillary tooth-to-lip relationship. Maxillary incisors may become intruded with a straight wire technique.

Extruding Midbuccal Teeth This technique is difficult if the midbuccal teeth are

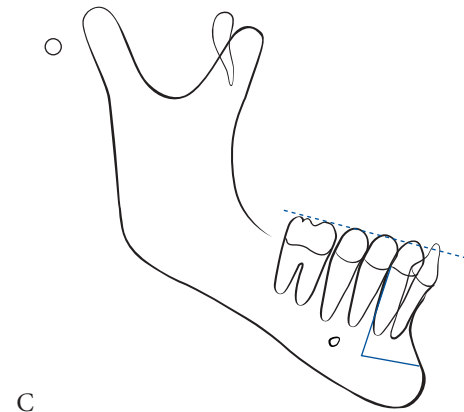

A

B

FIGURE 55-28 Subapical osteotomy correcting an accentuated curve of Spee in the mandibular arch. A, This can be accomplished with a subapical osteotomy composed of two interdental osteotomies and a subapical osteotomy to set the anterior teeth inferiorly. B, C, This is indicated when the anterior mandibular height is greater than normal, as this technique will shorten the anterior mandibular height. This same basic technique can be used to elevate the segment to correct a reverse curve of Spee.

C

in occlusion with mandibular teeth. However, the bite can be opened with a splint that affords contact on only the maxillary second molars and anterior teeth, with the maxillary midbuccal teeth out of contact with the splint. The midbuccal teeth (bicuspid and first molars) can then be extruded into position to improve the curve of Spee.

Open Spaces If the reverse curve of Spee is related to missing teeth or TSDs, then spaces can be opened to aid in increasing the axial inclination of the incisors and decreasing the reverse curve of Spee. These spaces can then be eliminated by bonding, crown and bridge, or dental implants and crowns.

Interdental Osteotomies Multiple maxillary osteotomies can be performed so that the maxilla can be repositioned in segments, enabling leveling of the arch. Presurgical orthodontics should be designed to align

the teeth at different vertical levels to facilitate the surgery and minimize orthodontic relapse potential. It is usually easiest and most applicable to make the osteotomies between the lateral incisors and cuspids. This may particularly be indicated when the maxilla must be repositioned anyway and maxillary expansion is also required. Performing a three-piece segmented maxillary osteotomy will then allow vertical alteration between the anterior and posterior segments to level the curve of Spee.

Correct Reverse Curve of Spee: Mandibular Arch

This condition is most commonly seen in patients with macroglossia, habitual tongue posturing, or tongue thrust, with an associated anterior open bite. The following techniques can be used to correct this type of condition.

Extruding Anterior Teeth Extrusion of anterior teeth may not be very stable long

FIGURE 55-29 A, B, Bilateral mandibular body osteotomies will permit leveling of the excessive curve of Spee without shortening the vertical height of the mandible and are indicated when the mandibular anterior dental height is normal or even slightly short vertically. This basic technique can also be used to correct a reverse curve of Spee by elevating the anterior segment.

term, and without permanent retention, could result in re-intrusion and redevelopment of an anterior open bite.

Intrusion of Midbuccal Teeth This is a difficult technique but may be accomplished with osseointegrated implants as anchors. However, it is not known if this would be stable long term.

Extract and Retract If the mandibular incisors are significantly overangulated, with or without crowding, bicuspid extractions can be performed and the incisors retracted, which will decrease the reverse curve of Spee.

Bonding the Mandibular Anteriors This technique can be used to level the arch by building up the incisors, increasing the crown height. However, care must be taken not to exceed a safe crown-root ratio and/or create an esthetic compromise.

Interdental Osteotomies Anterior subapical (see Figure 55-28) or anterior bilateral mandibular body osteotomies (see Figure 55-29) can be used to elevate the anterior teeth. If the anterior mandibular height is short, then the subapical osteotomy can also be used to increase the anterior height of the mandible. If the anterior

mandibular height is normal, then the bilateral anterior body osteotomies will permit elevation of the anterior teeth while maintaining the anterior height of the mandible.

Anteroposterior Arch Asymmetry (Maxilla or Mandible)

Anteroposterior arch asymmetry, when the cuspid on one side of the arch is anterior to the cuspid on the opposite side of the arch, is fairly common in patients with dentofacial deformities. Arch asymmetries can be related to developmental abnormalities, missing teeth, or ankylosed teeth. Dental midlines may not align with the facial midline.

Extract Unilaterally In some cases unilateral extraction and retraction will correct the problem. The decision must be made as to which tooth to extract. Extraction of a first bicuspid will allow greater anterior retraction compared with extracting a second bicuspid. This extraction would only be indicated if there were significant overangulation of the incisors, crowding, and/or significant midline dental shift.

Open Space Unilaterally This technique would be indicated if a tooth is missing,

there is significant decreased angulation of the incisors, and/or the midline is significantly deviated to one side.

Interarch Mechanics This technique can be effectively used by incorporating class II mechanics on one side and class III mechanics on the opposite side. Anterior cross-arch elastics can also be helpful. If only one arch is involved, then maximizing anchorage in the other arch is very important so that an asymmetry does not develop in the normal arch. Osseointegrated implants can be used as anchors to correct asymmetry in an arch without having to use interarch mechanics.

Osteotomies Osteotomies can be used in the maxillary arch by segmentalization of the maxilla and advancing one side more than the other side. Osteotomies in the mandibular arch to correct arch asymmetry can become somewhat complex. Anterior subapical osteotomies with removal of a unilateral tooth can correct some large discrepancies (6 to 9 mm). However, the subapical osteotomy may need to be combined with ramus sagittal split osteotomies and a unilateral or bilateral body osteotomy, with or without extraction, to shift the occlusion into a symmetric position. These types of movements require a high degree of surgical skill, but can provide high-quality outcomes.

Divergence of Roots Adjacent to Interdental Surgical Sites

When interdental osteotomies are planned it may be necessary for the orthodontist to tip the adjacent tooth roots away from the area of the planned osteotomy to prevent damage to the teeth (Figure 55-30). If the roots are too close together, postsurgical periodontal problems may develop with possible loss of interdental bone and teeth. Creating interdental space between the roots significantly improves the margin of safety. This can be easily achieved by selective

bracket placement. For the tooth mesial to the osteotomy, the bracket is slightly rotated so that the mesial aspect of the bracket is positioned slightly more gingivally compared with the distal aspect of the bracket (Figure 55-31). Conversely the distal tooth bracket is positioned so that the distal aspect of the bracket is placed slightly more gingivally compared with the mesial aspect of the bracket. With a straight wire technique the roots will diverge.

Postsurgically, periapical radiography may be necessary for the orthodontist to check for rebonding the adjacent teeth brackets to ensure proper root angulation at completion of treatment.

Extraction Versus Nonextraction

The decision to extract or not to extract can sometimes be difficult. There are a number of factors that may contribute to this determination.

Overangulated Anterior Teeth Excessive over-angulated anterior teeth may require extraction to set the teeth over basal bone. However, if the arch is to be expanded or teeth slenderized for TSD, for example, then extraction may not be necessary.

Crowding This is a common indicator, particularly with major crowding or

overangulated teeth. However, if crowding is mild to moderate, widening of the arch or teeth slenderizing for TSD may eliminate the need for extraction.

Tooth-Size Discrepancy TSDs of significant magnitude may indicate the need for extraction, particularly if the TSD of the anterior mandibular teeth is 5 mm or greater and the mandibular incisors are overangulated and/or crowded, in which case a mandibular incisor extraction could be considered.

Curve of Spee Accentuated curves of Spee in the maxillary arch usually have overangulated maxillary incisors, and reverse curves of Spee in the mandibular arch usually have overangulated mandibular incisors. Extraction of bilateral first or second bicuspid and retraction will result in leveling of the arches. However, arch expansion, when indicated, may create enough room so that extractions are not necessary.

Arch Asymmetries With significant anteroposterior arch asymmetries, unilateral or bilateral asymmetric extractions (ie, first bicuspid on one side and a second bicuspid on the opposite side) may be indicated when there is coexisting crowding overangulated incisors, or mid-line shift.

FIGURE 55-31 Selective bracket placement can create adequate interdentary space for osteotomies. On the tooth mesial to the osteotomy, slightly rotate the mesial aspect of the bracket gingivally, and on the distal tooth, slightly rotate the distal aspect of the bracket gingivally. A straight wire will then diverge the roots.

Coordination of Maxillary and Mandibular Arch Widths

In some cases transverse arch width discrepancies can be corrected with stable and predictable orthodontic movements, but in other cases orthodontic correction may be very unstable and fraught with relapse. It must be determined whether to correct width problems by orthodontics, orthopedics, SARPE, or surgical expansion. Even with SARPE using a fixed device, the palate only expands approximately one-third the amount of the expansion that occurs at the occlusal level, thus increasing the curve of Wilson.¹⁹ For example, if the maxilla is expanded with SARPE and the expansion at the occlusal level is 6 mm, then the expansion at the palatal level will only be 2 mm (see Figure 55-22). Patients with reverse curves of Wilson in the maxillary arch may benefit more from these techniques, but those with a pretreatment accentuated curve of Wilson may have unfavorable results, with subsequent difficulty getting the buccal cuspids to interdigitate. The following predictable changes will occur with maxillary arch expansion by orthodontic, orthopedic, or SARPE procedures.

FIGURE 55-30 Interdentary osteotomies. A, Pantomogram demonstrating inadequate room between the roots of the lateral incisors and cuspids. Performing osteotomies with roots in this position could result in severe periodontal compromise and possible loss of teeth. B, Adequate spaces for interdentary osteotomies can be created by selective bracket placement on the adjacent teeth.

1. The bite may open anteriorly, particularly if the maxillary incisors have significant initial vertical inclination. If the maxillary incisors are overangulated, then the bite may deepen anteriorly as the spacing is closed.
2. Buccal tipping of the maxillary posterior teeth will increase the curve of Wilson, because the lingual cusps will move downward relative to the buccal cusps. This may make it very difficult to properly interdigitate the buccal cusps orthodontically. Therefore, these techniques are not recommended, especially when there is a preexisting accentuated curve of Wilson.
3. Long-term or perhaps permanent retention may be necessary to counterbalance the orthodontic relapse potential seen in a high percentage of these patients.
4. In late adolescent and adult patients, SARPE will likely be necessary to expand the maxilla orthopedically since the midpalatal suture is usually closed.

Surgical expansion of the maxilla at the time of the Le Fort I procedure using multiple segmentation of the maxilla, stabilization with bone plates and palatal or occlusal splints, and hydroxyapatite synthetic bone grafting in the palate and lateral maxillary walls can provide a good outcome. This technique when properly performed is very stable and eliminates the orthodontic relapse potential inherent with the other techniques.

Missing Teeth

Teeth can be missing from the arches for a number of reasons such as congenital absence, uneruption, previous orthodontic extractions, extractions for periodontal or dental pathology, and trauma. In some cases (ie, congenital absence of maxillary lateral incisors, previous inappropriate bicuspid extraction) opening space to accommodate replacement teeth may be indicated. This is most applicable

when the incisors are decreased in angulation without appreciable crowding. If the incisors are already overangulated and/or crowding is present, then opening space orthodontically may be detrimental to stability and periodontal health. In this situation with missing maxillary lateral incisors, the cuspids can be used as lateral incisors, but may require considerable recontouring to esthetically and functionally conform to lateral incisor morphology. Although this cuspid substitution can work well for missing lateral incisors, it is done less frequently now that dental implants are so predictable and successful, thereby allowing the canine to be placed in its normal and more functional position.

When conditions permit, opening space for replacement teeth can be accomplished by appropriate mechanics to achieve the required space. Surgery can also be used to create spacing in some areas. In the mandibular arch, distraction osteogenesis can be used to create space. The missing teeth can then be replaced with dental implants, bridges, or partial dentures for example.

Correction of Rotated Teeth

Bracket placement and arch wire adaptation are the primary keys to correcting rotated teeth and it is usually best to achieve these corrections presurgery. However, if the malrotations do not interfere with the establishment of the desired dentoskeletal relationship, then the rotations can be corrected postsurgery. Severe rotations may require supracrestal fiberotomy to prevent relapse and improve permanent retention. This can often be done at the time of orthognathic surgery.

Management of Ankylosed Teeth

Treatment of ankylosed teeth depends on (1) whether the tooth is primary or permanent, (2) the surrounding dentition, (3) the eruption status, (4) tooth position and orientation, (5) the time of onset and

diagnosis, (6) the age of the patient and, (7) the treatment goals.

Ankylosed Primary Tooth This can impede the development and eruption of the permanent successor. If a primary tooth has a permanent successor, treatment is immediate extraction followed by space maintenance until the permanent tooth erupts. If no permanent successor is present and the primary tooth ankylosis occurs at an early stage in jaw growth and development with submergence of the tooth eminent, treatment includes extraction and space maintenance.²⁰ If the ankylosis occurs late with no permanent successor, the occlusal and proximal contacts can be reestablished with restorative dentistry to provide esthetics and function with perhaps many years of service.²¹

It is important to diagnose and treat the ankylosed tooth before the adolescent growth phase. Retaining an ankylosed tooth during jaw growth leads to arrested development of the alveolar ridge. The severity of alveolar growth loss depends on the amount of facial growth left at the time that the ankylosis occurs. Timing the removal of an ankylosed tooth just at the start of the pubertal phase of adolescent growth may achieve the treatment objective of maintaining alveolar ridge height while allowing the tooth to remain long enough to act as a space maintainer and esthetic temporary.²²

Ankylosed Permanent Tooth An unrecognized ankylosed permanent tooth tied into the arch wire can result in a significant malocclusion (Figure 55-32). There are several ways of treating the permanent ankylosed tooth. If ankylosis of the permanent tooth has an early onset during eruption, the tooth should be luxated, allowing for further eruption.² If repeated luxation proves ineffective, the tooth should be extracted to prevent submergence. If the onset of ankylosis occurs late in the normal eruption pattern, the tooth should be luxated. If the attempt is

FIGURE 55-32 An ankylosed first molar tied into the arch wire has prevented development of the alveolus and consequently created a significant posterior open bite.

unsuccessful and the tooth does not submerge, it may be vertically restored on growth maturity. A composite build-up or crown can be added to a partially erupted ankylosed tooth to level and align the arch.²¹ A deeply unerupted ankylosed tooth, primary or permanent, may be left undisturbed unless it is infected, alters the alveolar bone growth potential, or constitutes an immediate threat to the occlusion or adjacent teeth, or would impede the placement of an osseointegrated implant.³

Other treatment options include extraction followed by reimplantation, osseointegrated implant, or prosthetic replacement.²³ The patient's developmental age is very important in considering replacing an ankylosed tooth with an osseointegrated implant. The implant will have the same effect on growth of the alveolar ridge as the ankylosed tooth, and therefore should be considered for placement after alveolar growth is essentially complete.²⁴

Proffit suggests surgical luxation of the tooth with extraction forceps disrupting the cementum-bone fusion followed by immediate orthodontic traction to move the tooth into position.²⁰ Luxation involves breaking the bony bridge of ankylosis without damaging the apical nutrient vessels. This procedure forms fibrous inflammation tissue in the reparative process. This tissue forms a false periodontal membrane, and tooth erup-

tion may resume. Orthodontic movement should begin immediately. Complications include possible crown, root, and alveolar fractures, loss of viability and vitality, as well as re-ankylosis. When an ankylosed tooth is impacted, a similar technique can bring an impacted tooth (usually canines) into the arch. Exposure involves surgical uncovering, application of orthodontic bonding, and tension forces applied to direct the tooth into occlusion. However, if the tooth becomes re-ankylosed, the orthodontic forces will intrude adjacent teeth.

Orthodontics for Surgical Management of Ankylosed Teeth Presurgical orthodontics may be indicated to create adequate space (minimum of 2 to 3 mm) between the roots of the adjacent teeth to safely accommodate interdental osteotomies around the ankylosed tooth. Spacing is best assessed with pantomographic or periapical radiographs. The ankylosed tooth is left out of the arch wire, and all other teeth are properly aligned. If orthognathic surgery is required to correct a dentofacial deformity, the orthodontics are performed in the traditional manner, but the ankylosed tooth must remain out of the arch wire, unless it aligns well with one of the dental segments. Following surgery, orthodontic mechanics can be initiated immediately to help get the mobilized dental segment with the ankylosed tooth into the best possible position.

Osteotomy Performing single-tooth osteotomies or sectional-arch osteotomies with mobilization of the segment will permit immediate repositioning of the ankylosed tooth (Figure 55-33), or facilitate repositioning by distraction osteogenesis.

In select cases where an ankylosed primary molar is present, without a successor, a treatment option is to remove the ankylosed tooth and eliminate the extraction space by performing a vertical body osteotomy in conjunction with a mandibular

ramus osteotomy and advance the posterior teeth and mandibular body forward (Figure 55-34). This eliminates the need for osseointegrated implants and extensive dental reconstruction.

Final Presurgical Preparation

As presurgical orthodontic treatment progresses, new diagnostic records (lateral cephalograms, pantomograms, dental models) are taken to determine the feasibility and timing of surgical procedures. This will also aid the orthodontist in identifying specific areas that may need to be addressed in completing the presurgical orthodontic goals (ie, sectional leveling of the arch

FIGURE 55-33 Single-tooth osteotomies can be performed as isolated cases or they can be performed in combination with multiple maxillary osteotomies to allow individual movement of the dental osseous segments or application of immediate distraction osteogenesis to reposition the tooth properly. The case illustrated had an ankylosed maxillary right cuspid (see Figure 55-8) treated with segmental maxillary osteotomies including a single tooth segment containing the right cuspid (A, B)

FIGURE 55-34 A, B, An ankylosed submerged primary tooth without a permanent successor can be treated with extraction of the primary tooth as well as a vertical body osteotomy in conjunction with a mandibular ramus sagittal split osteotomy to advance the posterior teeth forward to eliminate the ankylosed tooth and associated space. This eliminates the need for an osseointegrated implant or crown-and-bridge work.

segments, marginal ridge alignment, vertical dental alignment, buccal surface alignment, additional TSD correction).

During surgery the jaws are usually wired together once or twice, as each jaw is independently mobilized and stabilized with rigid fixation. To facilitate wiring the jaws together as well as providing a means of using postsurgical elastics if required, fixtures attached to the brackets or arch wires are usually necessary. Fixtures attached to the brackets are dependent on the manufacturer but may include ball hooks built onto the brackets, T pins, and K hooks, (Figure 55-35). Fixtures attached to the arch wire include crimped-on hooks and soldered pins (Figure 55-36). Hooks built onto the brackets are preferred, followed by the other

hooks placed on the brackets (T pins, K hooks). The least preferred are the hooks on the arch wire. The reason is that if postsurgery elastics are required for an extended time, the elastics and hooks on the arch wire will activate the arch wire, possibly creating unwanted orthodontic forces and movements (ie, tipping the crowns lingually and the roots buccally). This undesirable torquing occurs to a much lesser degree when the hooks are directly on the brackets.

When the maxilla or mandible are to be segmentalized, it may be better for the orthodontist to section the arch wire (see Figure 55-15B) and bend the ends inward at the predetermined osteotomy areas immediately prior to surgery, or the surgeon can cut the wire at surgery.

The best type of arch wire to place prior to surgery is a rectangular stainless steel wire that fills the bracket slot. For example, with an 18 slot, a 17 × 25 gauge wire is recommended, and for a 22 slot, a 21 × 25 gauge wire is indicated. This will help stabilize the individual dental units together as a whole arch or in segments when segmental surgery is required. The final wire should be placed 2 to 3 months prior to surgery.

Postsurgical Orthodontics

In preparation for the postsurgery orthodontic phase of treatment, the surgical stabilizing splint, if used, is usually removed 4 to 6 weeks postsurgery. If the palatal splint design is used and a large maxillary expansion has been performed, the splint can remain for a longer period and the postsurgical orthodontics can be performed around it. The maintenance of the splint will enhance the transverse stability and it can be left in for 2 to 3 months or longer if necessary. It can be made into a removable appliance.

If rigid skeletal fixation is used, active orthodontics involving changing the arch wires can usually resume 4 to 6 weeks postsurgery, when patients are usually comfortable enough to tolerate changing their arch

FIGURE 55-35 Orthodontic hooks. Ball hooks built onto the brackets (blue arrows) provide the best stability. Other options include T pins and K hooks (white arrows) or other methods to provide attachments directly on the brackets.

wires. The orthodontist can be fairly aggressive at finishing the occlusion because the osseous segments can still be moved slightly. The teeth move much more rapidly for the first few months postsurgery because there is an increased bony metabolism as a result of the surgery. The orthodontist can therefore accomplish in 1 to 2 weeks what would normally take 4 to 6 weeks to complete. Applying active mechanics at this early postsurgical orthodontic phase of treatment and booking the patient for a routine orthodontic follow-up 4 to 6 weeks later could result in uncontrolled excessive orthodontic movements, resulting in an unfavorable outcome.

FIGURE 55-36 Soldered pins on the arch wire or crimped hooks (white arrows) onto the arch wire can also be used but are not preferred because the use of postsurgical elastics will activate the arch wire, possibly creating unwanted orthodontic movements.

For most cases the orthodontist should see the patient once a week for the first month, then every 2 weeks for the next 2 months for adjustments so that orthodontic changes can be closely monitored. At the initial appointments root positions are checked, loose brackets and bracket positions are evaluated and corrected, and new arch wires are placed if indicated. Interarch mechanics (ie, class II or III elastics, vertical elastics, and/or cross-arch elastics) can be applied as necessary to finalize the occlusion. Once the initial healing phase is completed (approximately 3 to 4 months postsurgery) and the occlusion is stable, the orthodontic appointment intervals can be extended to the more traditional time frame. The final positioning of the teeth usually takes from 3 to 12 months of postsurgical orthodontic treatment but could be longer depending on the postsurgical orthodontic requirements. Although reasonable stability from surgical healing occurs in approximately 3 to 4 months, the final postsurgical healing phase takes 9 to 12 months.

Principles of Mandibular Orthognathic Surgery

Dale S. Bloomquist, DDS, MS

Jessica J. Lee, DDS

The development of mandibular osteotomies for correction of dentofacial deformities closely parallels the advancement of oral and maxillofacial surgery as a specialty more than any other group of surgical techniques. From Hullihen, who in 1849 was the first to describe a mandibular osteotomy, to Obwegeser, who developed the sagittal osteotomy of the vertical ramus, there has been dramatic progress in the techniques of mandibular osteotomies. After Obwegeser's original paper in German, and especially since his description of techniques in the English literature, orthognathic surgery has seen dramatic changes in use as well as refinement of the osteotomies. Although the development of osteotomy techniques is ongoing, it is the purpose of this chapter not only to describe the most commonly used surgical procedures for the mandible but also to emphasize the refinements in technique that have been the result of the most recent clinical as well as basic research.

History

Hullihen corrected a patient with anterior open bite and mandibular dentoalveolar protrusion with an intraoral osteotomy, very similar to what we now describe as an anterior subapical osteotomy (Figure 56-1).¹ His

efforts did not seem to stimulate much interest, for it was almost 50 years later when Angle described a body osteotomy done by V.P. Blair (Figure 56-2A) for a patient with mandibular horizontal excess.^{2,3} This technique, with minor modifications, was advocated until the 1970s. Since then the only major modifications in the body osteotomy that have occurred are a greater emphasis being placed on preserving the inferior alveolar nerve and a switch to an intraoral approach.

The horizontal osteotomy of the vertical ramus popularized by Blair (Figure 56-2B) was accomplished through an extraoral route.⁴ As with many of the early mandibular procedures a horizontal bone cut was made above the lingula and was described for correcting both mandibular horizontal deficiency and horizontal excess. An intraoral technique was not suggested until Ernst discussed his procedure approximately 25 years later.⁵ This method of correcting mandibular deformities was used for almost 60 years, but because of its lack of postoperative stability, it has fallen into disuse.

The subcondylar osteotomy (Figure 56-2C), a form of which was first reported by Limberg as an extraoral technique, has undergone relatively minor refinement to

the intraoral vertical subcondylar osteotomy that is popular today.⁶ There has, however, been a substantial number of osteotomy designs through the vertical ramus that begin in the sigmoid notch, which has led to some confusion in the

nomenclature of what is a fairly closely related group of osteotomies. The names that have been developed have generally been based on the length and direction of the cuts made in the posterior portion of the vertical ramus. The subcondylar osteotomy was used to describe the condylar neck osteotomies of Kostecka and of Moose.^{7,8} Generally longer cuts that extended to the posterior border above the angle, such as described by Limberg, Thoma, and Robinson, were described as oblique osteotomies.⁵⁻¹⁰ Shira, however, coined the term oblique sliding osteotomy for this particular surgery.¹¹ Finally Caldwell and Letterman described a vertical

osteotomy of the mandibular ramus that included a cut from the sigmoid notch to the inferior border in front of the angle of the mandible.¹² The cut was kept behind the foramen of the mandibular nerve, and a portion of the lateral cortex of the distal fragment was decorticated to allow a larger area of bone contact. Generally these latter two groups of osteotomies are now being called vertical osteotomies, but some semantic differences still persist. Specifically the terms vertical subcondylar osteotomies (VSOs) and vertical ramus osteotomies (VROs) are still used interchangeably in the literature. Primarily this type of osteotomy was designed for correc-

tion of mandibular horizontal excess of mandibular asymmetries, although Robinson described its use with a bone graft for horizontal deficiencies.¹⁰

The intraoral approach to the subcondylar osteotomies is relatively new, having first been described by Moose in 1964.¹³ He approached the condylar neck medially with a straight bur. Winstanley suggested a lateral approach in 1968, but it was not until Hebert and colleagues described the use of a special oscillating saw that this approach became popular.^{14,15}

A variation of the vertical subcondylar osteotomy was suggested by Wassmund in 1927 (Figure 56-3A), which is similar to what is now called the inverted L osteotomy.¹⁶ Pichler and Trauner later suggested the use of bone grafts into the defect left by the advancement of the mandible.¹⁷ Caldwell and colleagues further modified the inverted L by adding a horizontal cut just above the inferior border of the mandible to create what is now called the C osteotomy (Figure 56-3B).¹⁸ The stated advantage of the C osteotomy was that the bone cut design made the use of a bone graft unnecessary. This advantage was further enhanced by the modification suggested by Hayes, with the splitting of the inferior limb sagittally so that more bone contact can be achieved.¹⁹ A further interesting approach to this group of vertical ramus osteotomies done for horizontal mandibular deficiency is the modified L osteotomy described by Fox and Tilson.²⁰ They deleted the superior horizontal cut of the C osteotomy and instead extended the vertical cut to the sigmoid notch. Then the coronoid process was removed and added as a free graft into the defect resulting from the mandibular advancement.

The greatest development in osteotomies of the vertical ramus is the sagittal osteotomy, credited to Obwegeser and Trauner, but generally now used in a fashion modified from the original technique described in 1955.²¹ Lane has been mentioned as the developer of a form of

FIGURE 56-3 A, L osteotomy. B, C osteotomy. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1417.

the sagittal osteotomy, with parallel horizontal bone cuts made through the medial and lateral cortices of the vertical ramus (Figure 56-4).²² The medial cut was made just above the lingula, with the lateral cut made just below it. This idea was expanded by Schuchardt before being refined and popularized by Obwegeser.²³ The major modifications in the osteotomy design were first made by DalPont with his vertical cut through the lateral cortex as well as the suggestion that the medial horizontal cut be extended only to a point above the

FIGURE 56-4 Lane's osteotomy. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1417.

lingula and not to the posterior border (Figure 56-5).²⁴ This latter technique shortens the split posteriorly, and as was further discussed by Hunsuck, decreases the trauma to the overlying soft tissue.²⁵ Many clinicians have offered suggestions for improving the sagittal osteotomy, but the only other major innovation to this technique has been the use of internal rigid fixation. Spiessl suggested the use of screws for fixation of the fragments in the sagittal osteotomy.²⁶ Although wire osseous fixation is still used by some surgeons, rigid internal fixation in some form has become the standard technique for the bilateral sagittal split osteotomy (BSSO).

Osteotomies of the mandibular body do not generally receive the same degree of attention as osteotomies of the vertical ramus, but they have undergone refinements and variations from the original anterior alveolar osteotomies of Hullihen and the body osteotomies of Blair. The first variation of Hullihen's procedure did not appear until 90 years after the original description, when Hofer demonstrated an anterior mandibular alveolar osteotomy to advance anterior teeth in correction of a mandibular dentoalveolar retrusion (Figure 56-6A).²⁷ Kole modified this procedure

by suggesting the use of bone grafts from the mental region to the defect caused by the rotation of the anterior dentoalveolar segment (Figure 56-6B).²⁸ Clinicians now

employing Hofer's osteotomy generally use some form of bone graft in the alveolar defect if significant movement of the fragment is planned. Mandibular alveolar osteotomies have expanded in primarily two ways from Hofer's original procedure. Kent and Hinds initially presented the use of the single-tooth osteotomies of the mandible in 1971, and MacIntosh closely followed with his description of the total mandibular alveolar osteotomy in 1974.^{29,30} This latter procedure continues to be popular, with minor variations being added by other clinicians.

Osteotomies of the body of the mandible have been described in almost every conceivable form, with the most durable advancements being the step osteotomy, initially described by Von Eiselberg in 1906 (Figure 56-7A), and the horizontal osteotomy of the symphysis described by Hofer in 1942 (Figure 56-7B).^{31,32} The step osteotomy was originally described for treatment of mandibular horizontal deficiency, but it has been used in various forms for mandibular horizontal excess as well as asymmetry. The horizontal osteotomy of the symphysis has

also developed a large degree of versatility, with its use in various forms being suggested for almost any skeletal deformity of the bony chin.

Anatomic and Physiologic Considerations of Mandibular Surgeries

Vascular Supply

A major concern with surgery of the facial skeleton is the vascular supply of the bone segments. This was dramatically demonstrated by the explosion of orthognathic

A

B

FIGURE 56-7 A, Von Eiselberg's step osteotomy. B, Hofer's horizontal osteotomy. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. surgery in the United States after Bell and Levy's studies of vascular effects of the osteotomies.³³ Although all of the techniques they looked at had been previously used in patients, there had not been any experimental evaluations of the physiologic basis for many of the procedures. Bell and Levy's work demonstrated that blood flow through the mandibular periosteum could easily maintain a sufficient blood supply to the teeth of a mobile segment, even when the labial periosteum was degloved. Blood flow from the periosteum was termed centripetal, to distinguish it from the blood flowing from endosteal vessels outward (centrifugal) that was associated with long bones. Previously clinicians felt that the inferior alveolar artery had a primary role in nourishing the mandible, but Bell and Levy demonstrated that there is also a sufficient blood supply from the surrounding soft tissues, even if the inferior alveolar artery was obstructed. More recent work in animals suggests that the blood supply to the body of the mandible under normal conditions comes almost entirely from the inferior alveolar artery.³⁴ However, when this source is obstructed, the peripheral blood vessels quickly take over for the anterior mandible. The posterior mandibular dentoalveolus, however, does not benefit from this kind of collateral blood supply, which calls into question the safety of posterior mandibular segmental alveolar osteotomies. Zisser and Gattinger showed pulpal necrosis in the molars of horizontal osteotomies done above the inferior alveolar nerve in the body of the mandible of dogs.³⁵

The safety of combined mandibular osteotomies, such as ramal procedures and body osteotomies, has been a concern because of the predominant role of the inferior alveolar artery.³⁶ The fragility of the vascular supply to the mandibular alveolus engenders some concern over the common use of subapical osteotomies. Although their relative safety has been demonstrated by both animal studies and

substantial clinical experience, subapical osteotomies need to be carefully planned to ensure as large a vascular pedicle as possible.^{33,37} Complications, such as pulpal necrosis, soft-tissue defects, and loss of teeth and bone, have demonstrated the delicate nature of the blood supply, especially when attempts at moving small dentoalveolar fragments are made. The effect of aging on the vascular supply to the mandibular body is an area about which very little information is known, particularly whether aging causes a switch from the centrifugal to centripetal blood supply. Bradley has demonstrated an apparent decreasing capacity of the inferior alveolar vessels that occurs with aging, but the impact of this effect on mandibular osteotomies is unknown.³⁸

Osteotomy designs of the vertical ramus have profited by studies of the effect of surgery on vascular supply. The proximal segment of the vertical subsigmoid osteotomy maintains its blood supply through the temporomandibular joint capsule and the attachment of the lateral pterygoid muscle. However, the inferior tip of this fragment has undergone vascular necrosis in experimental studies.³⁹ This led to the suggestion that fewer problems may occur if the cut was made above the angle of the mandible.³⁹

The importance of the periosteal blood supply as well as the endosteal supply in the vertical ramus has been explored by animal research.⁴⁰⁻⁴³ When the medial pterygoid and masseter muscles are stripped, both blood flow and blood supply studies have demonstrated the possibility of avascular necrosis in the proximal segment. Comparisons of extensive muscle stripping of the vertical ramus against preservation of the masseter attachment have demonstrated a significant difference in the vascularity of the inferior portion of the proximal fragment. These studies of blood supply of the vertical ramus may be of value in predicting the vascular effects of the C or L osteotomies. However, resorp-

tion of the proximal fragment has not been reported in these particular bone cuts possibly because of the rarity of their use. However, given the available research, it is wise to minimize the periosteal and muscle attachment stripping on the medial surface of the proximal fragment with either the C or L osteotomy or any of their variations.

The last unanswered question concerning vascular supply in mandibular orthognathic surgery is the determination of a safe distance away from the apex of the teeth to make horizontal bone cuts. Many of the references to this question are based on research done in the maxilla.⁴⁴ From these early animal studies the pulpal blood supply of a tooth should not be affected if a cut was made at least 5 mm away from the apex of the tooth. Zisser and Gattinger, however, saw pulpal changes in dogs with some horizontal cuts that were made 10 mm away from the apex.³⁵ Whether these distances have any relevance to humans is presumptive. Clinically the incidence of tooth devitalization from horizontal subapical osteotomies is extremely low and it can be assumed that, for the most part, 5 mm is a good guideline. A cut made 10 mm from the apices, although allowing a greater safety margin, is often impractical because of other anatomic limitations. The greater distance from the apices of the teeth not only minimizes direct pulpal injury but increases the vascular pedicle to the mobile segment as well.

Nerves

The surgeon working around the face must be constantly aware of the nerve network that exists in this area. Fortunately, on approaching the mandible, these concerns can be narrowed to essentially two major nerves: the marginal mandibular branch of the seventh cranial nerve and the third division of the trigeminal nerve, most frequently one of its branches, the inferior alveolar nerve. The marginal mandibular branch is usually only at risk during extraoral procedures. Although

trauma to this nerve has been reported to have occurred during intraoral approach, it is rare and for the most part appears to be preventable. Avoiding damage to this nerve during extraoral approaches to the mandible is a major surgical goal; in most cases in orthognathic surgery it is achieved because soft tissue anatomy in patients undergoing the surgery has not been disturbed by disease or trauma. The techniques of these approaches are covered elsewhere in these book volumes as well as are the methods for minimizing the risks of damage to the marginal mandibular branch. Damage to the third division of the trigeminal is, however, a much-discussed problem in mandibular surgery. The course of the inferior alveolar nerve into the vertical ramus and then through the body of the mandible makes it extremely susceptible to damage from almost every mandibular surgical procedure. In most cases the surgeon's main goal relative to this nerve is to minimize the trauma because its avoidance is almost impossible. In the past surgeons stressed the importance of looking for and sometimes freeing up the nerve as it either entered or left the mandible before making osteotomies in the areas of the foramina. However, there is a trend toward avoiding this step, unless it is absolutely necessary to make the osteotomy as close to the nerve as possible. The simple act of exposing the nerve seems to increase the chance for postoperative sensory deficiency.

Often the debates on whether one mandibular osteotomy is preferable to another are primarily based on the potential of damaging the inferior alveolar nerve. This has resulted in many clinicians trivializing the damage found following a certain technique. Well-defined standards for both long- and short-term follow-up of nerve damage during mandibular procedures have been discussed⁴⁵; however, in most papers these have not been used to evaluate sensory deficits. In addition very few controlled studies have been published com-

paring procedures; as a result not much can be said in support of any of the differing attempts to minimize nerve damage.

Studies looking at the loss of tooth sensibility from horizontal osteotomies below the dental apices, however, have been quite consistent. Most authors found a relatively high loss of response to pulp testing immediately after osteotomies, especially when teeth are close to a vertical osteotomy.⁴⁶⁻⁴⁸ However, this loss may not correlate with actual loss of tooth vitality and, thus, either tooth loss secondary to an osteotomy or the need for endodontic therapy is very low.

The Muscle

Orthognathic surgery affects muscles in primarily two ways: it changes the length of a muscle or it changes the direction of muscle function. Effects of these changes are still not understood, although various authors have emphasized the importance of controlling muscular changes. The muscles commonly discussed in orthognathic surgery of the mandible have been the muscles of mastication and the suprahyoid group of muscles. Recent interest on the soft tissue effects of facial skeletal surgery has expanded interest to the other facial muscles. This latter group, however, has generally not been discussed relative to mandibular osteotomies, with the possible exception of the effect of the anterior mandibular osteotomies on the attachment of the mentalis muscle. The muscles of mastication, however, have received considerable attention, dating back to the early vertical ramus procedures. Research interest on the effects of altering these muscles concentrated either on their effect on the skeletal changes, especially relapse following mandibular osteotomies, or on the changes in function of these muscles.

Distraction of the superior fragment of a horizontal osteotomy of the vertical ramus following surgery was noted early by surgeons who used this technique.⁴⁹

Evaluation of this procedure following correction of prognathism found a superior movement of the mandible in the gonial region as well as a downward and backward movement at the symphysis. This change, which was attributed to the forces of the pterygomasseteric sling, has received considerable attention, not only in mandibular setbacks done with osteotomies through the vertical ramus but also in mandibular advancements.⁵⁰⁻⁵⁵ The apparent shortening of the vertical ramus has been noted in a number of studies, and in some a correlation has been demonstrated between this change and the posterior movement of the symphysis. The exact reason for the change in the gonion has not been clearly demonstrated. Kohn demonstrated the movement of this point inferoanteriorly in mandibular advancements by way of a measurement he termed the gonial arc (Figure 56-8).⁵⁴ Most investigators feel this represents distraction of the condyle from the fossa, and this

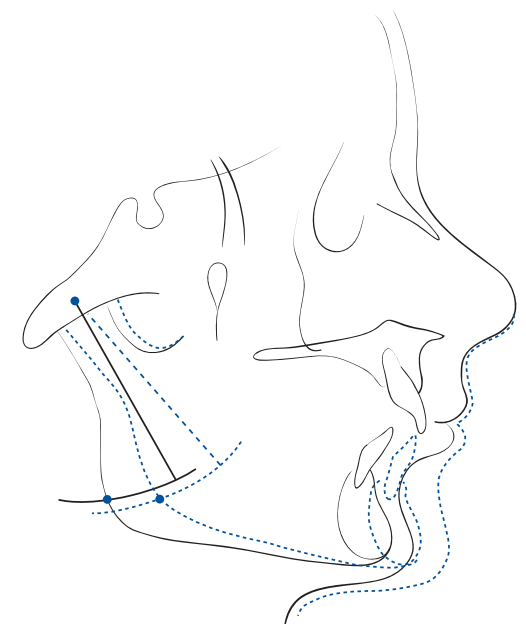

FIGURE 56-8 Gonial arc used for showing condylar position change with a mandibular osteotomy. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1422.

hypothesis was further supported by the migration of the gonion back during the postoperative period.^{54,55} The long-term postoperative decrease in gonial arc was generally believed to be due to remodeling, especially resorption that occurred at the mandibular angle.^{40,43} Especially in early studies, resorption could have accounted for this change because of the then-accepted technique of completely stripping muscle attachment from the proximal segment. However, in more recent studies in which minimal muscle stripping was done, a similar result has been noted.^{56,57} Will and colleagues noted a condyle distraction followed by an “overshoot” in the resettling of the condyle in the fossa.⁵⁸ This change in condylar position may be due to either displacement of the disk within the joint or compression of the soft tissues of the joint by increased pressures secondary to the muscles of the pterygomasseteric sling.

The rotational change in the proximal segment of a mandibular osteotomy has been implicated in relapse by multiple clinicians who believe that the muscles of the pterygomasseteric sling reassert themselves after the surgery.^{59,60} Therefore, there has been an emphasis on carefully repositioning the proximal segment close to its preoperative position. Unfortunately a correlation between mandibular ramus positioning and relapse in the case of mandibular advancements has never been demonstrated. There have been a few studies that have shown a relation between relapse of mandibular setback surgeries and the position of the vertical ramus.⁶¹ It has been noted in these surgeries that the degree of clockwise rotation of the proximal fragment in a sagittal osteotomy seems to relate to the amount of forward relapse of the distal segment. Franco and colleagues theorized that a stretching of the medial pterygoid muscle as well as the elongation of the anterior fibers of the masseter and temporalis muscles from the clockwise rotation of the proximal seg-

ment both can contribute to relapse in lengthening the muscles of the pterygomasseteric sling.⁶¹ This can result in a change in mandibular position as has been documented by Yellich and colleagues.⁶² The degree to which this is active in orthognathic surgery remains unclear.

The contribution of the suprahyoid muscles to relapse in mandibular advancement surgery is equivocal, with many clinicians claiming an existence of this relationship. Ellis and Carlson demonstrated in monkeys that relieving the suprahyoid muscles from the symphysis of the mandible decreased the amount of relapse when the mandibles were advanced.⁶³ Clinical studies, however, have failed to show a relation between suprahyoid myotomies and relapse.^{64,65} Animal studies have also demonstrated that adaptive changes occur in the connective tissues at the muscle-tendon and tendon-bone interfaces but only with large advancements.⁶⁶

The belief, however unsubstantiated, that muscle pull in some way does affect the stability of mandibular osteotomies has led to a variety of recommendations. Historically the most common method advocated is the attempt at minimizing the change in muscle position and length. The cutting of muscle attachments, such as has been recommended for the suprahyoid group, has the potential for increasing morbidity. Without significant evidence that this is of much value, this additional surgery cannot be justified. However, there has been recognition that muscles and their attachments seem to adapt fairly quickly if the bone is held rigidly for a long enough time.^{66,67} It is important to recognize that intermaxillary dental fixation does not provide a completely stable method of bone fixation, especially if the teeth have been under active orthodontic movement. Additionally the greatest amount of relapse of mandibular osteotomies seems to occur in the first 3 to 6 weeks after surgery. Whatever the causes of the instability during this time there

have been several techniques designed to provide increased stability for this initial period, to improve the stability of mandibular osteotomies. Primarily two techniques have been attempted: external supporting mechanisms and internal rigid fixation. The only external technique that has been of much value has been the wiring technique that has been termed skeletal fixation. With this procedure the bony skeletons are tied to one another, circumventing the periodontal ligaments of the teeth. This has been used with intermaxillary fixation, keeping the mandible immobilized for 6 to 8 weeks (Figure 56-9).^{58,67,68} The alternative procedures of internal rigid fixation techniques using plates or screws will be discussed in the succeeding sections on the osteotomies.

Osteotomy Techniques

Vertical Ramus Osteotomies

Osteotomies in the vertical ramus have been the preferred technique for correcting developmental deformities of the mandible. This preference has increased with closer cooperation between orthodontists and

FIGURE 56-9 Skeletal fixation used with maxillo-mandibular fixation or mandibular advancement. Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1423.

surgeons in treating dentofacial deformities. Most of the time the dental arch discrepancies can be orthodontically corrected, leaving the surgeon the responsibility for moving the coordinated dental arch into its new position, as dictated by functional and esthetic demands. Operations in the vertical ramus, therefore, have become almost automatically considered when the dental arch as a unit has to be moved. As previously noted there have been numerous techniques suggested for osteotomies of the ramus, but essentially three different procedures, with minor variations, have been accepted by the surgical community.

Vertical Subcondylar Osteotomies

Osteotomies extending from the sigmoid notch vertically behind the inferior alveolar nerve foramen to the inferior border or angle have had several different names, but generally, the VSOs seem to describe the procedure best (Figure 56-10). This osteotomy was initially done through an extraoral approach but with the development of small oscillating blades with a long shaft, the intraoral route has become preferred.

Indications The VSOs have most commonly been limited to deformities requiring the mandible to be set back for mandibular horizontal excess or to be rotated for mandibular asymmetry. Robinson and Lytle have stated that this osteotomy can be used for mandibular advancement but generally this recommendation was not taken seriously because of the question of stability.⁶⁹ Hall and McKenna revived this indication for minor (2 to 3 mm) advancements.⁷⁰

Techniques When preparing for an intraoral VSO, one needs to closely evaluate the panoramic and lateral head films for the position of the inferior alveolar foramen relative to the posterior border of the mandible. The incision is made in the mucosa from midway up the anterior border of the ramus to the first molar area. The periosteum is reflected laterally to expose the entire ramus, with the exception of the condyle neck and coronoid tip. The posterior and inferior borders can be cleared of periosteum; muscle attachments at the angle are generally difficult to elevate and should be left to ensure blood supply to this area. A special retractor can be placed that

fits around the posterior border and, at the same time, retracts tissue laterally so that an oscillating saw can be used (Figure 56-11A).

The saw chosen should have a rounded blade that is set at an obtuse angle to the long shaft to facilitate the cut. The blade should be used first to score the proposed osteotomy line on the lateral cortex. This line is then closely checked for its position relative to the sigmoid notch, posterior border, and angle. The use of the so-called antilingula has been proposed as the landmark for the mandibular foramen, but has generally fallen into disfavor, both because of the difficulties with its identification and its lack of predictable relation to the foramen.^{12,71,72} The cut should be made no more than 5 to 7 mm anterior to the posterior border at the anticipated level of the foramen, using the retractor as a guide to the posterior border.⁷³ The cut is carried through the medial cortex, starting in the middle of the ramus. It is carried superiorly to the sigmoid notch and then finished at the inferior border (Figure 56-11B). As the cut is completed, antero-lateral tension is kept on the retractor so that the proximal fragment will be brought out laterally. A straight clamp can

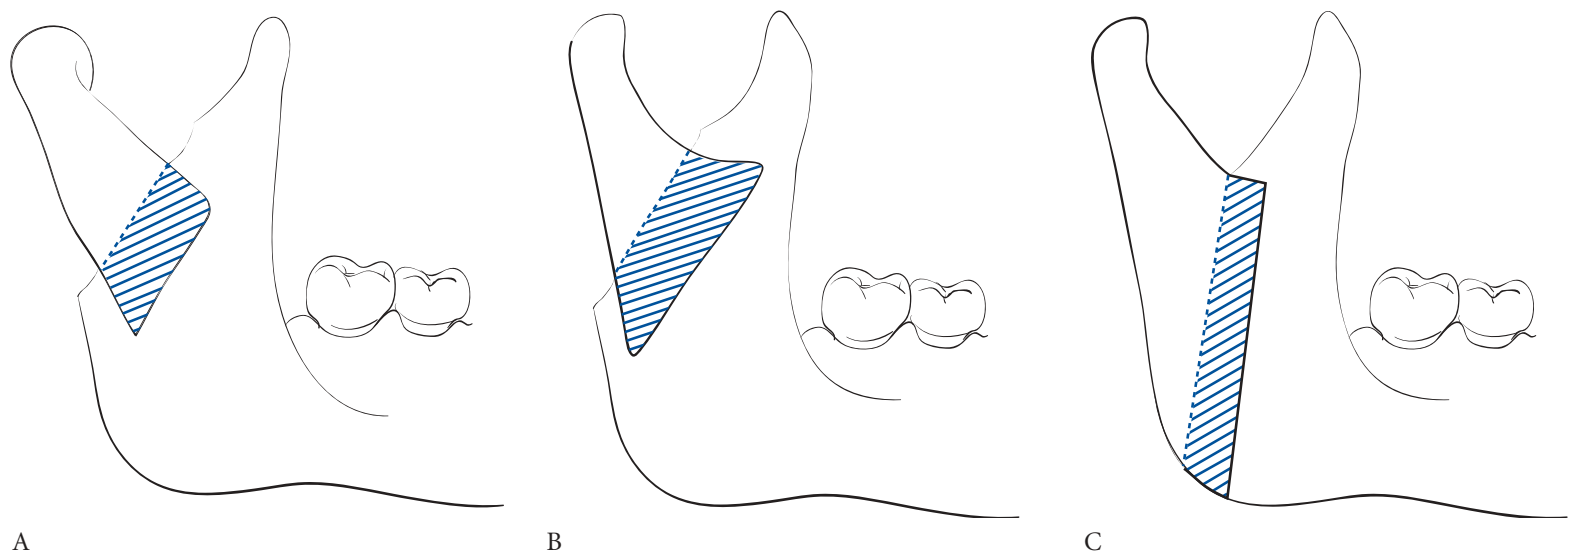

FIGURE 56-10 Different lengths of the osteotomy in the vertical subcondylar osteotomies. Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1423.

be used to rotate the segment laterally after the cut is made and then to stabilize it while periosteum and muscle are stripped from the medial cortex down to the angle (Figure 56-11C). Again a small attachment is left at the angle to ensure a blood supply. This proximal fragment can be held forward and laterally by a small gauze pack while the opposite side is being completed. If the proximal fragment is lost medially, it usually can be brought into the field with the help of a small periosteal elevator that is inserted posteromedially at the level of the sigmoid notch while the distal fragment is being pulled forward. The mandibular dentition is brought into its new position after the completion of both osteotomies, as established by a preformed occlusal splint and stabilized with maxillo-mandibular fixation.

Attention is directed back into the wound and toward the placement and stabilization of the proximal fragment.

Wire osseous fixation is generally not needed, although advocated by some surgeons. Most important is the achievement of as broad a bone contact as possible, without displacing or rotating the condyle. Adjustment of the lateral cortex of the distal fragment may be performed with a straight fissure or small acrylic bur to permit the proximal fragment to lie as flat as possible against the vertical ramus. Care should be taken to ensure that the long axis of the proximal fragment does not differ appreciably from its preoperative position. After a thorough irrigation of the wound the mucosa is closed with a running stitch, using a resorbable suture. No drains or external dressings are placed, and the patient is left in fixation for 6 to 8 weeks. Postsurgical radiographs should be taken as soon as possible to confirm that the condyles have not been displaced. A small amount of forward and downward position of the condyle is common, and this gener-

ally resolves during the period of maxillo-mandibular fixation (Figure 56-12).

Submentovertex radiographs have been suggested to identify divergence of the posterior border. It has been suggested that an angle smaller than 130° produces such a significant surgical problem that this type of patient should be avoided and another technique used. The use of this radiograph as a criterion for choosing this technique has been questioned, but some still feel that it can be pursued to identify the more difficult cases.^{73,74}

A large number of variations of the VSO have come in the osteotomy design. Oblique versions with the cut ending above the angle have been described by many clinicians, with the only apparent benefit being the relative ease in the technique.

Theoretically there should also be less chance of damaging the inferior alveolar nerve, but there has been no study to confirm this benefit. Interestingly the one

Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1426.

potential drawback, that of decreased skeletal stability, appears not to be demonstrable.⁷⁵ In contrast with this shorter cut others have recommended that a larger portion of the inferior border be left with the proximal fragment, especially in the larger mandibular setbacks.⁷⁰ This permits a good attachment of the medial pterygoid muscle to be left at the mandibular angle, which has been

claimed to help seat the condyle in the fossa as the patient awakens from anesthesia. This variation, including the use of 8 weeks of fixation, is claimed to decrease one of the problems of the intraoral VSO, specifically that of condylar sag and the resulting open bite that can occur on the release of fixation. Unfortunately no clinical data have been reported that back this claim. The use of osseous wire fixation has

been advocated to ensure the seating of the condyle. Again no study comparing wire osseous fixation with no fixation has shown any advantage for the use of the wire.^{76–78} This may be explicable in the intraoral procedures by the technical difficulties of wire placement. However, Ritzau and colleagues showed in an excellent prospective study that even from an extraoral approach, the position of the

condyle in the fossa is not improved with the use of wire osseous fixation.⁷⁷

The effect of the temporalis on relapse has led to other recommendations that include either stripping the temporalis attachment completely off the coronoid or cutting off the coronoid. The use of this latter coronoidotomy has been recommended by some clinicians for large setbacks, with a few using this modification routinely. The advantage of the coronoidotomy relative to prevention of relapse has not been studied, but the stability of the intraoral vertical subcondylar osteotomy (IVSO) with coronoidotomy, compared with the sagittal split osteotomy of the vertical ramus in mandibular setbacks, has been investigated and the IVSO seemed to be more stable.⁷⁹

The use of the inverted L osteotomy is another way to neutralize the temporalis. This modification of the IVSO requires stripping of the medial periosteum to identify the lingula so that a horizontal cut can be made without increasing the risk of damaging the inferior alveolar nerve. A further modification of the

inverted L osteotomy has been the use of rigid internal fixation. Although technically a difficult surgery it permits the early release from maxillomandibular fixation. Unfortunately there are no long-term studies on the stability of any of the inverted L techniques.

Alternative Techniques The major variation of the described technique is the use of an extraoral approach. The soft tissue incision is similar to that commonly used for an external approach to a fracture of the mandibular angle, with an approximately 4 cm incision made 2 cm below the angle and the inferior border of the mandible (Figure 56-13A). A combination of sharp and blunt dissection is used to get to the inferior border of the mandible. Care is taken to avoid damaging the marginal mandibular branch of the facial nerve. After incising through the periosteum, the bone cuts are similar to those that have been described (Figure 56-13B).

The external approach has been advocated for large mandibular setbacks of

greater than 10 mm, difficult asymmetries, or large vertical moves in patients with unusual facial structure. Except for the risk of the scar, the risks of this technique have been reported as being comparable with the intraoral technique.^{50,80}

Complications Stability Postoperative change in skeletal and dental position following the use of a VSO in the treatment of mandibular horizontal excess has received much attention. Goldstein was the first to use serial cephalograms to evaluate the postoperative change of the mandible after surgical correction of the mandibular prognathism.⁸¹ He noted the anterior relapse that has now been well documented. Poulton and colleagues recommended overcorrecting the mandibular setback by 2 mm to provide for the relapse they noted.⁸² This amount of average relapse has surprisingly remained fairly consistent throughout the history of this technique, even though technical changes in procedures have been made.^{80,83} Stella and colleagues noted that the variation in

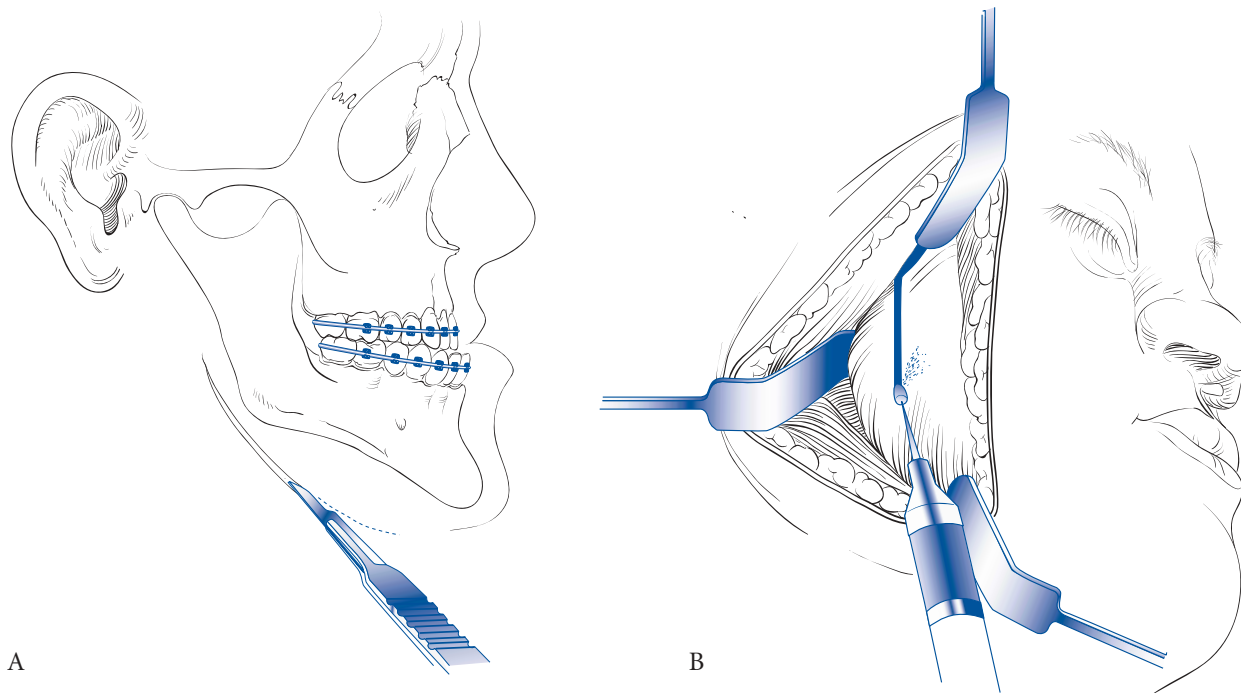

FIGURE 56-13 The extraoral vertical subcondylar osteotomy. Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1428.

the amount of relapse in mandibular setbacks was large and attempts at identifying controllable variables should be made.⁸⁴ They suggested that the proximal fragment rotation affects the short-term pogonion changes, although they did not present any corroborative research. The finding that the pogonion tends to move posteroinferiorly during intermaxillary fixation has been well documented.⁵² This movement, later followed by the anterosuperior “relapse” that occurs after skeletal fixation wires, does seem to stabilize the initial movement but does not affect the long-term relapse.^{50,51,56}

Vertical instability of the VSO develops soon after the release of intermaxillary fixation in many patients. This problem was initially attributed to the “condylar sag” seen on x-ray films taken soon after surgery.⁷³ Although condylar sag may be one cause of relapse, a major contributor seems to be insufficient time of fixation. The VSO is generally not considered an appropriate surgery for correction of anterior open bite. In Scandinavian countries, however, this surgical procedure has been successfully used for patients with mandibular horizontal excess and anterior open bite.⁸⁵

Neural Damage The chance of damaging the marginal mandibular branch of the facial nerve is one of the reasons given by several surgeons for avoiding the extraoral approach to the VSO. This concern, however, seems to be unsubstantiated, in that almost all of the clinicians reporting on the results of this approach have noted very little, if any, motor nerve damage. Damage to the inferior alveolar nerve, however, is a concern in using a VSO. The incidence of trauma to the inferior alveolar nerve at the time of surgery has been reported to vary from being “rare” to occurring 36% of the time.⁷⁰ Long-term sensory defects have also been reported to vary from none to 35%.^{45,86} These apparent discrepancies can be explained by the differences in the sensitivity of the mea-

surement techniques; in addition there is a wide variation in the time after surgery during which the patients were tested. Other variables, such as whether the osteotomy was approached intraorally or extraorally as well as variations in the length of the cut, theoretically could affect the incidence of sensory problems, but comparison studies have not been done. From studies that have been done the incidence of damage to the inferior alveolar nerve is low with the VSO compared with the sagittal osteotomy.^{86,87} The patient, however, should be warned that short-term sensory loss is a definite risk, and permanent neuropathy is possible.

Temporomandibular Joint Dysfunction

There has been interesting literature published on changes in temporomandibular joint function after a VSO. These have included a number of radiographic studies documenting positional change of the condyle relative to the fossa. Radiographically there is an initial downward and forward movement of the condyle, with a subsequent tendency to return to its preoperative position.^{77,78,82} Sometimes a double contour of the condyle appears approximately 6 months postoperatively, which has been attributed to the condyle’s remodeling after the surgery.⁸⁸ Remodeling of the glenoid fossa has also been documented.⁷⁸

In one early review of 100 cases 6 patients were reported to have temporomandibular joint problems at 1 year after surgery.⁸⁹ A form of the VSO has been used to treat patients with temporomandibular pain and dysfunction. It appears that the VSO does not put the temporomandibular joint at any significant risk, and it may in fact be salutary for patients with temporomandibular joint dysfunction.⁹⁰⁻⁹²

Other Complications Among the other reported complications of the VSO, vascular necrosis of the proximal segment

seems to be the most potentially devastating. The maintenance of some muscle attachment to the angles makes this possibility unlikely.

Inverted L and C Ramus Osteotomies

Osteotomy designs in the vertical ramus that include both the condyle and coronoid in the same segment have varied from Blair’s simple horizontal osteotomy to the modified C osteotomy of Hayes. The horizontal osteotomy of the vertical ramus has generally fallen into disuse because of the substantial relapse potential, but many of the remaining suggested variations continue to have treatment value. The two procedures that seem to be the most popular are the inverted L and the C osteotomies. Both are generally approached extraorally, although intraoral variants are possible.⁹³ Clinical studies of either technique are rare, but those that exist seem to demonstrate reasonable success in correcting skeletal deformities with minimal complications.

Indications The C osteotomy is generally reserved for treatment of horizontal mandibular deficiencies, with some authors suggesting that it can be used to close anterior open bite. The inverted L, however, has been used for the correction of most kinds of mandibular horizontal discrepancies, including anterior open bite. Generally advancements of the distal segment with either technique require bone grafting to ensure adequate bone union.

Techniques The basic techniques for an extraoral approach to do a C and inverted L are the same, with the only modification being the inferior horizontal cut in the C osteotomy. For that reason the inverted L will be described first, with various modifications of the C discussed later. The patient is prepared and draped, such that access to both the mouth and the submandibular incision area can occur with-

out contamination of the skin wound by oral organisms. This can be accomplished in a variety of ways, but most surgeons use a plastic drape with adhesive on one edge to separate the two areas. The external drapes should be arranged so that they allow turning of the head for access to the submandibular wounds as well as access to the mouth.

The submandibular incision is made 2 cm below the angle and inferior border of the mandible. The posterior portion is curved superiorly to follow the cervical skin line as well as to improve the access to the entire vertical ramus. Generally the incision is approximately 6 cm in length. Sharp dissection is used down through the platysma, and then blunt dissection is begun to minimize risk to the marginal mandibular branch of the facial nerve. The incision through the pterygo-mandibular sling and periosteum is made along the inferior border and is carried around the angle and up the posterior border about 2 cm. Periosteum and

attachments for the masseter are completely stripped off the lateral cortex of the vertical ramus up to the level of the sigmoid notch. Very little periosteum is stripped off the medial side, especially at the angle, to retain as much blood supply as possible to the proximal fragment. The posterior vertical osteotomy is made at least 7 mm in front of the posterior border and extends to a point of the inferior border just in front of the angle. The horizontal cut is made above the anticipated position of the inferior alveolar foramen (Figure 56-14A). As mentioned above with the VSO it is wise to have a good radiographic view of the ramus so that the position of this foramen can be more accurately located. The study by Reitzik and colleagues of the position of the foramen relative to the lateral landmarks is helpful to review to lessen trauma to the neurovascular bundle.⁷²

Once the cuts are made the medial periosteum may have to be elevated from some of the distal fragment to allow its

advancement. Moist gauze is placed in the wound, and a similar procedure is done on the opposite side. After completion of the second side, drapes are pulled back and shifted such that the oral cavity can be entered to place the mandibular teeth into the new occlusal position and secured with maxillomandibular dental fixation. The surgeons who are involved in the intraoral fixation should change gloves and surgical gowns before the drapes are replaced so that the skin incisions can again be approached. The next step varies depending on the type of mandibular movement that occurred; however, the importance of maintaining the proximal fragment close to its preoperative position remains. If the distal segment is set back, then the proximal segment has to be overlapped laterally (Figure 56-14B). As described with the VSO some adjustments of the lateral cortex of the distal segment may be necessary to permit passive position of the proximal fragment as well as to provide a good area of bone contact. The use of some form of

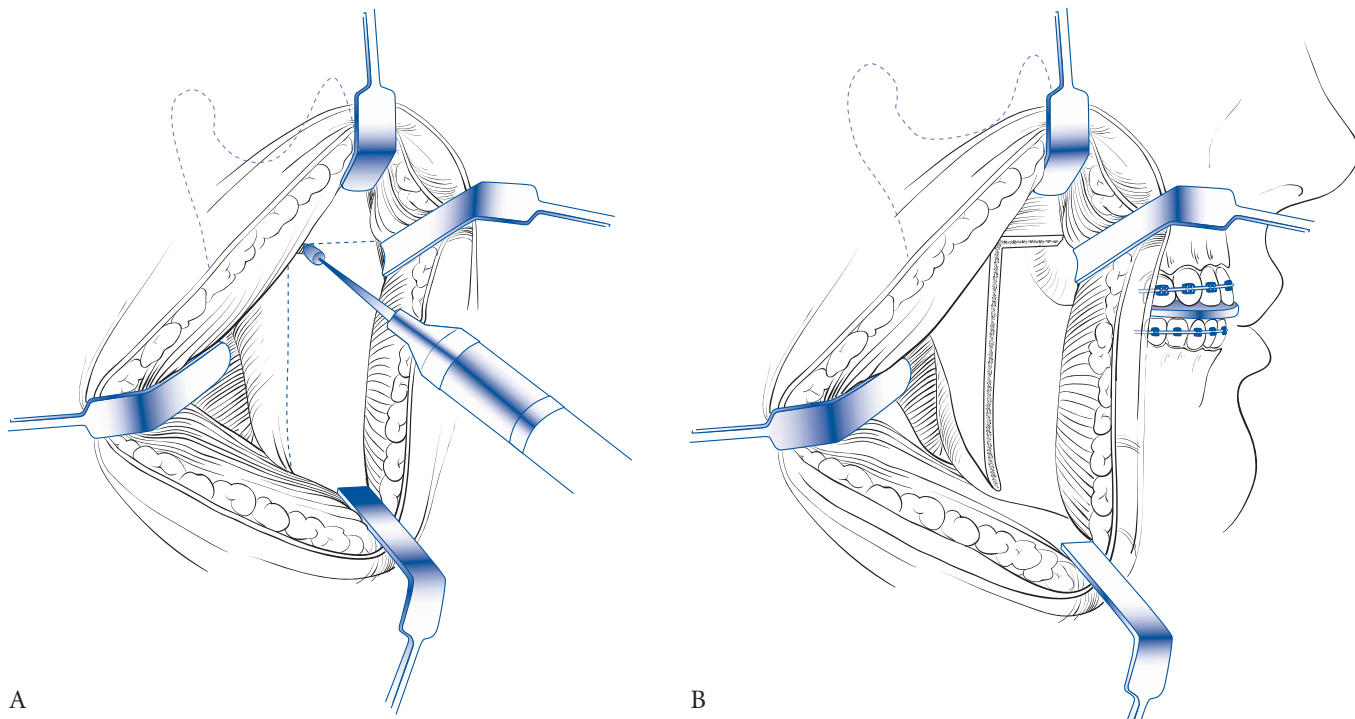

FIGURE 56-14 The extraoral inverted L osteotomy. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1430.

fixation is generally recommended, although the use of no interosseous fixation has been suggested.⁹³ The type of

osseous fixation varies widely; however, rigid internal fixation with metal plates or mesh secured with screws has become

more popular (Figure 56-15).⁹³ After irrigation the wound is closed in layers by whatever suturing method and material

the surgeon prefers. Care should be taken to ensure hemostasis as the wound is closed. If there is any concern about hematoma formation a small drain should be placed. External pressure dressings are maintained for 24 to 48 hours. When the bone has been stabilized with wire fixation, maxillomandibular fixation is kept in place for at least 6 weeks and preferably 8 weeks.

Alternative Techniques The most commonly used variation of the previously mentioned technique is the **C** osteotomy. This technique was first described jointly by Caldwell and colleagues in an article reviewing their experiences with what they called a vertical **L** osteotomy.¹⁸ They described a variation of their basic vertical **L** with the addition of a horizontal cut that extended forward from the vertical cut below the inferior alveolar canal (Figure 56-16A). This permitted a larger amount of bone contact when the mandible was advanced. They also realized the problems caused by advancing the coronoid process and recommended either cutting the coronoid loose (coronoidotomy) or including it with the proximal segment (**C** osteotomy). Arcing the inferior cut was suggested to permit increased bone contact as the distal segment was advanced (Figure 56-16B).⁹⁵ Unfortunately the proposed arc cannot always be made since the position of the neurovascular bundle may interfere. Sagittal splitting of the inferior limb of the **C** osteotomy was proposed both to increase the bone contact area when the mandible was advanced and to decrease the problem of “notching” of the inferior border (Figure 56-16C).¹⁹ This latter problem, which is noticeable in some patients, is caused by the defect along the inferior border resulting from the advanced distal segment of the mandible. A further variation used to improve bone healing includes a bone graft taken from the lateral cortex of the distal segment and transferred back into the gap of the midramus area (Figure 56-16D). The coronoid

process has also been recommended as a free graft in to this defect.²⁰

A further major modification of the described techniques is the use of rigid internal fixation.^{94,96,97} The use of vitalium mesh with two screws in each fragment has been demonstrated as being effective, but any rigid plate with screws can be used to permit the early release of maxillo-mandibular dental fixation.

Complications The skeletal stability of the inverted **L** and its modifications,

unlike the VSO, seems to be technique-sensitive to the type of fixation used. Like stability studies for almost all aspects of orthognathic surgery, controlled clinical studies are nonexistent, and the comparison of techniques by a single institution, if reported, lacks sufficient numbers of patients to make valid conclusions. Farrell and Kent looked at inverted **L** and **C** osteotomies and reported skeletal relapse similar to what had been reported for the BSSO.⁹³ However, because there were different criteria for the use of these two

FIGURE 56-16 Different forms of the **C** osteotomy. Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1434.

types of osteotomies, comparisons between them are questionable. Greebe and Tuinzing compared the stability of mandibular advancement by way of an inverted L or a BSSO.⁹⁸ With only a few patients they did not show any difference between the groups, but they did claim that skeletal relapse was dependent on the ratio of posterior facial height to anterior facial height. The largest studies of the stability of the inverted L included the use of rigid internal fixation in patients who had the mandible advanced. These seem to demonstrate that the use of rigid fixation for this type of procedure is more stable than simple maxillomandibular fixation.^{96,97} However, statements relative to stability of mandibular setbacks or the closure of open bites cannot be made, although a few authors seem to advocate these skeletal deformities as indications for the use of the inverted L osteotomy.^{96,99}

The incidence of facial nerve damage has not been mentioned in any review of these techniques, although it can be inferred to be quite low, given the reports for the external approach to the VSO. The incidence of damage to the inferior alveolar nerve should be higher than the extraoral VSO because of the horizontal portions of the osteotomy, but Reitzik and colleagues reported only a 6% incidence of permanent anesthesia with inverted L osteotomies.⁹⁶ The incidence of unsightly scars, which many clinicians claim deters them from using this approach, is unknown with this group of osteotomies.

Bilateral Sagittal Split Osteotomy of the Vertical Ramus

The BSSO of the vertical ramus has in a relatively short time become the predominant orthognathic procedure of the mandible. Schuchardt is generally given credit for the use of an intraoral approach to what some call the “step” osteotomy of the vertical ramus.²³ Specifically he described parallel horizontal cuts through the cortex of the vertical ramus, the medial

cut being placed above the lingula and a lateral cut being made about 1 cm below that. A split was then made between these two cortices, and the distal segment could then be advanced or set back. Lane evidently described a very similar procedure earlier, but it probably was done extraorally (see Figure 56-4).²² The singular credit for improving on this osteotomy, as well as being its strongest advocate, belongs to Obwegeser, who together with Trauner in 1955 described a sagittal split of the vertical ramus.²¹ This intraoral technique included the medial horizontal cut above the lingula, but the lateral horizontal cut was lower than Schuchardt’s and extended to a point just above the angle, at least 25 mm below the lingual cortical cut (Figure 56-17A). A wide-splitting osteotome was then used to obtain a split between the cortices, with care taken to preserve the inferior alveolar nerve and vascular bundle. This procedure was later slightly modified by Obwegeser by angling the lateral cut more toward the inferior border of the mandible (Figure 56-17B). The major modifications still in use today were suggested by DalPont.²⁴ The change commonly attributed to DalPont is the vertical cut through the lateral cortex behind the second molar. But he also suggested the use of

a medial cut that extends just past the lingula so that the posterior split would occur in the mylohyoid groove instead of back at the inferior border. Multiple other modifications have been suggested, but surprisingly the present-day osteotomy remains very similar to that initially described by Obwegeser and DalPont.

Indications The BSSO has been advocated for almost every possible move that includes the entire horizontal ramus of the mandible.

Technique This osteotomy has had multiple variations suggested, as would be expected for such a popular procedure, but many of them are based on a surgeon’s individual preference, and their effect on the outcome of the osteotomy is questionable. Therefore, only the basic procedures to be followed will be outlined, as well as the significant modifications that have been shown to affect the outcome or seem to have a good theoretical basis.

The incision is started on the anterior portion of the vertical ramus, midway between the occlusal planes. It is carried downward through the middle of the retro-molar fossa to a point about 5 mm behind the second (or in some cases third) molar.

FIGURE 56-17 Obwegeser’s osteotomies of the ramus. A, Original cortical cuts. B, Later lateral cortex cuts. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1435.

Then the incisions wind laterally and forward to a point distal of the first molar (Figure 56-18A). The incision should be kept lateral enough to allow easy closure of the wound with the teeth in fixation. The periosteum is reflected to expose the lateral cortex to the mandible down to the inferior border. The exposure should be limited posteriorly to maximize the blood supply to the proximal fragment; this usually means the exposure ends at about the antegonial notch. A lateral channel retractor can be placed at this time to assist in retraction as the periosteum is elevated from the retro-molar area up the anterior border of the vertical ramus. Special periosteal strippers have been developed to assist this portion of the surgery. The attachment of the temporalis muscle can be tenacious, but it has to be removed to at least the level of the sigmoid notch to ensure adequate access for the medial cut. Most times this means stripping about a centimeter of the temporalis attachment off the anterior border of the coronoid. The periosteum is then elevated from the medial surface of the vertical ramus, starting at about the level of the sigmoid notch and extending back to the medial flare at the start of the condylar neck. Inferiorly the medial cortex is exposed to the lingula, with care being used to minimize trauma to the inferior alveolar nerve as it exits behind and below this point. The periosteal elevation can be extended inferoanteriorly along the internal oblique line to the distal of the second molar to allow better exposure of the osteotomy site. A variety of retractors are available for the protection of the medial soft tissue and nerve, but it is wise to choose one that permits as much visualization as possible while at the same time protecting the soft tissue (Figure 56-18B). Excessive medial retraction should not be done in order to minimize neural damage. It should be noted that no attempt is made to carry the exposure to the posterior border of the vertical ramus.

The osteotomy is started by making a horizontal bone cut through the medial

cortex of the vertical ramus that extends from a point just posterior to and above the lingula to the anterior border. Anteriorly the cut is made about halfway through the ramus, but in the concavity above and behind the lingula it should be shallow to allow the posterior medial split to initiate in the mylohyoid groove (Figure 56-18C). Sometimes it is helpful to use a large round or acrylic bur to remove bone from the internal oblique ridge so that the depth of this concavity can be visualized. Occasionally at the level of this horizontal cut there is no significant cancellous bone to delineate the cortices. Here the use of a half thickness of the ramus is the most practical guideline for judging the depth of this cut.

The vertical cut through the buccal cortex is generally made just distal to the second molar and extends from the inferior border superiorly to the external oblique ridge. Sometimes the mandible is thin and the external oblique ridge ends at the distal buccal aspect of the second molar. In this case the superior aspect of the vertical cut should be posterolateral enough so that the roots of the second molar are not placed at risk. The cut should be as close to perpendicular to the inferior border as possible and extended just into cancellous bone. Caution must be used such that the cut is not taken any deeper because the inferior alveolar nerve can be just medial to the cortex.

The vertical and horizontal cortical cuts are connected, starting superiorly at the anterior border of vertical ramus and continuing down just inside the external oblique ridge to the vertical cut (Figure 56-18D). Again the cut is made into cancellous bone, when at all possible, with the superior part of this connection being as deep as possible, especially if there is no cancellous bone present. This will minimize the chance of an inadvertent fracture of the medial cortex. Difficulty is encountered often if a third molar is present and has been scheduled to be removed at the

time of surgery. It is generally wise to plan for the mandibular third molars to be removed well in advance of the sagittal osteotomy since they can make the surgery more difficult. Experienced surgeons can remove the tooth and obtain a successful split, but almost all try to avoid this situation because it may increase the risk of an unplanned buccal or lingual cortical plate fracture and can make rigid fixation with the use of screws more difficult.

Techniques vary widely in how the split is accomplished. The method to be described is an attempt to be as universal as possible. First, steps are taken to ensure that the limits of the split occur as defined by the horizontal and vertical bone cuts. A narrow (4 mm) thin osteotome is driven along the horizontal cut and directed so that it cuts through the medial cortex above and behind the lingula. It is also used to ensure that the split at the base of the vertical cut is started through the midpoint of the inferior border. Many surgeons also use this type of thin osteotome to “step” along the connecting cut to help ensure that the split stays close to the lateral bone cortex. Traditionally wide-wedging osteotomes have been used to slowly complete the split. More often today a special spreading instrument is used along with a smaller osteotome to allow more control of the split. Generally the movement is initiated along the vertical cut and carefully extended posteriorly. The fine osteotome can be used to keep the split close to the lateral cortex. If the nerve is encountered it is carefully separated from the proximal fragment. The split along the inferior border can be difficult to control, and the judicious use of a thin osteotome will assist in this area. Finally as the posterior split through the medial cortex is made care should be used to prevent the split from continuing behind the mylohyoid fossa and starting up the neck of the condyle. The speed of the split often varies, depending on the elasticity of the bone. In older patients, in

FIGURE 56-18 The bilateral sagittal split osteotomy. A, Incision. B and C, Medial exposure and horizontal cut. D, Vertical cut. E, Bone removal for setback. F, Bone removal for large adjustments. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1436–7.

whom the bone is not as elastic, the split can occur very suddenly. Preventing inappropriate fractures is dependent on the care used not only in making the cortical bone cuts but also in ensuring that the splits occur as planned at the posterior aspect of the horizontal cut and along the inferior border.

Periosteum of the muscle attachment of the medial pterygoid is stripped off the proximal fragment to permit freedom of movement between the two fragments. If the mandibular teeth are scheduled to be moved posteriorly, either on one side when correcting an asymmetry or bilaterally for correction of horizontal mandibular

excess, an appropriate amount of bone is removed at this time from the anterior edge of the proximal fragment. The amount of removal can be based on model surgery or on the prediction tracings. On large setbacks, bone will need to be removed from the anterior edge of the vertical ramus to prevent this area from interfering with

the patient's ability to clean the mandibular second molars (Figure 56-18E). Conversely in large advancements, bone sometimes has to be removed from the remaining portion of the anterior border of the vertical ramus of the distal segment just anterior to the lingula, to prevent encroachment of the segment against the tuberosity (Figure 56-18F). After the opposite side is split the mandible is moved into its new position and stabilized by maxillomandibular fixation. It is preferable that an occlusal splint be used to ensure accurate position of the mandible relative to the maxilla, based on the presurgical model surgery. It is rare that teeth occlude well enough that a splint is not needed.

The placement of osseous fixation is made at this point. As multiple techniques are possible, different options will be described in the following section "Alternative Techniques." After placement of osseous fixation, if rigid fixation is used, the maxillomandibular fixation is released, allowing the occlusion to be checked. The wounds are thoroughly irrigated and closed with the use of a resorbable running suture. No drains or external dressings are generally necessary (Figure 56-19).

Alternative Techniques There are many variations to the foregoing technique. In this section only the major ones will be discussed. The design of the osteotomy itself is an area that has received much attention, with each of these variations generally representing an attempt to decrease the incidence of one or more complications. There is very little supportive research for any of the modifications. Obwegeser was responsible for two variations, the first being his original design, in which the buccal cut was horizontal and parallel to the lingual cut through the cortex of the vertical ramus (see Figure 56-17A). This original technique was modified by making the lateral cortical cut at an angle to the medial cut so that the posterior portion of the osteotomy ended just above the angle (see Figure 56-17B).¹⁰⁰

A popular modification of DalPont's vertical osteotomy is the continuation of this cut completely through the inferior border, which, according to its advocates, made the split easier.⁵⁹ This technique, however, makes the use of rigid fixation with screws difficult.¹⁰¹ A few modifications have been suggested for the connecting cut, with the primary goal of allowing

better control of the proximal fragment. These modifications appear to be primarily personal preferences as there is no evidence that these changes improve the success of the procedure.

A major area of variation for the sagittal split osteotomy of the vertical ramus occurs in the use, or nonuse, of osseous fixation.^{21,25,102,103} The original Obwegeser technique used wire through the superior lateral and medial cortices.¹⁰⁴ This technique, with minor variation, became the standard for the sagittal osteotomy until screw fixation became popular.⁵⁹ The use of circummandibular wire and inferior border wires have also been suggested as possibly better ways of controlling the proximal fragment.¹⁰⁵ No evidence exists that any of these wire techniques have an advantage for minimizing complications.²⁶

Spiessl introduced the concept of using screws for the "rigid internal fixation" of the sagittal osteotomy.²⁶ Following its introduction in 1974 there was a slow acceptance of this method of osseous fixation. Currently there is little debate on the advantages of using rigid internal fixation. However, there exists a wide variety of methods and materials used. Initially the use of three 2.7 mm

FIGURE 56-19 Patient who was treated with bilateral sagittal split osteotomies (for mandibular horizontal deficiency). A–E, Preoperative photographs and head radiograph. (CONTINUED ON NEXT PAGE)

“lag” screws on each side was advocated. A lag screw is placed by drilling a “guiding” hole with a larger drill through the lateral cortex, followed by a smaller hole through the medial cortex that is threaded with the use of a tap. Lag screws are then used to fix the proximal fragment tightly to the distal fragment. Compression across the osteotomy site is felt to be important to speed the healing of the osteotomy as well as to ensure the stability of the mandible. Concern exists that compression may cause increased nerve damage and displacement of the condyles, with subsequent temporomandibular joint dysfunction.^{106,107} An alternative technique, the position screw or bicortical screw, in which both cortices are tapped, has been advocated for stabilizing osteotomy segments.¹⁰⁰ This technique permits mainte-

nance of the gaps that may occur between the proximal and distal fragments, with no effort being made to compress the two segments together. Standardization of techniques does not exist in rigid fixation of the sagittal osteotomy as there are differences in screw sizes, number of screws, materials used, and whether plates are used across the osteotomy sites. Most of the research in the United States has centered on the use of three screws that are 2 mm in diameter. Direct comparisons of differing rigid fixation techniques are rare and do not demonstrate that any one technique is an advantage.¹⁰⁸⁻¹¹⁰ One exception was noted by Fujioka and colleagues, who found that there was more rotation through the osteotomy sites in patients with monocortical plate and screw fixation.¹¹¹

The use of resorbable screws has been a recent addition to fixation techniques. First attempted in Finland, the screws are made from polyglycolic acid using different manufacturing techniques and formulas. Development of these self-reinforced polylactic/polyglycolic polymers that have reliable strength to withstand forces of mastication have made their use possible in orthognathic surgery. The obvious advantage of resorbable fixation is to obviate the need for future hardware removal, which has become important with patient concerns over the potential risks of any kind of permanent implants. The key features that are crucial in its application in orthognathic surgery are the material’s rigidity and strength with an ability to resorb in a timely fashion. A few small studies have shown

apparent stability of these resorbable implants comparable to the metallic fixation; however, some inherent problems with material handling and early fixation failures have been reported.¹¹²⁻¹¹⁴ Suuronen and colleagues reported on the use of poly-L-lactic acid (PLLA) screws for fixation in BSSO, with no apparent malocclusion or skeletal relapse.¹¹² Harada and Enomoto and later Ferretti and Reyneke compared titanium and resorbable screws and noted no difference in healing between two groups and no statistically significant difference in skeletal relapse.^{113,114} However, Harada and Enomoto's patients were placed in maxillomandibular fixation for a period ranging from 9 to 14 days following surgery.¹¹² Kallela and colleagues used self-reinforced PLLA (SR-PLLA) screws for mandibular osteotomies and no maxillo-mandibular fixation was used postoperatively.¹¹⁵ Mean advancement was 4.57 mm at B point, and the mean relapse was 17%. In their 2-year follow-up study in 1999, the authors reported osteolytic changes seen around the resorbable screws in 27% of cases, and the screw canals remained as radiolucent shadows without bony filling. Turvey and colleagues reported their experience with resorbable fixation for 194 osteotomies of the maxilla and/or mandible.¹¹⁶ Forty-three of the patients had a sagittal osteotomy with 2 mm screws placed on each side for fixation. They reported only one infection at a sagittal osteotomy site and one patient who exhibited abnormal masticatory pressures that resulted in loosening of the fixation. Acceptance of the routine use of resorbable fixation with the sagittal split is going to require long-term evaluations with well-designed studies comparing these materials to the metal hardware. The major potential risk of permanent metal fixation is the possibility of bone remodeling, causing the hardware to become noticeable and possibly irritating to the patient. Although not reported in the literature oral and maxillofacial surgeons have had experience

with patients returning to have plates and screws removed simply because these implants have become noticeable. This problem has to be weighed against the still unexplored or unknown side effects of the resorbable materials. A good example of these unknowns is the precise time needed for total resorption and degradation of PLLA in human tissues, which is reported to range anywhere from 90 days to 5 years. Surgeons are going to have to closely follow the literature to determine the practicality of these new materials.

An interesting suggested modification in the BSSO technique is the purposeful changing of the rotational position of the proximal fragment to control the direction of mandibular growth. It has generally been recommended that the proximal segment be maintained as close as possible to its preoperative position. O'Ryan and Epker have further suggested that rotating the proximal fragment in a growing patient can change the vector of condylar growth and, thereby, influence the final mandibular position.¹¹⁷ Studies have failed to support this contention.¹¹⁸ Also there is concern in using a sagittal osteotomy in growing children, especially those requiring long advancement. Huang and Ross demonstrated what they felt to be a stoppage in mandibular growth and condylar resorption in growing patients in whom sagittal osteotomies were performed.¹¹⁹ Whether this was a problem of the techniques used or a problem with performing surgery in such a young group of patients is unknown, but this effect has not been noted in any further literature.

A final modification of the BSSO is the concomitant use of a midsymphysal osteotomy to allow for correction of width discrepancies in the dental arch. Although this procedure could be used with any of the ramal osteotomies, it has only been described with the sagittal osteotomies. First mentioned by Bell, it has become more practical with the use of rigid internal fixation.¹²⁰ A single four-hole plate across the

bone cut, along with an intact orthodontic arch wire, provides sufficient stability.¹²¹ Concerns of adverse effects on the temporomandibular joint and the periodontium were also shown to be insignificant.¹²²

Complications Stability The stability of the sagittal osteotomy of the vertical ramus is the most studied complication in orthognathic surgery. Since the relapse patterns differ between mandibular advancements and setbacks, their particular causes most likely differ; however, many of the principles in preventing relapse may be the same. Whereas much of the research on mandibular advancement has been done in the United States, mandibular prognathism has generally received the greatest interest in the Scandinavian countries and the Far East. This highlights one of the major problems for surgeons attempting to decide on which techniques to use to minimize postoperative skeletal change. There are large variations in research techniques as well as surgical approaches that exist not only between surgical centers in different countries but also within the same country. Fortunately there is enough corroboration in the literature that some general statements can be made.

One of the most important findings made in the stability of mandibular osteotomies was that intermaxillary fixation does not prevent postoperative skeletal change. Although this is true of any type of mandibular osteotomy, it was first recognized in the evaluation of mandibular sagittal osteotomies. It is generally felt that soft tissue pressures and muscle pull are the major factors influencing relapse, especially in mandibular advancement.^{52,53,122} However, early attempts at minimizing these effects, such as suprahyoid myotomies and external supportive devices, have not been shown to be effective.⁶⁴ Internal support techniques, however, have been shown to be effective. Before rigid fixation screws and plates were used,

a type of internal support called skeletal fixation was shown to be effective in decreasing the down and back relapse pattern of mandibular advancements.⁶⁴ This fixation was usually used in addition to maxillomandibular fixation and consists of wires running from the piriform rim to circummandibular wires placed in the cuspid or molar areas (see Figure 56-9). Interestingly, Van Sickles noted a decrease in relapse in patients with large advancements when skeletal fixation was combined with rigid internal screw fixation.¹²³

Other possible causes of relapse that have been implicated are patient's age, preoperative mandibular plane steepness, rotational position of the proximal fragment, amount of distal segment advancement, and the displacement of condyle from the fossa. The effect of mandibular plane steepness is somewhat controversial because of variable results reported in the literature, most of which looked at patients who had wire osseous fixation with intermaxillary fixation. Mobarak and colleagues did clearly find decreased stability in patients with steep mandibular plane angles when rigid internal fixation was used.¹²⁴ Of the remaining variables only the last two appear to be definitively supported by clinical studies as being important. In their multicenter study, Schendel and Epker found that displacement of the condyle from the fossa was a significant predictor of relapse.⁶⁴ This was further confirmed by Lake and colleagues, who also showed the relation between the amount of advancement and the amount of relapse.⁵⁵

The final area that has been considered as possibly affecting relapse in both mandibular advancement and setback is the rigidity of the fixation across the osteotomy site. Early investigators felt that fixation across the osteotomy site may hinder the normal repositioning of the condyle in the fossa that occurs during maxillomandibular fixation.¹⁰³ Later studies showed that wire osteosynthesis was superior to no osseous fixation in frag-

ment position, and the incidence of relapse was less.¹⁰² However, the search for a superior osseous wiring technique that would decrease relapse has not been successful, with most studies that looked at osseous wiring techniques being very consistent in finding a mean relapse of approximately 30%. The large range of individual relapses that does exist has led many surgeons to believe that there are multiple factors that influence relapse.

The use of rigid internal fixation techniques has become the preferred method for minimizing skeletal relapse in the BSSO. Spiessl together with Schmoker and colleagues first discussed the advantages of lag screws in mandibular sagittal split osteotomies. Their initial study of skeletal stability looked at mandibular setbacks, comparing the use of three 2.7 mm screws against wire fixation and one or two screws.¹²⁵ It was not until 1985 that Van Sickles and Flanary showed evidence that a similar rigid fixation technique provided increased stability in mandibular advancements.¹²⁶ Furthermore larger and longer studies have clearly shown the stability of using three bicortical screws for fixation of the sagittal osteotomy.¹²⁷⁻¹³⁰ These studies have reported a mean relapse rate of between 0 and 8%. The majority of studies comparing rigid internal fixation techniques against the use of wire osseous fixation have also confirmed a significant difference in stability between the techniques.¹³¹⁻¹³⁵ Interestingly the only clinical study that evaluated the stability of osseous wire fixation versus rigid screw fixation on patients treated at the same center seemed to show a comparable long-term stability.¹³⁶ This study, however, reported an unusually high stability of the wire osseous fixation group and did nothing to dispute the stability of the screw fixation. The number of screws may very well influence the stability, although only Spiessl's original study demonstrated a difference.

Another common method for rigid internal fixation of the BSSO is the use of

miniplates with monocortical screws. Generally 2 mm systems are used with two screws placed on either side of the osteotomy.¹³⁷⁻¹⁴⁰ Questions remain over the minimum number of screws necessary to prevent relapse and whether more or larger screws will improve stability in longer advancements. It has been shown that a single 2 mm screw does not seem to increase mandibular stability over wire osseous fixation, and thus it could be argued, in light of the previously reviewed research, that an increase in number or size of screws can result in more osseous stability.^{130,141}

Nerve Damage The possibility of damage to the inferior alveolar nerve during the sagittal osteotomy has been well known since the technique was first described, but surprisingly the problem was minimized by early surgeons. Kole first mentioned a high incidence of sensory problems immediately after surgery for patients with sagittal osteotomies, but most clinicians claimed a very low incidence of long-term problems.^{142,143} Walter and Gregg, during an objective study of sensory problems, noted a large incidence of long-term problems.⁴⁵ Since this first definitive study there has continued to be a variety of reported instances of both immediate postsurgical as well as chronic sensory disturbances.

Westermarck and colleagues evaluated 496 sagittal osteotomies for possible correlations between neurosensory dysfunction and other variables, such as the age of the patient, mandibular movement, type of split technique and fixation, degree of intraoperative nerve encounter, and surgical skill.¹⁴⁴ Nerve dysfunction developed in 40% of the cases. The patient's age had a significant influence on the recovery of the neurosensory function as well as the severity of neurosensory disturbance. Intraoperative nerve encounter and nerve manipulation as well as surgical experience were also reported to have an effect on nerve dysfunction. Other variables had

no significant effects on the incidence of neurosensory dysfunction. Ylikontiola and colleagues also found a statistically significant positive correlation between subjective neurosensory loss and the patient's age and, in addition, magnitude of mandibular movement and degree of manipulation of the nerve.¹⁴⁵

A number of other clinical researchers have noted a significant relation between the patient's age and nerve recovery. This finding was noted early on by MacIntosh, who emphasized that he does not use this osteotomy for patients over age 40 years.¹⁴⁶ The only other interesting correlation was made by Van Sickels and colleagues who reported that patients with a concurrent genioplasty had a greater loss of sensation initially.¹⁴⁷ Unfortunately the wide variation in measurement protocols makes comparisons of these various reports difficult. This also makes difficult the evaluation of techniques that have been suggested to decrease the incidence of nerve damage.

White and colleagues pointed out that damage to the inferior alveolar nerve most likely occurs either during the medial retraction of the soft tissues and the nerve as it enters the canal or during the vertical bone cut.¹⁴⁸ Guernsey and DeChamplain felt that damage occurred during the splitting of the mandible and reported the problem of parts of the nerve staying in the proximal fragment after the split.¹⁴⁹ This has led some surgeons to recommend the use of a small flat (spatula) osteotome during the split, instead of the wide-splitting osteotome.¹⁵⁰ The fine osteotome is malleted carefully along the lateral cortex and cancellous bone junction. The nerve is exposed less often during the split by this technique, and consequently it has been assumed that this results in less sensory disturbances.^{151,152} Unfortunately this technique has not been directly compared with any other, and the comparison of the occurrence of sensory disturbance between reports is impossible. Yoshida and colleagues and later Yamamoto and colleagues,

found that nerves that were close to the lateral cortex, as determined by radiographs, were more likely to have severe sensory alteration after surgery.^{152,153} The deficits were also more likely to be present 1 year after surgery when the marrow space between the mandibular canal and the external cortical bone was 0.8 mm or less. Some authors feel that by making the vertical cut in the lateral cortex more posterior, a lower incidence of sensory problems occurs.^{152,154} This has not been substantiated in comparison studies.

Another possible cause of sensory loss to the nerve may be due to the sharp bone irregularities of the proximal fragment or to compression of the nerve when the proximal fragment is positioned and fixed.^{155,156} A round or acrylic bur can be used to remove any bone spicules as well as to widen and deepen the canal in the proximal fragment to prevent this effect. Care must be taken when working around the nerve so that instruments used during the osteotomy do not themselves cause direct damage. This concern was heightened with the use of screw fixation. Paulis and Steinhauser noted slightly higher incidences of long-term sensory loss in patients with rigid screw fixation compared with simple osseous fixation but statistics were not used and the significance of their numbers is highly suspect.¹⁵⁷ Nishioka and colleagues did a comprehensive study involving sensory loss after the use of screw fixation and found the incidence of inferior alveolar sensory loss to be high but well within the range of sensory loss reported by other well-designed objective studies.¹⁵⁸ Subsequently the effect of type of fixation on the neurosensory functional outcome was extensively studied by a number of authors using different methods of clinical testing.¹⁵⁹⁻¹⁶² Brush stroke detection was diminished to a greater extent in the rigid fixation group compared with the wire fixation group from 8 weeks through 2 years postoperatively; however, monofilament detection

did not show significant difference between types of fixation throughout the 2-year follow-up.¹⁵⁹ Despite a great number of studies on neurosensory disturbance following orthognathic surgery, the severity of inferior alveolar nerve injury is difficult to compare across different studies since there is lack of standardization as to which neurosensory tests were used, ways the tests were performed, and how the results were interpreted. Certain neurosensory tests are more sensitive in detecting sensory nerve deficit than others. Tests that evaluate patients' abilities to discriminate direction have been shown to be more sensitive indicators of trigeminal neurosensory impairment than other tests such as light touch detection. Westermarck and colleagues used visual analog scale, light touch perception, and temperature testing and concluded that there is a good positive correlation with nerve dysfunction.¹⁶⁰ Alternatively, Chen and colleagues compared three methods of assessing neurosensory disturbance following BSSO: two-point discrimination, pressure-pain thresholds, and perceived sensation changes in specific facial regions.¹⁶¹ The two-point discrimination test was consistent with patients' self-ratings of neurosensory problems using facial maps, but the pressure-pain test was the least sensitive to neurosensory changes. The frequency of the inferior alveolar nerve disturbance ranged from 10 to 94% depending on the test method and the test site used. In a well-controlled study by Nakagawa and colleagues, the occurrence of a long-lasting postoperative trigeminal sensory hypoesthesia was found to be dependent on the nerve involvement at the bone split interface, the manner of fixation, or the intraoperative handling of the tissue surrounding the nerve.¹⁶²

Although the neurosensory function of the inferior alveolar nerve following sagittal split osteotomy has received a great deal of attention, very few studies have documented the incidence of lingual nerve

dysfunction. Jacks and colleagues retrospectively reviewed the patient-reported incidence, duration, and perceived deficit associated with lingual nerve function.¹⁶³ In the BSSO patients 19% reported lingual nerve sensory changes of whom 69% reported a resolution of symptoms within a year and 88% reported altered daily activities. When compared with the inferior alveolar nerve, lingual nerve sensory changes occurred much less frequently and resolved more frequently and sooner, but they were associated with greater perceived deficits in patients' daily activities. Zuniga and colleagues were the first to report on studies performed to assess the effect of lingual nerve injury and repair on human taste perception.¹⁶⁴ Gent and colleagues later examined perceived taste intensity and taste quality identification on localized regions of the tongue after orthognathic surgery.¹⁶⁵ Lingual nerve function in taste perception was diminished at 1 to 2 months after surgery, likely due to impaired chorda tympani nerve function, but it improved by 6 to 9 months after surgery.

Temporomandibular Joint Dysfunction

The incidence of temporomandibular joint dysfunction will be considered in two ways: first, the incidence of temporomandibular joint symptoms that are present after surgery compared with preoperative findings; and second, the change in mandibular range of motion. The latter may obviously not be related to temporomandibular joint dysfunction; on the other hand it has to be considered if evaluating the effects of the surgery on the temporomandibular joint. Unfortunately very few authors related these two areas when they reported on the effect of the sagittal osteotomy. Another factor that must be taken into account in evaluating the effects on the temporomandibular joint in any recent orthognathic surgery is the possible contribution of the orthodontics as provided in conjunction with the

surgery. There is still debate on how much orthodontics itself may help or cause temporomandibular joint dysfunction.

Similar to sensory loss the potential of the sagittal osteotomy causing temporomandibular joint dysfunction was recognized early in its use.²⁴ Reporting of the incidence of temporomandibular joint problems, however, has been highly variable, with most authors recording only the postoperative complaint without any reference to the preoperative condition. Some of the first reviews that did look at pre- and postoperative temporomandibular joint symptoms seemed to imply an increase in joint noises, but not in pain, following the sagittal osteotomy.^{56,166,167} The use of rigid screw fixation was felt by some to cause an increase in temporomandibular joint problems.¹⁶⁸ This concern was highlighted by radiographic findings of condylar changes that occurred with rigid screw fixation. Kundert and Hadjiangelou demonstrated that this tendency occurred with both wires and screws but was greater with rigid fixation than with a wire osseous fixation technique.¹⁰⁶ In neither study was there a discussion of whether these changes had any clinical consequences. Hackney and colleagues found in their study of patients, in whom bicortical screw fixation with mandibular sagittal split was used for mandibular advancements, that little change in condylar position occurred, and there was no significant effect of the surgery on temporomandibular joint symptoms.¹⁶⁹ Paulis and Steinhauser compared preoperative and postoperative temporomandibular joint symptoms in two large groups who had either rigid screw fixation or wire osseous fixation of sagittal osteotomies.¹⁵⁷ They could find no difference in postoperative incidence between the two groups and in fact found a notable decrease in temporomandibular joint pain in both groups. The possibility that the sagittal osteotomy may benefit many patients with temporomandibular joint

symptoms was suggested by Martis and Karabouta.^{170,171} He reported that only 11% of the patients who had temporomandibular joint symptoms before surgery had any symptoms after, whereas about 4% of the asymptomatic patients had problems after surgery. These results were better than but consistent with a study of all types of orthognathic surgery patients, which showed an improvement in a large percentage of patients, with relatively small risk for the asymptomatic patient.¹⁷²

There is, surprisingly, a body of evidence in the literature that sagittal split osteotomy may have a beneficial effect on preexisting temporomandibular joint dysfunction. It is generally believed that temporomandibular joint dysfunction is found at a higher incidence in Class II patients compared with patients with Class I and III malocclusions. The use of the sagittal split osteotomy as an alternative to the mandibular condylotomy to treat patients with painful temporomandibular joint dysfunction has been proposed by some authors.¹⁷³ They suggest repositioning the proximal segment and increasing the joint space, both of which are thought to have an unloading effect on the highly innervated retrodiskal tissues. However, this is controversial and there has not been adequate research to confirm this impression.

Debate on rigid versus wire fixation relative to their effects on the temporomandibular joint has led to a number of studies. Most have shown that there is no significant difference in the incidence of temporomandibular joint symptoms between patients who have received rigid fixation versus wire osteosynthesis during sagittal split osteotomies.¹⁷⁴ Feinerman and Piecuch compared the temporomandibular joint outcomes of the miniplate with monocortical screw group versus the superior border wire fixation with maxillomandibular fixation group.¹⁷⁵ They found no demonstrable long-term differences between the two groups with respect to mandibular vertical opening,

crepitation, and temporomandibular joint pain. In fact masticatory muscle pain and temporomandibular joint clicking improved with rigid fixation and worsened with nonrigid fixation.

The only negative report on the effects of BSSOs on the temporomandibular joint was submitted by Wolford and colleagues.¹⁷⁶ They evaluated changes in temporomandibular joint dysfunction in patients with presurgical temporomandibular joint internal derangement as well as the long-term stability of patients who underwent orthognathic surgery. Unlike other clinicians they observed the appearance of new or an aggravation of existing temporomandibular joint symptoms in a group of patients who were an average of 14 months postsurgery. Therefore, the authors recommended that surgical correction of preexisting temporomandibular joint pathology be considered, either preceding or simultaneous with the orthognathic surgery. In summary it appears that there is a low risk of worsening temporomandibular joint symptoms in patients who do have some form of temporomandibular joint dysfunction when using the BSSO. Conversely this osteotomy may result in improved symptoms in a greater number of patients. Unfortunately methods of predicting this outcome in individual patients have not been developed.

Mechanical displacement of the condyle out of its correct position has been implicated as a significant factor in postsurgical skeletal relapse after sagittal split osteotomy. For this reason, as well as in an attempt to minimize temporomandibular joint problems, a great deal of interest has been focused by early investigators on the issues of condylar position after sagittal split osteotomy.¹⁷⁷ There have been a myriad of technical notes on how to maintain the preoperative condylar position and use of different condylar repositioning devices, based on anecdotal reports of individual surgeon's experiences. Harris and colleagues examined fac-

tors influencing condylar position after sagittal split osteotomy fixed with rigid fixation.¹⁷⁸ The amount of advancement did not correlate with condylar displacement. Condyle angulation and superior-inferior movement did correlate somewhat with the amount of advancement. In addition Van Sickels and colleagues found that the condylar position was slightly different with rigid fixation versus wire osteosynthesis beyond 8 weeks postoperatively, but the ultimate position of the condyle was not different.¹⁷⁹ They found, as have many others, that the final condylar position was posterior and superior after a mandibular advancement. Renzi and colleagues specifically examined Class III patients without preoperative temporomandibular joint dysfunction; half of the patient population was treated with a condylar positioning device whereas the other half of patients was treated with manual control of condylar position.¹⁸⁰ The condylar repositioning device did not prevent the changes in condyle positions in all cases. Neither group had any skeletal or occlusal relapse or postsurgical temporomandibular joint dysfunction. However, the incidence of new onset of temporomandibular joint dysfunction in healthy individuals following orthognathic surgery is known to be low as previously mentioned, and this study only included patients without preoperative temporomandibular joint symptoms. Therefore, it is not surprising that the patients did not develop any postsurgical temporomandibular joint dysfunction. The clinical implication of condylar position in the healthy versus the preexisting temporomandibular joint dysfunction groups may be different; therefore, the true clinical significance of condylar position in exacerbation of temporomandibular joint symptoms remains an enigma.

Computed tomography (CT) has enabled clinicians to assess and quantify condylar position changes in three planes of space. Alder and colleagues reported

that changes in condylar position occurred in all planes of space, but the most common postoperative condyle position was more lateral with increased condyle angle, the coronoid process was higher, and the condyle was again reported to be more superior and posterior in the fossa.¹⁸¹ Rebellato and colleagues found in their study group that there was increased superior postsurgical movement of the condyles with increasing magnitudes of surgical advancement of the mandible.¹⁸²

Magnetic resonance imaging (MRI) has revolutionized the examination of the temporomandibular joint, in that it allows not only the evaluation of condylar position but also provides information on the disk. Gaggl and colleagues reported clinical and MRI findings of the temporomandibular joint in Class II patients, preoperatively and 3 months postoperatively.¹⁸³ Clinically patients had improvements in joint pain and abnormal joint sounds such as clicking. The MRI showed displacement of the disk in 38 of the 50 joints preoperatively and in 28 postoperatively. No correlation was made between the change in disk position and improvement in temporomandibular joint symptoms, which is consistent with other MRI studies. Ueki and colleagues made interesting comparisons of the condylar and disk positions after BSSO and intraoral vertical ramus osteotomy (IVRO) and correlated these findings with temporomandibular joint symptoms postoperatively.¹⁸⁴ Fewer or no temporomandibular joint symptoms were reported by 88% of the patients who underwent IVRO and by 66% of patients who underwent BSSO. MRI study showed no change in anterior disk displacement after BSSO; however, improvement was seen in 44% of patients who underwent IVRO, at least in the early postsurgical period.

The effect of the sagittal osteotomy of the vertical ramus on mandibular range of motion has been extensively studied. Whereas Stacy found that patients who underwent mandibular setbacks with

maxillomandibular fixation generally returned to presurgical limits within 9 months following surgery without any physical therapy, other authors have found very different results.¹⁸⁵ Storum and Bell found that without active physical therapy after the release of maxillomandibular fixation there was a decrease in the patient's ability to achieve preoperative opening when compared with patients who had an active rehabilitation program.¹⁸⁶ This latter study is consistent with most clinicians' experience, and some form of active physical therapy is recommended after release from maxillomandibular fixation. However, there is some evidence that rigid internal fixation that permits mandibular movement soon after surgery may result in a more rapid return to preoperative mandibular movement.¹⁸⁷ Nishimura and colleagues found that final postoperative mouth opening was not significantly influenced by the type of fixation.¹⁸⁸

A final poorly understood temporomandibular joint complication is spontaneous resorption of condyles following sagittal osteotomies.¹⁸⁹ This is a process that may be different from standard relapse with the abnormal resorption being seen primarily in a specific group of patients—young females who have had a history of temporomandibular joint dysfunction before surgery and have undergone a mandibular advancement. Remodeling of the condyles is now accepted to occur after sagittal osteotomies, but fortunately only rarely has this condylar resorption resulted in significant clinical changes. Cutbirth and colleagues evaluated long-term condylar resorption after mandibular advancement stabilized with bicortical screws.¹⁹⁰ Large advancement and preoperative temporomandibular joint symptoms significantly correlated with long-term postoperative condylar resorption at the mean follow-up of 3 years. The amount of vertical resorption did not directly correlate with the amount of relapse seen between 6 to 8 weeks and

long term. Surprisingly there was an improvement in temporomandibular joint symptoms for the group as a whole and even among the group who developed condylar resorption. It should be noted, however, that it is often difficult to draw a line between normal condylar remodeling and condylar resorption. In the Cutbirth study, the authors arbitrarily established a parameter of less than 10% loss of height of the condyle to be considered as "normal remodeling."¹⁹⁰ Attempts to delineate the normal versus pathologic process are difficult, and may lead to an underestimation of the number of condylar resorptions that may occur.

Hoppenreijns and colleagues evaluated the long-term treatment results of 26 patients (23 women and 3 men) who developed progressive condylar resorption following orthognathic surgery.¹⁹¹ The preoperative condylar configuration was noted in patients with deep bites to have more resorption on the superior aspect of the condyle, whereas patients with anterior or open bites had resorption on the superior and anterior surfaces of the condyle. Thirteen patients were managed without surgery after the diagnosis of condylar resorption, and only 3 patients had Class I occlusion at the end of treatment. Thirteen patients underwent a second surgical correction, with 7 patients having satisfactory occlusal results. Four of the patients had relapse with a stable occlusion not requiring further treatment, and 2 patients had complete relapse requiring a third surgical procedure. It was suggested that without surgical intervention after condylar resorption, further resorption ceased after approximately 2 years. The authors speculated that either the mechanical loading during or after BSSO and/or the impediment of blood flow to the condylar segment and the temporomandibular joint capsule may play a role in the condylar resorption. However, the etiology for this process is still unclear, but it does seem to be self-limiting and the resulting

dental skeletal deformity can usually be successfully treated with further mandibular surgery.

Miscellaneous Complications A wide variety of other complications have been reported following the sagittal split osteotomy of the mandibular ramus. Early reviews of complications from this procedure noted some trouble with excess blood loss, postoperative airway compromise, large aseptic bone loss, and facial nerve damage. Greater experience and better instrumentation seem to have dramatically decreased the incidence of these problems. Bleeding is generally easily managed by direct or indirect pressure over the bleeding soft tissue and vessels. Lanigan and colleagues, reporting on a questionnaire sent to a large number of oral and maxillofacial surgeons, found only 21 cases of significant bleeding following mandibular osteotomies.¹⁹² Suspected sources of bleeding included the inferior alveolar artery, facial artery, maxillary artery, and retromandibular vein. Management primarily included direct pressure packing or ligation of the vessel via the open wound. Extraoral approaches to gain access to the facial or external carotid artery can be ineffective due to the collateral circulation. Angiography with embolization is considered appropriate in cases of acute persistent postoperative arterial bleeding.

One group of problems that seems to persist is the inappropriate fracture in the proximal segment or the posterior lingual aspect of the distal segment. Good surgical technique minimizes these problems, and care used during the split is worth the effort, as correcting a "bad" split can be difficult. Fortunately the use of screws and plates does improve the chance of obtaining a satisfactory result, in light of an unexpected fracture, with minimum further morbidity to the patient.¹⁹³ It has been felt that one of the major risk factors predisposing to buccal cortex fracture is the pres-

ence of impacted third molars. Precious and colleagues retrospectively reviewed two groups of patients: one group with retained impacted third molars removed during BSSO and the other group with third molars having been removed at least 6 months before BSSO.¹⁹⁴ There was a 1.9% incidence of unfavorable fractures, and the majority of fractures occurred with the group who had the third molars removed at least 6 months before the BSSO. Mehra and colleagues reported 2.2% unfavorable fractures in 500 procedures.¹⁹⁵ They noted a larger percentage of unfavorable fractures in the patients with retained third molars (3.2% vs 1.2%). This finding is consistent with that of Reyneke and colleagues who found that the presence of unerupted third molars increased the degree of difficulty of BSSO, and all 4 (out of 139 patients) unfavorable fractures occurred in those patients with unerupted third molars present at the time of surgery.¹⁹⁶ Ideally third molars should be extracted at least 6 (preferably 9) months prior to the mandibular osteotomy, both to minimize unfavorable fractures and to allow optimal bony healing, especially when using internal rigid fixation.

Airway patency has become an area of concern to some clinicians, especially in the cases where the mandible is set back. Riley and colleagues reported two patients who were surgically treated for prognathism and later developed sleep apnea.¹⁹⁷ Kawamata and colleagues studied patients with mandibular prognathism who were treated with either sagittal split osteotomy or IVRO for mandibular setback.¹⁹⁸ Using three-dimensional CT images they quantified the airway space after surgery and found that the lateral and frontal widths of the pharyngeal airway had decreased by 23% and 11%, respectively. This reduction in airway dimension did not resolve at 1 year after surgery. However, in the longer postoperative period, a visible recovery of pharyngeal width was seen in some cases. These findings of the decreased airways sec-

ondary to mandibular setback have been confirmed by other investigators. Noteworthy, however, is that only one of these clinical studies had a reported incidence of a patient developing sleep apnea following orthognathic surgery. Therefore one should be cognizant of any physiologic and medical etiologic factors that may have contributed to the emergence of sleep apnea symptoms, rather than simply using the measurement of the posterior airway space following mandibular osteotomies as the sole means of predicting a new onset of sleep apnea disorders.

In general, the risk of infection seems to be low with the BSSO. In their clinical review of 700 consecutive cases of mandibular osteotomies, Bouwman and colleagues reported that screw removal due to infection was performed in 2.8% of cases.¹⁹⁹ Screw loosening occurred in the first postoperative week, which resulted in an occlusal discrepancy in four patients. Fifteen sides required one or more screws to be removed as a result of infection. In a large study of complications in orthognathic surgery, Acebal-Bianco and colleagues reported 36 infections out of 802 mandibular osteotomies (0.05%), but only 5 patients had hardware removed due to infections.²⁰⁰

Horizontal Ramus Osteotomies

Since Blair's first description of his osteotomy of the horizontal ramus, there have been a variety of osteotomy designs documented. Initially the surgeons used extraoral, or a combination of extraoral and intraoral techniques, but since the early 1950s the advocated approaches have primarily been intraoral. It is difficult to choose a representative technique for the body osteotomies because of the wide variations described as well as the relative infrequency of these techniques. Of the described procedures, the step osteotomy will be reviewed because of its versatility and its apparent common use in some centers.

Indications The largest limitation of body osteotomies is that the osteotomy has to be made through the dental alveolus and, thus, edentulous spaces are usually required. Because these osteotomies are made in front of the pterygomasseteric sling, some surgeons feel that the results are more stable and, therefore, prefer body osteotomies in the treatment of prognathism when there are already edentulous spaces. Other unusual mandibular abnormalities, such as asymmetries, may also be treated more appropriately with one of these forms of osteotomy.

With the step osteotomy the surgeon has to be concerned about the horizontal component of the "step," which often has to be made between the inferior alveolar nerve and the apices of the teeth. Sufficient room should therefore be available for this cut, unless the surgeon plans to externalize part of the inferior alveolar nerve so that the cut can be made at the level of or below the canal.

Technique An incision is made 4 to 5 mm below the level of the attached gingiva (enough tissue is left superiorly to permit later suturing) and is carried forward at this level until the cuspid, where it can be dropped down 5 mm and extended forward to the midline (Figure 56-20A). The periosteum is elevated inferiorly until the mental foramen is located and then the remainder of the periosteum is stripped to expose the area of the osteotomy. The attached gingiva is also carefully elevated in the area of the dental alveolar cut so that it can be protected during the osteotomy.

The vertical cut through the alveolus is made with either a saw or bur. A finger should be kept on the lingula to prevent the power instrument from penetrating the mucosa. When the surgical plan includes a mandibular setback, a block of bone needs to be removed to permit this movement. The distance between the parallel cuts necessary to remove the bone should be as close as possible to the planned setback, as

determined by the model surgery. The vertical cuts are taken inferiorly to the level of the planned horizontal cut, which would be at least 5 mm below the dental apices. The inferior vertical cuts are then made, again using parallel cuts as necessary for a setback of the distal fragment. Finally the horizontal cut is made, preferably by a saw, to minimize bone removal and endangerment of the apices or the inferior alveolar nerve (Figure 56-20B).

The distal segment is related to the proximal segment with an occlusal splint and fixed with maxillomandibular fixation. If the mandible is set back any distance a wedge of attached tissue over the alveolar vertical osteotomy needs to be removed to permit the setback. This wedge should be narrower than the planned movement to allow tight mucosal contact. This eliminates the need for suturing in this area, which is often difficult, if not impossible. Osseous wire fixation can be placed at the inferior border or, if a rigid fixation technique is desired, straight four-holed plates with

monocortical screws can be placed above and below the nerve. With a rigid fixation technique the maxillomandibular wires can be cut and the segment's stability and position are checked before closure of the wound. The surgical sites are thoroughly irrigated and the mucosa is then closed with a resorbable suture. Maxillomandibular fixation, if used, is maintained for 6 to 8 weeks (Figure 56-21).

Alternative Techniques There are multiple variations of body osteotomies. Generally the mucosal approaches are similar, although some surgeons prefer to make a cervical incision posterior to the mental foramen and then carry it below the attached tissue in the anterior symphyseal region. This approach unfortunately presents some difficulty in wound closure, especially if maxillomandibular fixation is chosen.

One of the most difficult variations in the surgical approach occurs when there is a need for visualization or exteriorization

of the inferior alveolar nerve, if an osteotomy is planned through the canal. The easiest method for this is similar to that described by Epker.²⁰¹

After the lateral surface of the mandible is exposed in the area of the planned osteotomies, parallel horizontal cortical cuts are made on either side of the anticipated route of the nerve. These cuts are extended beyond either side of the planned osteotomy, sufficient to permit adequate approach to the nerve, as well as to permit enough freedom of the nerve during stretching or compression that will occur with the planned segment movements. Perpendicular cuts are made just through the cortex at about 1 cm intervals (Figure 56-22). Starting with the forward cuts a thin sharp 4 mm osteotome is carefully used to start a cleavage line through the cancellous bone, preferably just below the cortex. As each individual section is broken away the medial aspect of the fragment needs to be checked to ensure that a nerve is not still attached to it. After all the small lateral cor-

tical segments have been removed, often the nerve has been exposed and judicious use of a small surgical curette is all that is needed to remove any bone spicules over the nerve as well as carefully lift the nerve out of its canal. If cancellous bone is still covering the nerve, then a medium-sized round bur can be used to carefully remove the overlying bone. A small periosteal elevator or a surgical curette can be positioned in the lateral aspect of the canal when the nerve is exposed and the thin bur used to remove the remaining overlying bone. Following the visualization or exteriorization of the nerve the osteotomies can proceed as planned.

Although primarily used for distal fragment setback, the step osteotomy can be used for advancement. To accomplish that, a horizontal incision has to be made on the lingual side of the alveolus, posterior to the vertical alveolar bone cut. The mucoperiosteum below this cut can then be elevated to allow it to be stretched with the advance-

ment. The lateral incision is designed to permit the labial tissue to be pulled lingually, without tension, so that soft tissue closure can be done. Bone grafts are generally used in the gaps created by the advancements, especially in the alveolar area, where prostheses may later be placed.

Sagittal osteotomies of the horizontal ramus have been described with either an extraoral or intraoral approach possible.^{202,203} In the intraoral approach the lingual exposure has to be increased to make the vertical cortical cut. This generally requires that the incision on the lingual side of the teeth be brought forward, close to the midline, so that retraction may occur without endangering the surrounding soft tissue. The advantage of this type of osteotomy is that it allows the use of rigid internal fixation with bicortical screws, and generally a bone graft is not needed if the distal segment is advanced.

Complications Reports of body osteotomies in the literature include mostly case histories; hence, there are few series reporting an incidence of complications. The wide variety of techniques makes it impossible to make any definitive statements about body osteotomies. Therefore, this section will be primarily limited to the listing of the reported complications, many of which can be anticipated simply from the knowledge of the anatomy of the area.

Stability One of the primary reasons given by surgeons for using a body procedure is the stability of the technique. Sandor and colleagues looked at relapse of the step osteotomy and found it to be very stable.²⁰⁴ Most other authors have not strictly analyzed the results but claim a good long-term stability with their particular technique.^{205,206}

Neural Complications Those studies that include reports of the incidence or duration of neurosensory damage report a high recovery ratio.^{205,206} Unfortunately

these studies are of questionable value because of the inadequate testing method. It can be expected, however, that immediate postoperative sensory loss will be present after any of the body osteotomies, especially those that require visualization or exteriorization of the nerve. The incidence of devitalization of teeth on either side of the osteotomy, or of those teeth above the horizontal cut of the step osteotomy, is unknown, although it is probably similar to those reported with mandibular subapical osteotomies.

The increased potential of nonunion in body osteotomies has been discussed, but the incidence is unknown. The possibility of this occurring is probably very low if, as has been suggested, care is used in osteotomy design to ensure sufficient bone contact as well as in the provision of adequate fixation.

The possibility of periodontal defects does exist for osteotomies made close to the teeth where the surrounding soft tissue pedicle may be injured. As has been noted earlier the possibility of this occurring in midline osteotomies is low, but whether this can be related to other parts of the dental alveolus is doubtful.²⁰⁷

Subapical Osteotomies

There are essentially three types of mandibular subapical osteotomies: the anterior subapical, the posterior subapical, and the total alveolar osteotomy. Each has a place in orthognathic surgery and, therefore, the indications and techniques of each shall be described individually. Their complications are similar; accordingly they will be discussed together in one section.

Anterior Subapical Osteotomy Indications The subapical osteotomy has historically been popular because of its versatility, and it has been used to move the anterior mandibular teeth and alveolus in almost every conceivable direction. The biggest concern of surgeons in this procedure is the potential of damaging teeth and, therefore,

space must be present or made to permit a safe vertical cut in the dental alveolus.

Procedure If necessary, teeth are removed to permit the osteotomies or to provide space for the planned alveolar movement. The incision is started about 1 cm behind the planned vertical osteotomy and is carried forward about 4 to 5 mm below the attached tissue until reaching the cuspid, at which time it can be dropped down and carried to the midline to connect with an opposing incision. Periosteum is elevated, exposing the lateral cortex of the mandible, with care being used around the mental foramen as well as some attachments being left at the inferior border to ensure stability of the soft tissue chin. The attached tissue at the planned vertical osteotomy site needs to be elevated, and if posterior movement of the segment is anticipated, some of this tissue may have to be removed. As mentioned with the step osteotomy the width of the tissue removed should be less than the planned posterior movement to ensure adequate soft tissue contact.

The vertical osteotomies are made using parallel cuts when the posterior movement of the segment is planned. Good preoperative radiologic evaluation and planning will minimize the chance of

damage to the inferior alveolar nerve. Most anterior subapical osteotomies are designed to include the cuspids and the incisors, which generally place the vertical cuts anterior to the mental foramen. Difficulties arise if the planned osteotomy includes extraction of the first bicuspid or if the cut is planned behind this point. The importance of being able to make the horizontal cut at least 5 mm below the teeth apices cannot be overemphasized. Not only the vitality of the teeth but the whole segment is affected by the level of the horizontal cut. If parallel horizontal cuts are planned to move the anterior segment apically, the superior cut is made first. The inferior cut is then made, and the segment of bone is removed without overly manipulating the dental alveolar segment and increasing the likelihood of injuring the soft tissue pedicle (Figure 56-23A). Beveling of the cut from anterior to posteroinferior will minimize the amount of bone to be removed and increase the size of the lingual pedicle. Usually, on trying to position the mobile dental alveolar segment to the rest of the mandible, further bone interferences are found. These exist primarily on the lingual cortex of the vertical cuts and care must be used in the rotation of the mobile segment to access this cortex. If possible a

retractor should be placed between the bone and the thin lingual mucosa to minimize the soft tissue trauma.

After ensuring a good fit in the surgical splint the segment is stabilized by either wiring the splint to the teeth individually (Figure 56-23B) or by circumferential mandibular wires that can be combined with intermaxillary fixation. Osseous wires or plates with monocortical screws are rarely needed for stability but can be used if desired. Bone gaps caused by movement of the segment, especially by vertical movement necessary for the closure of an anterior open bite, should be grafted. The use of cortical bone from the symphysis, as advocated by Kole, has been popular because many patients with an anterior open bite have the long anterior face which can be improved by removal of the bone (Figure 56-23C).²⁸ The surgical site is then irrigated thoroughly and closed with resorbable sutures.

Posterior Subapical Osteotomy Indications The posterior subapical osteotomy has few indications, especially if orthodontics are available to the patient. Primarily it can be used as a correction of supereruption of posterior mandibular teeth or ankylosis of one or more posterior teeth. Abnormal buccal or lingual posi-

FIGURE 56-23 The anterior subapical osteotomy. A, Osteotomy. B, Occlusal splint. C, Bone graft from chin for correction of anterior open bite (Kole). Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1450.

tion of these teeth can also be improved on when orthodontics is not feasible.²⁰⁸

Technique The following technique is that of Peterson, who first described this osteotomy.²⁰⁸ This procedure can be done under local anesthesia with sedation as well as with general anesthesia. An incision is started 3 to 4 mm laterally to the attached gingiva, beginning at the anterior border of the vertical ramus. This incision is made down into the bone and is carried forward to the cuspid. Periosteum is stripped superiorly and inferiorly sufficiently to expose the lateral cortex for the planned osteotomies (Figure 56-24). The osteotomy is outlined with a bur, based on the preoperative radiographic analysis of the length of the roots and the position of the nerve. The vertical cuts are made first through both cortices with a fine osteotome or thin saws. The horizontal cut is carried only through the buccal cortex, and a thick splitting osteotome is used to complete the osteotomy. Care is taken to

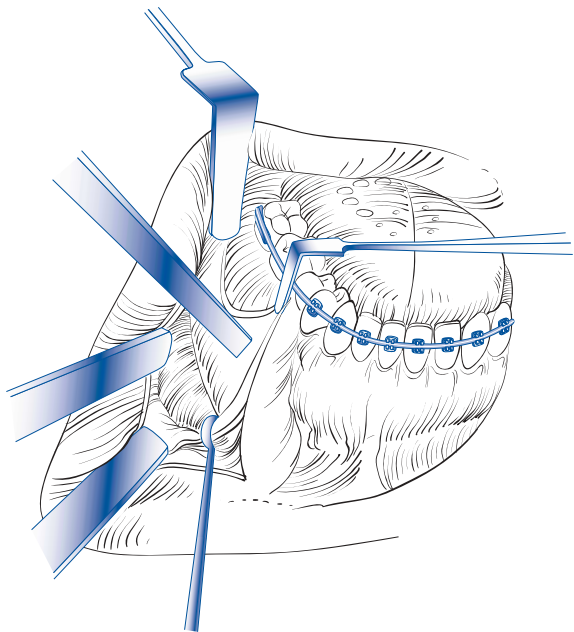

FIGURE 56-24 The posterior subapical osteotomy. Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillo-facial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1451.

ensure that the nerve is not caught in the mobile segment and that appropriate bone adjustments are made to permit the planned movement. The segment is positioned and stabilized with an acrylic splint and wire. Grafting is used if a bone gap remains. The mucosa is closed with a running resorbable suture.

Alternative Techniques Major modification of the foregoing technique would be appropriate if insufficient distance lay between the dental apices and the inferior alveolar nerve. In that situation the nerve can be externalized, as described previously, and a horizontal cut made through the canal. Periapical radiographs taken intraoperatively after the buccal horizontal cut will ensure that the osteotomies lie safely away from the teeth and nerve. This latter technique has been found to be useful, as a good visual angle is difficult with the posterior teeth. Also, with either of these techniques, the horizontal cut can be taken safely through the lingual cortex, which does away with the unpredictability of the lingual cortical fracture.

Total Alveolar Osteotomy

Indications The total mandibular alveolar osteotomy, first described by MacIntosh and Carlotti, has limited application but can prove valuable in mandibular dental alveolar protrusion or retrusion.²⁰⁹ It has also been advocated for the closure of anterior open bite when used with a bone graft.

Technique An incision is started on the external oblique ridge of the base of the vertical ramus. The incision is carried down to bone and extends forward 4 to 5 mm below the attached gingiva. The incision can drop lower as the canine is passed and meets the contralateral incision at the midline. The periosteum is elevated to expose the lateral cortex, with care

used around the mental nerve, as well as leaving some attachment at the inferior border of the symphysis for the soft tissue chin. The vertical cut posterior to the last molar is made first and is taken down to the level of the planned horizontal osteotomy. As with the step osteotomies the horizontal cut needs to be well placed, based on periapical radiographs. If this cut cannot be made safely between the dental apices and the inferior alveolar nerve, then the nerve needs to be exteriorized or the cut placed below the nerve (Figure 56-25A). The horizontal cut can then be placed low enough to be away from dental apices as well as allowing a good vascular pedicle to the dental alveolus. The angle of the horizontal cut can be made to facilitate the segment movement; for instance, a flat cut permits the straight advancement of the segment without changing mandibular height, at the same time maintaining a large area of bone contact.

The mobile segment is related to the maxilla with an acrylic occlusal splint and intermaxillary fixation. Osseous fixation is achieved, with the lateral cortical wires being placed in the first bicuspid area. As with correction of an anterior open bite any bone gaps created are filled with graft material. The wound is thoroughly irrigated and closed with resorbable suture.

Technique Variations Booth and colleagues suggested a variation of the total mandibular subapical osteotomy that combines the sagittal split osteotomy of the vertical ramus with the total mandibular alveolar osteotomy (Figure 56-25B).²¹⁰ This modification has a number of advantages over the original technique. First the osteotomy is made below the inferior alveolar nerve, thereby decreasing the risk of damaging the inferior alveolar nerve and the apices of the teeth, at the same time preserving much of the vascular supply to the mobile segment. Also the sagittal part of the osteotomy allows a larger bone contact area to assist in healing.

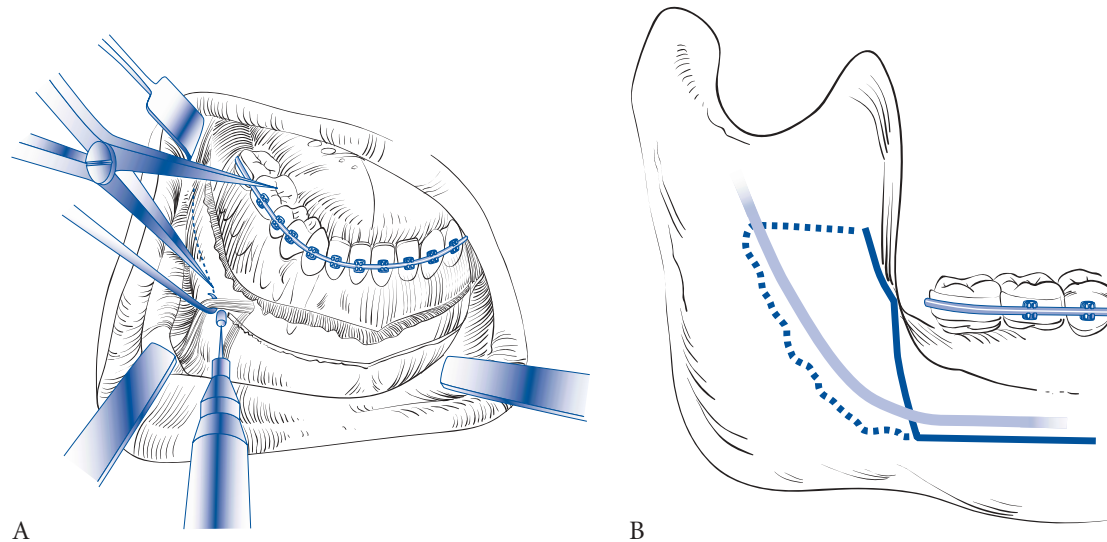

FIGURE 56-25 A and B, Variations of the total mandibular alveolar osteotomy. Adapted from Bloomquist DS. Principles of mandibular orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1451.

The total mandibular alveolar osteotomy can also be divided into interdental segments to correct axial inclination of teeth or to close the edentulous area. These modifications are not easily done with Booth's osteotomy but can be valuable as a variation of the original procedure.

Complications The complications of all mandibular alveolar osteotomies will be considered together because of their similarities. Stability is often mentioned as one of the advantages of any of the alveolar osteotomies because of the minimal soft tissue forces generally placed on these areas. Unfortunately there have been very few studies to document this claim. Those that have been done question the stability of these segmental osteotomies. Theisen and Guernsey evaluated six patients who had anterior subapical osteotomies.²¹¹ At 1 year after surgery, an average of 1 mm of movement of incisors was noted on lateral cephalograms. In contrast Kloosterman evaluated a much larger group and found a 30% recurrence of open bite after anterior maxillary osteotomies.⁴⁸

Unlike segment stability, neurologic and vascular complications have received a lot of

attention. Most of this evaluation has been directed at pulpal changes and not at peripheral inferior alveolar sensory loss or avascular bone loss. Both of these latter problems are recognized complications of mandibular subapical osteotomies, but there are no clinical studies noting their incidence.^{28,36} Many authors report some incidence of sensory change of the lip but claim there have been no permanent problems; normal sensation returns in about 3 months.^{209,211,212}

Clinical and animal studies of the effect of mandibular osteotomies on the pulp are numerous.^{35,37,39,40} An early animal study did not note many vascular changes when a lingual vascular pedicle was maintained.³³ However, all subsequent studies have noted a significant decrease in blood flow, especially to the dental pulp.²¹³ Histologic studies of dental pulp after subapical osteotomies reveal some pulpal necrosis in most teeth.^{35,214} Whether this is of clinical importance is questionable, as there were relatively few teeth in clinical series that required endodontics or that needed to be extracted.^{47,48} It is likely that some pulpal necrosis occurs in greater numbers of teeth than are clinically obvious.²¹⁵ The only way the pulpal changes

have been assessed clinically is with "vitality testing." A change in pulpal nerve sensation obviously may not be related to a decrease in pulpal vascularity. However, the rate of recovery of sensory loss seems to give some measure of the trauma to the teeth. Early clinical studies seem to show that teeth in mandibular alveolar osteotomies fare better than their maxillary counterparts.²¹⁶ More recent and larger studies, however, have demonstrated the reverse.^{47,48} One report found that approximately 40% of the teeth in the repositioned segment remain unreactive at 1 year.⁴⁷ This high incidence of pulpal trauma was attributed to technical errors during surgeries. The incidence of teeth requiring endodontics range from 1.5 to 10%. The teeth at greatest risk for damage are those in the mobile segment next to a vertical osteotomy. The teeth immediately posterior to the vertical cut are approximately equal in risk to the teeth in the center of the mobile segment.

Periodontal problems have been briefly mentioned by authors reviewing mandibular alveolar osteotomies.^{48,211} The incidence and quantitative evaluations of soft and hard tissue loss have not been done,

although individual cases of significant interdental bone loss have been noted. Periodontal problems are seen less frequently when the vertical cuts are made in extraction sites than when the cuts are attempted between teeth without extraction.⁴⁸

Horizontal Osteotomy of the Symphysis

The horizontal osteotomy of the symphysis differs very little from that originally described by Hofer, except that the procedure is done intraorally.³² The versatility of this procedure for skeletal deformities of the chin is impressive.

Indications This osteotomy with minor variations can be used to improve almost every conceivable skeletal abnormality of the chin. The technique is primarily used only for esthetic reasons. Therefore, its use depends on the patient's concern about appearance of this area of the face. Often the surgeon has to bring to the patient's attention the need for a genioplasty when other facial osteotomies are planned because of the impact that these osteotomies will have on chin prominence. The indications, there-

fore, are often made apparent by comprehensive treatment planning by the surgeon.

Technique The horizontal osteotomy of the symphysis is often done in conjunction with other major osteotomies and, thus, is frequently accomplished under a general anesthetic. However, it can be performed as a separate procedure on an outpatient basis under sedation and local anesthesia.

The mucosal incision is made on the labial side of the vestibule at about 1 cm above its depth and extends posteriorly to the first bicuspid. This incision is carried just below the mucosa to the depth of the vestibule and then angled directly to the labial cortex through the mentalis muscle (Figure 56-26A). Periosteum is elevated inferiorly to a point just below the intended level of osteotomy. Laterally the periosteum is elevated to the mental foramen and then extended posteroinferiorly to the inferior mandibular border. The extent of the posterior cortical exposure is generally determined by the position of the mental foramen and the vertical height of the mandible in this area. In many cases this means that it will end in about the first molar area.

No attempt is generally made to expose the mental nerve by releasing the soft tissue around it, primarily because the nerve can be small and friable, making inadvertent severing possible. The periosteal elevation behind the foramen is minimized to just that needed for placement of a narrow retractor and the saw blade or bur.

It is helpful at this point to inscribe a vertical mark (or marks) into the bone across the planned osteotomy site so that the transverse position of the inferior fragment can be more easily oriented after the osteotomy. The osteotomy cut is then made with a reciprocating saw (Figure 56-26B). The length and angle of the horizontal cut can have profound effects on postsurgical results. Further osteotomies or osteoplasties are made after mobilization of the lower segment. The stabilization of the segment in its new position can be made with cortical wires, circummandibular wires, or plates and screws. The wound is irrigated and closed in two layers (muscle and mucosa) with resorbable suture. Tape placed across the lip and chin is maintained for 24 to 48 hours to minimize hematoma formation as well as to help support the suture lines. Patients should be instructed not to pull their lip to minimize dehiscence of the wound.

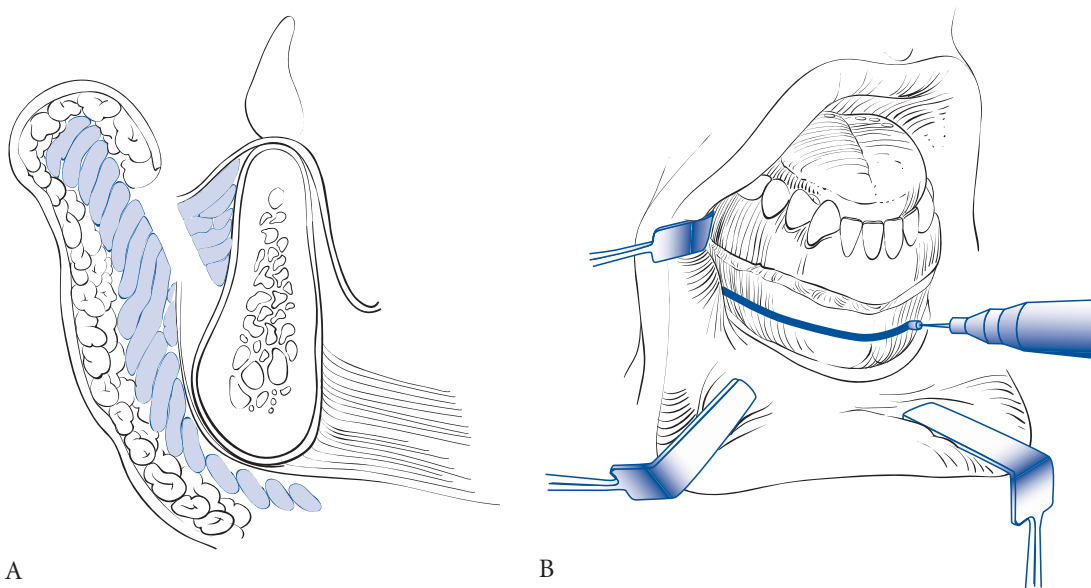

FIGURE 56-26 The surgical approach for the horizontal osteotomy. A, Soft tissue approach. B, Osteotomy. Adapted from Bloomquist DS. *Principles of mandibular orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1453.

Alternative Techniques The primary technique differences for the horizontal osteotomy center on the osteotomy design, and these design differences depend on the symphyseal deformity that is being corrected. Obwegeser concentrated on correction of horizontal deficiency of the chin when he described the basic procedure (Figure 56-27A).¹⁰⁰ He suggested that a midsagittal osteotomy of the inferior fragment may be helpful in preventing the prominence of the posterior ends of the fragment, relative to the body of the mandible, as the fragment is advanced (Figure 56-27B). A narrower chin point can also be obtained by taking a wedge of bone out from the lingual aspect of this cut (Figure 56-27C). The length of

the cut posteriorly has important esthetic consequences. Most notably larger advancements require a larger cut to the first or second molar region. This permits a smoother line to the inferior border of the mandible. Overlapping an advanced inferior fragment on the lateral cortex of the symphysis allows both an increase in horizontal prominence as well as a decrease in the anterior mandibular

vertical height (Figure 56-27D).²¹⁷ Larger advancements of the inferior fragment can be obtained by double or triple osteotomies, rotation of the fragment combined with a graft at the posterior gap, and bone graft between the symphysis and the fragment (Figure 56-27E–G).^{218,219}

Horizontal chin excess is traditionally treated by moving the inferior fragment

posteriorly.²²⁰ Depending on the angle of the cut this will also increase facial height. Sometimes when this is done it is necessary to remove the posterior ends of the inferior fragment to prevent unsightly protrusions from the inferior border of the mandible (Figure 56-27H). When the patient has normal facial height, the plane of the osteotomy should parallel the Frankfort

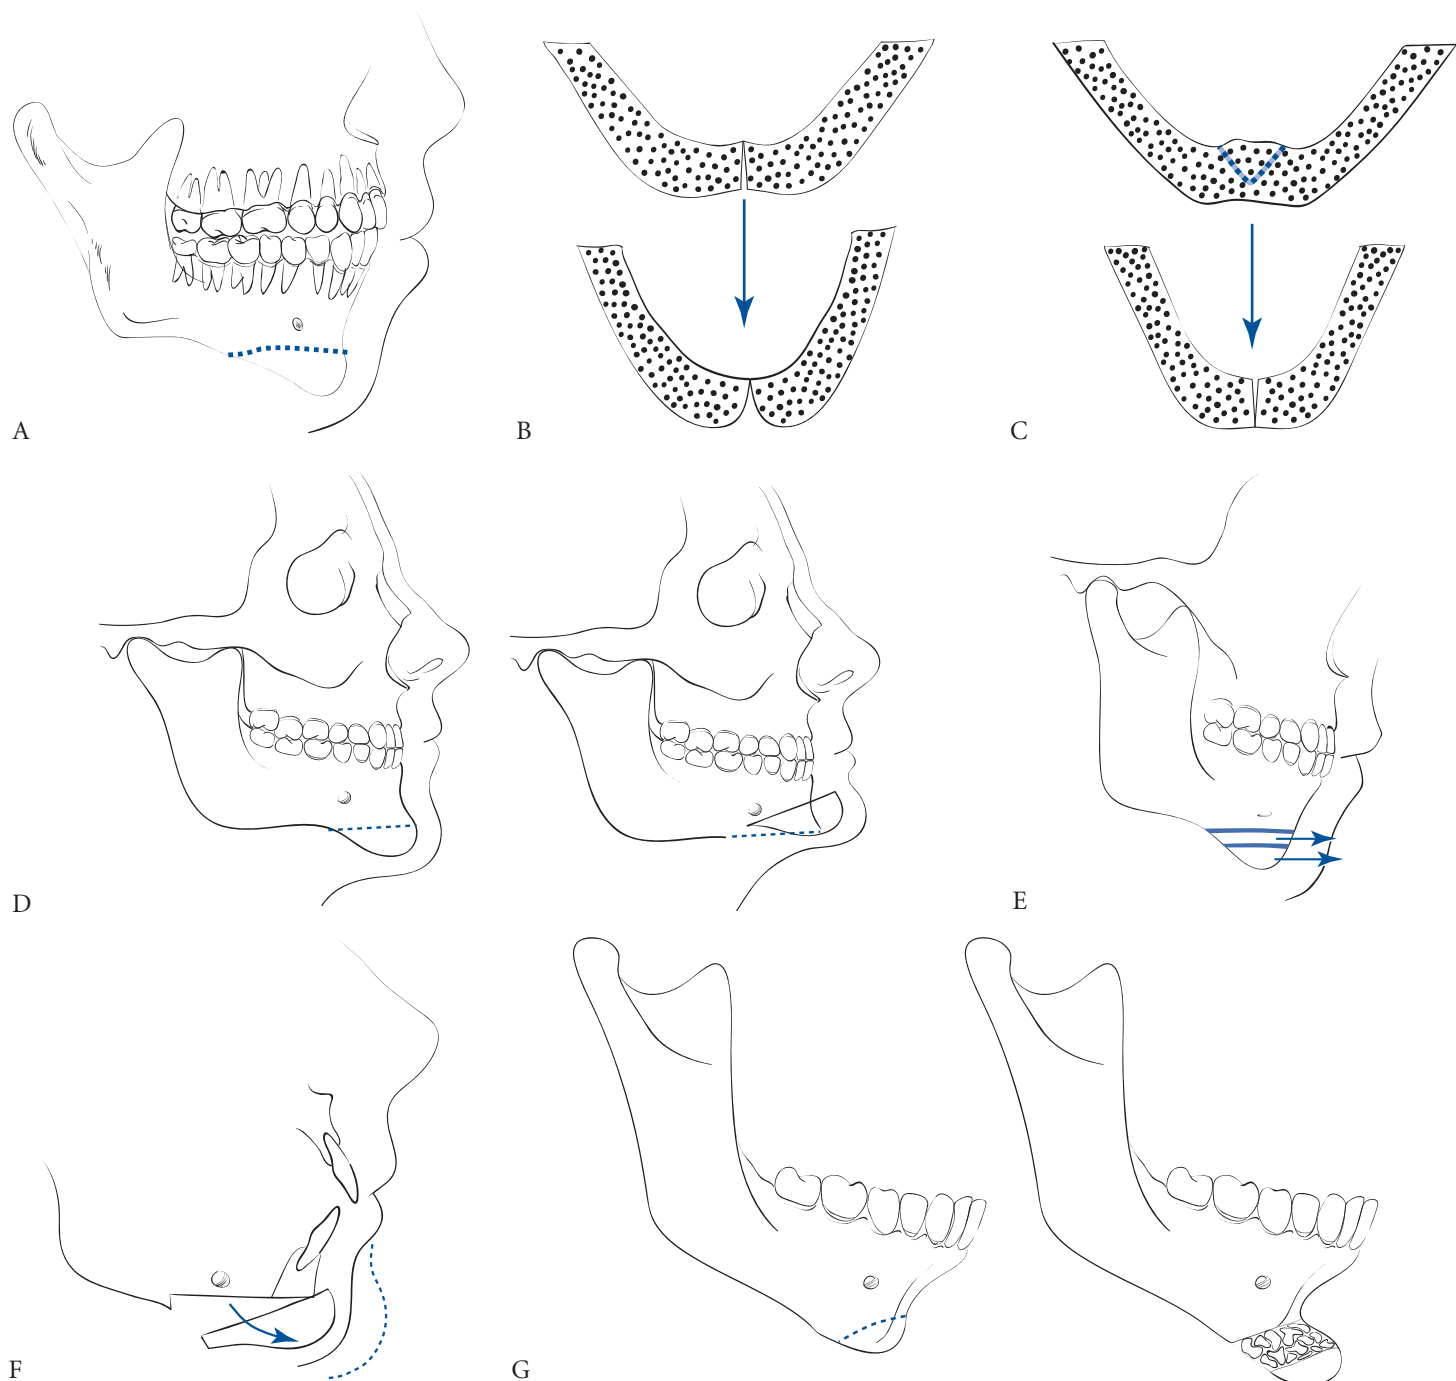

FIGURE 56-27 A–G, Various forms of the horizontal osteotomy. (CONTINUED ON NEXT PAGE)

horizontal or natural head position, if at all possible. The anterior chin projection can be reduced by using parallel or V-shaped osteotomies cut in a more vertical plane, with the middle segment removed (Figure 56-27I).

Vertical symphyseal excess can be reduced by removing the middle segment of bone when the plane of two parallel osteotomies is more horizontal

(Figure 56-27J). These cuts, however, do not always need to be parallel and in fact should be designed to fit the particular structural problem. This design also permits the correction of a mild horizontal deficiency that is combined with a mild vertical excess (Figure 56-27K). This skeletal problem can also be corrected by making a single osteotomy more vertical and moving the segment anteriorly and

forward (Figure 56-27L). Vertical symphyseal deficiency can be handled only by some type of interpositional material, with either bone grafts or implants (Figure 56-27M). Even the use of plates alone to hold the fragment in a lower position has been suggested (Figures 56-28 and 56-29).

The use of wires, screws, or plate and screws for the fixation of the inferior frag-

ment is still common. Precious and colleagues evaluated the changes that occur as the bone remodels following a horizontal osteotomy.²²¹ They recommended that the fixation take into account these changes, especially the positioning of rigid fixation such as plates. Plates along the superior border of the inferior fragment may become noticeable to the patient as the bone remodels.

Complications The incidence of post-operative problems after a horizontal osteotomy of the symphysis is rarely mentioned. This may be because genioplasties are frequently done in conjunction with other osteotomies, which makes the attribution of various complications difficult. Most of the literature concerning genioplasties concentrates on the soft tissue response to the skeletal movement.

Reports of relapse after genioplasties are sparse and conflicting. Some clinicians report that there is essentially no relapse after a genioplasty, with a rounding of the sharp corners of the advanced segment occurring with time.^{222–225} These studies, however, follow patients for only up to 1 year. Two other studies with follow-up of at least 1 year do seem to show some instability of the skeletal advancement.^{226,227} The mean relapse with a genial advancement varies widely (2.6 to 30%). The one seemingly consistent finding is that much of the skeletal relapse occurs within the first year. As with stability studies of other osteotomies there exists a large variation in individual relapse, and no attempt has been made to identify the causes. However, there are probably many factors involved, including the magnitude of advancement. There have been no studies in the stability of this surgery in correction of other symphyseal deformities. Martinez and colleagues found that regeneration of the cortical thickness of the symphysis was significantly better in patients younger than 15 years of age.²²⁴ They suggested that this may be beneficial if

further surgical advancement of the chin is to be considered.

The predictable possibility of sensory loss from this procedure has not been adequately evaluated. In one study it was noted that postsurgical sensory loss was found in all patients but was temporary, with normal sensation returning within 12 months.²²⁸ Another study reported a 3.5% long-term incidence of sensory deficits following genioplasties. Other complications such as bone loss and infections have been reported, but small samples preclude any definitive statements on incidence.²²⁹

Maxillary Orthognathic Surgery

Vincent J. Perciaccante, DDS

Robert A. Bays, DDS

History

Orthognathic surgery of the maxilla was first described in 1859 by von Langenbeck for the removal of nasopharyngeal polyps.¹ The first American report of a maxillary osteotomy was by Cheever in 1867 for the treatment of complete nasal obstruction secondary to recurrent epistaxis for which a right hemimaxillary down-fracture was used.² Over the next 70 years numerous authors described osteotomy techniques that mobilized the entire maxilla for the treatment of pathologic processes.

In 1901 Le Fort published his classic description of the natural planes of maxillary fracture.³ In 1927 Wassmund first described the Le Fort I osteotomy for the correction of midface deformities.⁴ However, total mobilization of the maxilla with immediate repositioning was not performed until 1934 by Axhausen.⁵ Separation of the pterygomaxillary junction was advocated by Schuchardt in 1942.⁶ Moore and Ward in 1949 recommended horizontal transection of the pterygoid plates for advancement.⁷ Willmar reported on over 40 cases treated this way and of severe bleeding in most, thereby abandoning this procedure in favor of separation at the pterygomaxillary junction.⁸ Most of these techniques simply mobilized the maxilla to one degree or another, and then placed orthopedic forces on it to achieve the

desired repositioning—a sort of unintentional distraction osteogenesis. These methods were associated with high levels of relapse.

In 1965 Obwegeser suggested complete mobilization of the maxilla so that repositioning could be accomplished without tension.⁹ This proved to be a major advance in stabilization, as documented by Hogemann and Willmar, de Haller, and Perko, respectively.^{10–12}

Anterior segmentalization of the maxilla was also addressed in the early descriptions, including those by Wassmund, by Cohn-Stock, and by Spanier.^{4,13,14} Again, complete mobilization of the maxilla with vascular compromise was avoided, and multiple segments contributed to poor stability. Cupar, Kole, and Wunderer, respectively, reported more direct surgical access to these procedures with improved mobilization and maintenance of blood supply.^{15–18} Posterior segmentalization of the maxilla was used by Schuchardt but it had limited stability also owing to incomplete mobilization.¹⁹ Kufner improved on this technique by completely mobilizing the osteotomized segment prior to repositioning.²⁰ Logically, anterior and posterior segmental osteotomies were combined to accomplish total maxillary alveolar osteotomy for repositioning and segmental manipulation simultaneously.^{21,22} Several forms of total maxillary osteotomies

were described by Cupar, Converse and Shapiro, and Kole, respectively.^{15,23,24} Willmar further established the stability of the Le Fort I osteotomy, and Bell and colleagues documented the overall superiority of the total down-fracture Le Fort I osteotomy for segmental and one-piece maxillary osteotomy.^{8,25} Bone grafting to enhance stabilization was advocated by Cupar, Gillies and Rowe, and Obwegeser, respectively, who first advocated grafting in the pterygomaxillary fissure.^{15,16,26,27} Interestingly, Willmar did not find a difference in stability with and without bone grafting in nonclefted cases.⁸

Early descriptions of the rigid fixation of maxillary osteotomies were published by Michelet and colleagues in 1973, Horster in 1980, Drommer and Luhr in 1981, and Luyk and Ward-Booth in 1985.^{28–31} Since that time, many methods have been advocated for the rigid fixation of maxillary osteotomies. These have included bone plates, metallic mesh, pins, the rigid adjustable pin (RAP) system, and resorbable fixation.^{32–34} Since these landmark papers, volumes have been written regarding a wide variety of technical factors, many of which reflect operator preference.

Basic Principles

Maxillary deformities may manifest in any of the three planes of space: sagittal, axial, and coronal. Patients displaying abnormal

facial anatomy often exhibit elements of maxillary and mandibular deformities. Therefore, the clinician must recognize and be prepared to treat maxillary and midface deformities. Subjectively, patients with maxillary deformities often describe their problem in terms of the relative mandibular appearance. Patient expectations clearly demonstrate the importance of the chin in patient satisfaction.³⁵ This perceptual preoccupation with apparent mandibular excess or deficiency in the absence of a significant absolute mandibular abnormality may necessitate extensive consultation and guidance from the surgeon to assist the patient in recognition of the contribution made by the midface and maxilla to overall facial appearance. Similarly the patient may relate the importance of nasal prominence or deficiency in describing his or her chief complaint.

Scrutiny of physical characteristics, model surgery, and cephalometric analysis with prediction tracings will assist in obtaining a satisfactory treatment plan. These important diagnostic and treatment planning modalities are discussed extensively elsewhere in the text; however, model surgery is the most valuable tool in preparing for orthognathic correction of skeletal facial deformities. While model surgery is essential for immediate preoperative surgical simulation and splint construction, it may be even more important in early treatment planning. Prior to any orthodontic or surgical treatment, model surgery is the best method to determine the postoperative position of the *mandible* as well as the maxilla. No cephalometric prediction (computer generated or hand drawn) or photographic manipulation can reveal all of the three-dimensional and occlusal information gleaned from accurate model surgery. In the pretreatment state the teeth may not fit together perfectly during this preliminary model surgery, but orthodontics can be simulated to permit an accurate projection of the specific movements required of the maxilla and

mandible to achieve the desired results. The model measurements made at the time of this exercise should be exactly the same as those used for the actual preoperative model surgery (see below). Pretreatment model surgery is essential when contemplating maxillary surgery alone and very useful when planning two-jaw surgery. Pretreatment model surgery permits the *three-dimensional* evaluation of the maxilla and the mandible, whether the mandible is autorotated without surgery or also osteotomized.

Model Surgery, Reference Marks, and Intraoperative Positioning

The purposes of preoperative model surgery are to (1) mark the models to facilitate three-dimensional measurement of the pre- and postoperative positioning; (2) place the jaw models into the desired positions based on all of the database including three-dimensional clinical assessment (the most important), radiographic analysis, model studies and patient desires; (3) evaluate the feasibility of the planned surgical moves using the measurements and make necessary adjustments; (4) determine the vertical change that will be achieved at the time of surgery in such a way that it can be accurately duplicated intraoperatively; and (5) construct the surgical splint(s).

The following method has been used successfully for over 20 years by the senior author (RAB). The technique is based on three simple principles:

1. A measurement is made from a point above the osteotomy to a point below it at model surgery and intraoperatively. After the maxilla is moved the same superior point is used but the point on the maxilla has been moved along a predetermined plane. This creates a triangle defined by one superior point and two inferior points (pre- and postoperatively). This triangle can

be measured accurately on models and on the patient at surgery.

2. Central incisor vertical measurements can be made directly on the models.
3. If the measurements made on the models and at surgery have the same pre- and postoperative *differences*, the incisor vertical will be correct.

Centric relation mounted models are marked to record all possible surgical movements anteriorly and posteriorly (Figure 57-1). For the purpose of illustration Figure 57-1A and B demonstrate the measurements that are necessary for intraoperative control of the vertical position of the maxilla. The vertical measurements at the maxillary canines and first molars are the critical ones for use intraoperatively (see Figure 57-1C). The bilateral vertical measurements must be made from stable points on the top of the mounting ring, not just anywhere along the mounting ring (points A and P) to cusp tips. Gingival cuffs will be used intraoperatively (Figure 57-2) on the canines (point B) and first molars (point C). The maxillary model is then moved to the desired position, including vertical. The measurement of the vertical position of the incisor is made by placing the Boley gauge flat on the top of the mounting ring (parallel to the Frankfort horizontal) to the tip of the incisor (see Figure 57-1D). This vertical measurement of the maxillary central incisor is constantly controlled while the maxilla is positioned in all other planes of space (see Figure 57-2A). After the maxillary model has been fixed in the proper position, an imaginary triangle is created by points A, B, and B' and by points P, C, and C'. The lines A-B and P-C are the preoperative vertical values and the lines A-B' and P-C' are the hypotenuses of the triangles and the postoperative vertical values (see Figure 57-2B). The *differences* between lines A-B and A-B' and lines P-C and P-C' are the important values. The absolute numbers are not.

FIGURE 57-1 A, Mounted models marked for orthognathic surgery with vertical preoperative values recorded. B, Frontal view shows midline markings that can be seen on either side of the pin when it is placed. C, Straight-line measurements are made from points A to B and points P to C on each side. D, Maxillary central incisor is measured perpendicular to the Frankfort horizontal, which is from the top of the mounting ring. (Note: This is not a straight point-to-point measurement, but a perpendicular to Frankfort one.)

Intraoperatively marks are made above the proposed osteotomy sites in the piriform rims and the first molar/butress areas (points A and P) (see Figure 57-2C). Measurements are made from point A to the gingival cuff of the canine (point B) and from point P to the first molar (point C). The gingival cuffs are used because the cusps will be hidden under the splint and the brackets may come loose during surgery. During maxillary positioning, lines A-B' and P-C' can be measured until the *difference* between lines A-B and A-B' and lines P-C and P-C' are as predicted by

the models (see Figures 57-2D and E). When this is accomplished the anterior vertical changes of the central incisors will be as they were on the models, so that no direct measurement of incisors is necessary. Usually the maxilla is repositioned anteroposteriorly and sometimes mediolaterally as it is moving vertically. This method of measurement is especially important when large anteroposterior or mediolateral moves are included.

Our experience and that of others has shown that external reference marks add nothing to the accuracy of vertical maxil-

lary positioning if the internal reference method is as outlined above.^{36,37}

Surgical Anatomy

Osseous Structures

The body of the maxilla contains the maxillary sinus in its entirety, except rarely when the apex extends into the zygomatic bone.³⁸ The anterior surface of the maxilla is the anterolateral wall of the sinus. The infraorbital foramen is located at variable distances below the inferior orbital rim. Continuing inferiorly is the

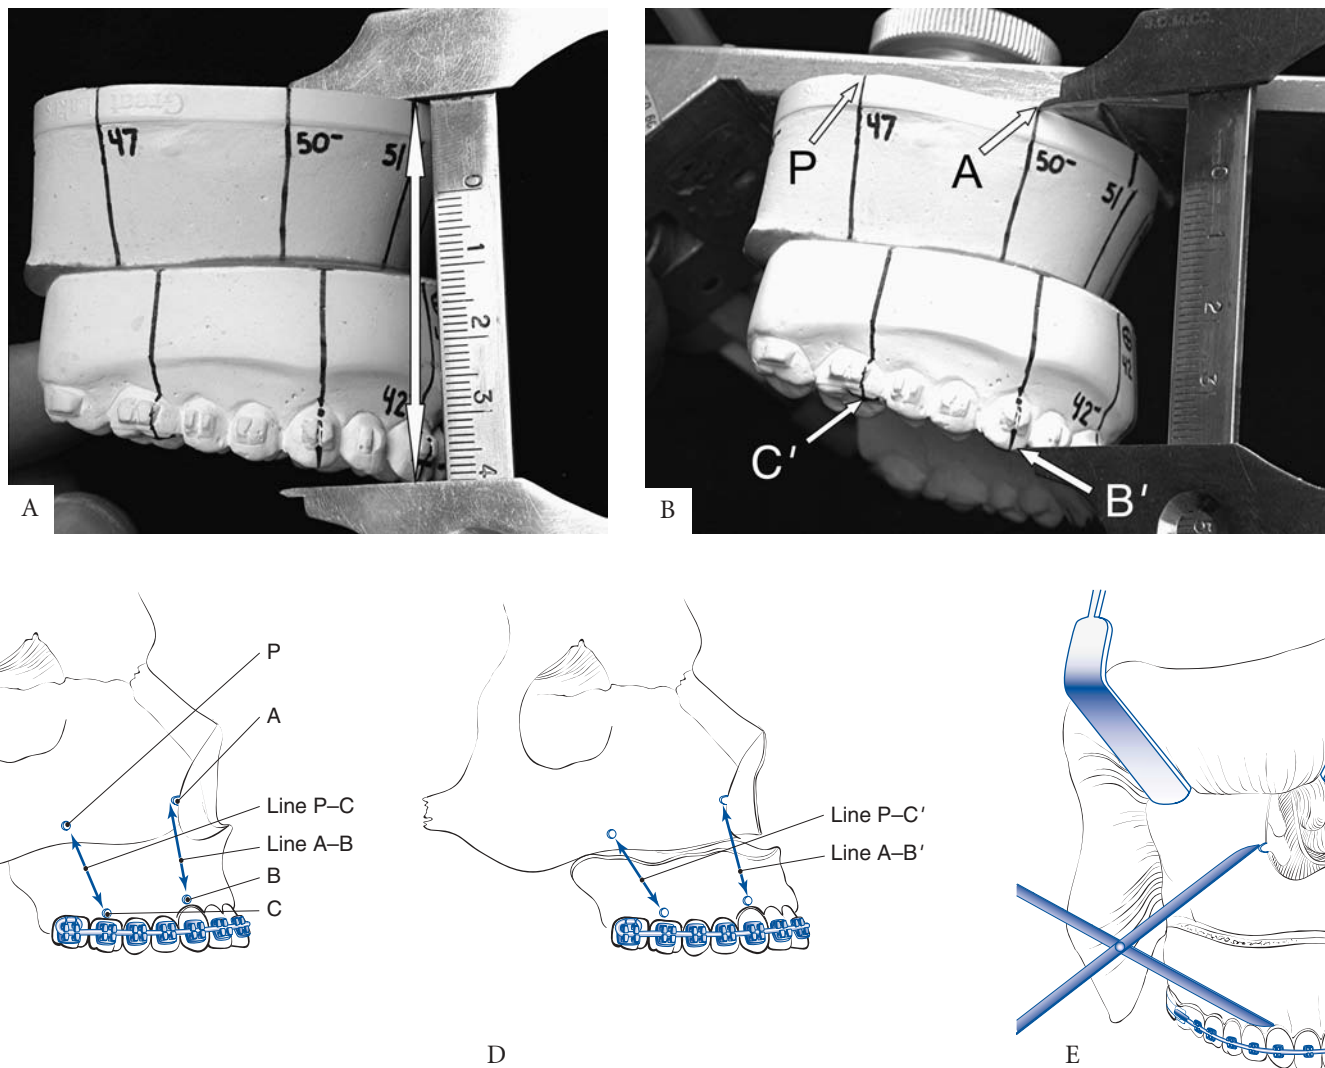

FIGURE 57-2 A, Maxillary model has been moved into desired position including vertical. Maxillary incisor is again measured perpendicular to the Frankfort horizontal (ie, from the top of the mounting ring). B, Straight line measurements are made from points A to B' and P to C' bilaterally. C, At surgery, slots are made in the piriform rim and holes in the buttress to simulate points A and P bilaterally. The gingival cuffs of the canines and first molars represent points B and C. D, Following mobilization of the maxilla it is placed so that the differences between lines A-B and A-B' are the same as they were on the models. Lines P-C and P-C' can be used similarly. Note: If this is done precisely, the vertical change at the central incisors will be the same as it was on the models so that there is no need to make a direct measurement of the centrals. E, Illustration of measurement method at surgery.

canine fossa lateral to the canine tooth. The anterior alveolar process of each maxilla surrounds the piriform aperture, and they unite in the midline to form the anterior nasal spine. This bony spine is the most anterior and inferior attachment for the mobile anterior cartilaginous nasal septum. An elevated sharp crest at the junction of the anterior and nasal surfaces of the maxilla, which forms the nasal floor, inclines this structure superiorly at the aperture. The body of the maxilla and its frontal process

form the superolateral boundary of the piriform aperture as a thin edge of bone (Figure 57-3).

In the midline the nasal crest of the maxilla articulates with the septal or quadrangular cartilage and vomer.^{39,40} The septal cartilage rests in a central groove, which extends posterior to the anterior nasal spine. This articulation is flexible but strengthened by the perichondrium-periosteum continuity and interposed connective tissue. In the midline at the junction of the maxilla and the premaxilla is the incisive fossa, which

typically presents the openings of four canals through which the nasopalatine arteries and nerves are conducted.

The palate is formed by the palatine process of the two maxillas and the horizontal lamina of the palatine bones.⁴¹ The transverse suture between the maxilla and palatine bones lies roughly 1 cm anterior to the posterior margin of the hard palate. At its lateral extent the suture widens into the greater palatine foramen, which is approximately 1 cm posteromedial to the second molar (Figure 57-4).

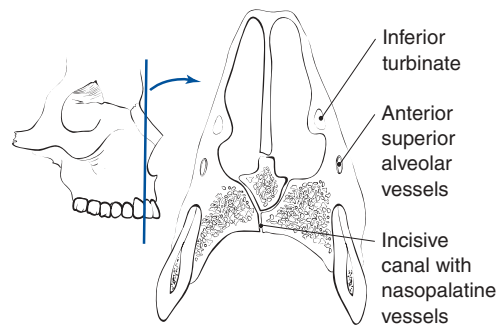

FIGURE 57-3 Cross-sectional anatomy of the maxilla at the piriform rim.

The greater palatine canal is formed similarly between the perpendicular laminae of the palatine and maxillary bones, which form the inferior lateral nasal wall. The inferior nasal concha also articulates with the maxillary and palatine components of the lateral nasal wall.

Posterolaterally the maxillary tuberosity is behind the third molar. Above this tuberosity the posterior superior alveolar foramina may be observed through which the nerves and vessels emerge. The pyramidal process of the palatine bone unites the two pterygoid plates of the sphenoid bone with each other and to the maxilla. The pterygomaxillary junction, formed by the palatine bone, ends superiorly in the pterygomaxillary fissure leading into the pterygopalatine fossa.^{42,43} The foramen rotundum enters the posterior wall of the pterygopalatine fossa and the pterygoid or vidian canal. Medially the sphenopalatine foramen leads to the lateral nasal cavity posterior to the middle nasal concha of the ethmoid bone. Anteriorly the infraorbital and zygomatic nerves and infraorbital vessels run in the infraorbital canal, and inferiorly the descending palatine artery and greater palatine nerves course within the greater palatine canal.

Vascular Structures

Although numerous texts describe the anatomy of the intact maxilla, several aspects of maxillary blood flow remain in doubt following maxillary osteotomy.

The Le Fort I maxillary osteotomy had been performed for over 100 years before Bell first identified the exact nature of blood vessels in the osteotomized maxilla, which provided information regarding the viability to the pedicled maxilla.^{44,45} It was obvious that even though the direct blood supply to the maxillary teeth and periodontium was interrupted, collateral circulation existed to perfuse the dental pulp and surrounding structures (Figures 57-5 and 57-6). This same circulation was also responsible for the survival of the rest of the maxilla; however, the exact nature of the various factors affecting maxillary perfusion is still not well documented or understood. Bell's studies revealed that saving the descending palatine arteries made little difference, indicating that a collateral vasculature existed, probably from the soft palate, which was adequate for maxillary perfusion. The down-fractured maxilla has a rich blood supply via the ascending pharyngeal artery and the ascending palatine branch of the facial artery.⁴⁶

Bell also verified the revascularization of anterior maxillary osteotomies using the microangiographic technique.⁴⁵ Brusati and Bottoli performed revascularization studies similar to those of Bell and found quite different results.⁴⁷ They found

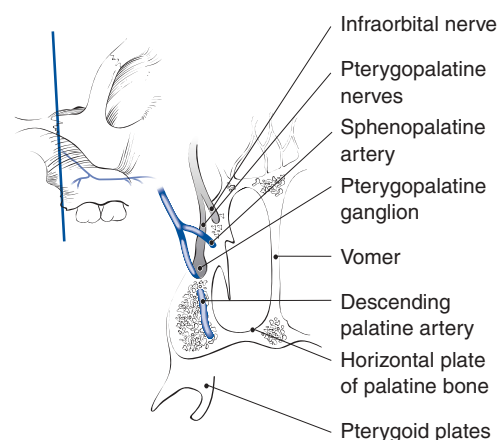

FIGURE 57-4 Cross-sectional anatomy at the pterygomaxillary junction. Note the position of the greater palatine foramen and perpendicular plate of the palatine bone.

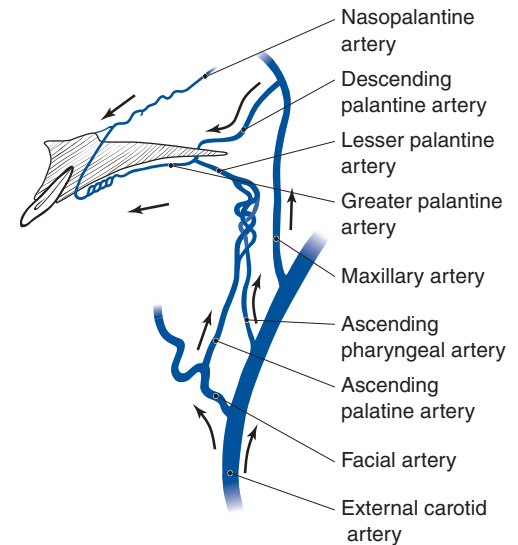

FIGURE 57-5 Pathway of the ascending palatine, ascending pharyngeal, and descending palatine arteries as they continue into the greater palatine arteries.

the tunneling technique to be superior in maintaining the blood supply, especially to the pulpal tissues, when compared with the labial pedicled anterior maxillary procedures.^{17,18} This was just the opposite from the findings of Bell.⁴⁵ A possible explanation for this discrepancy is that Bell used monkeys whereas Brusati and Bottoli used dogs, which they claimed possess a more similar maxillary vasculature to that of the human.⁴⁸ The clinical significance of these differences is not clear to this day.

Revascularization does not necessarily represent blood flow, and therefore Nelson and colleagues used a radioactive microsphere technique to evaluate maxillary blood flow.⁴⁹ Unfortunately several variables were present in this study that make interpretation difficult. In none of the above-mentioned studies were the maxillas moved to a new position, which may represent the largest insult to the blood supply at the time of actual maxillary osteotomy. Additionally, in Nelson's study, severance of the descending palatine vessels was inadvertent and no ligation was performed.⁴⁹ This allowed bleeding to occur through the lacerated vessels and prevented a pressure head

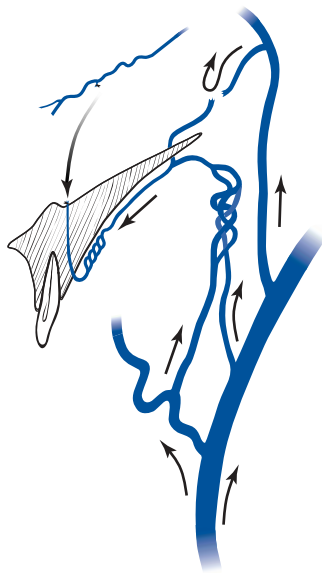

FIGURE 57-6 Soft palatal, ascending pharyngeal, and ascending palatal vessels anastomose with the greater palatine artery. Major vessels have been sectioned and tied. The arrows signify direction of blood flow.

from developing to maintain distal flow to the anterior maxilla. Also there were large differences in the preoperative microspheres values between animals such that postoperative comparisons were impossible. In other studies involving anterior maxillary osteotomies, Nelson and colleagues found no significant differences among three different techniques that were similar to the ones described by Brusati and Bottoli, plus a third procedure using only a palatal pedicle.^{47,50} Although no statistical difference was seen, the palatal flap seemed to be slightly superior to the others. Again the same problems existed with this study as before, rendering conclusions impossible.

Soft Tissue Envelope of the Maxilla

The midfacial superficial fascia or subcutaneous tissue contains a variable amount of adipose tissue with the muscles of facial expression in its deep layer. This is tightly bound to bone except adjacent to the buccal fat pad and in the lower eyelids. Hollinshead divided the mimetic or facial muscles into five chief groups concerning the mouth, nose, orbit, ear, and scalp.⁴² Of concern to the present discussion are the

muscles of the mouth and nose, which are innervated at their posterior inferior aspect by the facial nerve. They insert into the skin and most arise from periosteum of the facial skeleton.

The upper oral group of muscles radiates from their insertions near the corner of the labial commissure. From a horizontal to vertical orientation and inferior to superior the risorius, zygomaticus major and minor, and the levators (levator labii superioris alaeque nasi) insert and blend with the skin and orbicularis oris. The risorius does not arise from bone but originates from the superficial fascia over the parotid gland. The risorius, zygomaticus major, and zygomaticus minor elevate and retract the corner of the mouth and upper lip laterally. The superficial levator muscles and a third deeper one, the levator anguli oris, elevate the lateral upper lip. In addition the levator labii superioris alaeque nasi attaches to the skin and greater alar cartilage of the nose, thus lifting the ala and widening the naris.

The orbicularis oris is composed of many multidirectional fiber groups that blend with other surrounding facial muscles, encircle the mouth, originate from periosteum covering the roots of the canine teeth, insert laterally at the corner of the mouth, and pass at right angles to the encircling sphincter fillers connecting skin to labial mucosa. This diverse muscle draws the lips together, purses the lips, presses the lips against the teeth, and pulls the corners of the lips inward.

The buccinator arises from the mandible and maxilla and the pterygomandibular raphe, by which it is separated from the superior pharyngeal constrictor. The fibers pass forward and slightly inferiorly to blend with the orbicularis oris and attach to the mucosa and skin of the labial region. The buccinator flattens the cheek against the teeth.

Both Lightoller and Nairn place emphasis on the modiolus, which is the point at the lateral aspect and just superi-

or to the corner of the mouth where muscles of the oral group of the mimetic muscles converge.^{51,52} The orbicularis oris and buccinator joined at the modiolus form a continuous muscular sheet on either side of the midline. The zygomaticus major, levator anguli oris, and depressor anguli oris (as a group referred to as “modiolar stays”) immobilize the modiolus in any position. Additionally the marginal and peripheral parts of the orbicularis oris muscle are distinguished. The peripheral aspect of the muscle lies parallel with the inner labial mucosal surface, and the marginal part curls outward following the vermilion surface. As tension is expressed in the orbicularis oris, the marginal aspect of the muscle is thought to straighten and decrease vermilion exposure, thereby pulling the upper and lower lips toward each other and against the dentition.

The nasal group of facial muscles dilates and compresses the nares. The nasalis arises from the maxilla lateral and inferior to the ala. The transverse portion unites with the contralateral muscle over the dorsum of the nose. The alar part inserts into the greater alar cartilage. Thus, the two parts compress and dilate the nasal apertures respectively. The depressor septi muscle lies beneath the orbicularis oris and attaches to the base of the columella and posterior ala. Its action narrows the naris. The posterior and anterior dilator muscles are intrinsic muscles of the nose that course from the alar cartilages to the margin of the pads. The nasal mucoperiosteum is firmly fixed to the elevated piriform rim above the floor of the nose, to the lateral margin of the nasal aperture and the anterior nasal spine. The premaxillary wings that flare laterally from the anterior midline nasal crest provide an irregular attachment of the mucoperiosteum along the inferoanterior nasal floor.

The palate is covered by mucosa firmly adherent to the periosteum and containing mucous minor salivary glands. The mucosa is thin in the central palate and

thickens toward the alveolar process. The palatine crest is a transverse elevation at the posterior border of the horizontal plate of the palatine bone that gives attachment to the tensor veli palatini muscle. The larger lateral pterygoid plate is the origin of the inferior head of the lateral and the medial pterygoid muscles. A small part of the medial pterygoid also arises from the maxillary tuberosity. The tensor veli palatini muscle curves around the hamulus, which is the inferior end of the medial pterygoid plate. From the hamulus the tensor muscle of the palate enters the soft palatal tissues. The tensor aponeurosis is an adherent connective tissue sheath continuous with the periosteum, which covers the posterior hard palate attaching laterally to the submucosal layer of the pharynx and the tensor veli palatini tendon.

Surgical Techniques

Soft Tissue Incision and Surgical Exposure of the Maxilla

Exposure of the anterior, lateral, and pterygomaxillary regions is most commonly achieved by incising horizontally through the buccolabial mucoperiosteum above the attached gingival margin at the level of the maxillary teeth apices (Figure 57-7A). The vestibular incision courses from the first molar to the contralateral first molar (Figure 57-7B). The parotid papilla is identified and retracted superolaterally during completion of the incision posteriorly. The incision can be made with electrocautery or steel as there have been no studies performed that show a difference between the two. After initial penetration of the mucosa the natural tendency to cut more superiorly with deeper penetration must be avoided. This is particularly important in the incisor area, as this would carry one into the nasal cavity.

The superior tissues are reflected subperiosteally, first at the piriform aperture margins (Figure 57-7C). Progressively more superior exposure lateral to the nasal

FIGURE 57-7 A, The soft tissue incision for maxillary surgery. B, The circumvestibular incision extends from the area of the first molar to the same location on the opposite side. C, The nasal mucosa is elevated beginning on the superolateral surface of the piriform rim.

aperture will expose the infraorbital nerve exiting from its foramen. Posterior reflection proceeding from the delineated infraorbital foramen reveals the zygomaticomaxillary suture, zygomatic buttress, and the most anterior aspect of the zygomatic arch. Inferiorly, with subperiosteal tunneling, the lateral aspect of the maxillary tuberosity and its junction with palatine bone and pterygoid plates of the sphenoid bone are identified. Care should be taken to direct this subperiosteal dissection inferiorly, toward the mucogingival junction, as it is carried back toward the pterygomaxillary fissure, to avoid vascular structures. Meticulous maintenance of the subperiosteal plane of dissection will prevent troublesome exposure of buccal fat pad tissue, which impairs visualization and retraction of soft tissue during subsequent osseous surgery. A retractor with a curvilinear end is placed in the pterygomaxillary junction to facilitate exposure. Attention should be paid to the placement of this retractor, as it too can be responsible for periosteal rents and exposure of the buccal fat.

Tissues inferior to the horizontal incision are elevated minimally. In areas of interdental osteotomies for segmentalization of the maxillary arch the inferior attached gingiva and periosteum are elevated conservatively, with a Woodson elevator, while retraction laterally is provided by skin hooks (Figure 57-8A). Since the alveolar osteotomy will be accomplished with thin osteotomes, osseous exposure requirements at the alveolar crest level are minimal.

When intersegmental movement will be great and may result in tearing of the gingival papilla, an alternative approach to the interdental region may be used. Additionally a wider exposure of alveolar bone is frequently needed when an osteotomy is to be performed in an edentulous or extraction space. In these situations a vertical mucosal incision at the line angle, one-tooth distant from the osteotomy site (Figure 57-8B), will facilitate wider exposure for osseous procedures. This incision should be used only when an anterior labial pedicle is maintained to maximize the labial vascular pedicle during multisegmental osteotomy.

FIGURE 57-8 If segmentalization is necessary, it is best to perform interdentary osteotomies before horizontal osteotomies and down-fracture. A, Minimal exposure technique for interdentary osteotomies. B, Vertical incision for interdentary osteotomies.

For one-, two-, and most routine three-piece maxillary osteotomies, a circumvestibular incision with minimal interdentary exposure is preferred. For three-piece maxillary osteotomies that involve exceptionally wide expansion or extreme changes at the interdentary site, four-piece maxillary osteotomies, and osteotomies in some ex-cleft patients, soft tissue incisions can be modified from second molar to first premolar to maintain an anterior labial pedicle (Figure 57-9). A midline vertical incision is placed to gain access to the midline of the maxilla.

Once the labial incisions are completed the nasal mucoperiosteum is elevated to complete soft tissue exposure of the osseous surgical site (see Figure 57-7C). Initial establishment of a subperiosteal dissection plane is imperative for completion of nasal tissue dissection without disruption of mucoperiosteal integrity. Because the nasal cavity is more voluminous inside the piriform rim than at the piriform aperture, the elevator should be held at an oblique angle to the surrounding maxillary bone adjacent to the nasal aperture. While maintaining the elevator tip against bone, the mucoperiosteum is

reflected from the nasal floor, lateral nasal wall, and nasal crest of the maxilla. The dissection should continue superiorly for a centimeter up the vertical nasal walls to prevent tearing during osteotomy or down-fracture of the maxilla, particularly at the superior reflections of the nasal floor medially and laterally. The anteroposterior depth of this soft tissue dissection is approximately 15 to 20 mm. The remaining posterior soft tissue is reflected more precisely after initial down-fracture of the maxilla.

Osseous Surgery

After recording the reference measurements as outlined earlier (see Figure 57-2), the osteotomy is performed. The design of the osteotomy will depend on the maxillary movement desired. Regardless of the design of the osteotomy the measurement marks are used as illustrated in Figure 57-2. Initially the basic horizontal osteotomy will be discussed and then alterations will be described for specific situations. *Segmentalization* of the maxilla may be necessary in certain cases. Specifics of this procedure will be discussed at the end of the basic horizontal technique. The lateral

maxillary osteotomy (Figure 57-10) is started at the greatest convexity of the zygomatic buttress because that is the easiest starting surface for the reciprocating saw. It is advanced anteriorly through the lateral piriform rim below the inferior turbinate while the nasal mucoperiosteum is retracted and protected using a periosteal elevator. For the basic maxillary osteotomy this horizontal osteotomy is parallel to the maxillary arch wire approximately coincident with the cut performed previously during model surgery. After the anterior osteotomy is completed, it is continued posteriorly by tapering inferiorly toward the pterygomaxillary junction. A thin reciprocating saw blade and copious irrigation are used for this osseous cut. The most posterior centimeter or so of the lateral wall can be cut with the same saw, but from inside out (Figure 57-11).

Next a nasal septal osteotome is directed slightly downward and posterior (Figure 57-12) beginning just above the anterior nasal spine while the anterior nasal mucoperiosteum is retracted. Proceeding posteriorly the osteotome is carefully maintained in the midline. The tendency toward superior deviation while separating the cartilaginous and vomerine septum from the nasal crest of the maxilla

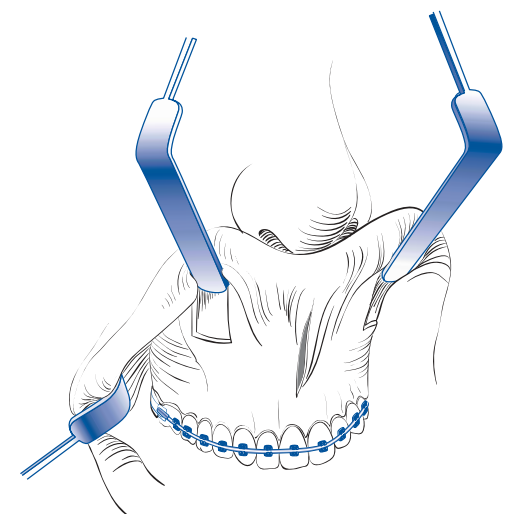

FIGURE 57-9 Bilateral vestibular incisions are made from the first premolar to the second molar; shown with a midline vertical incision.

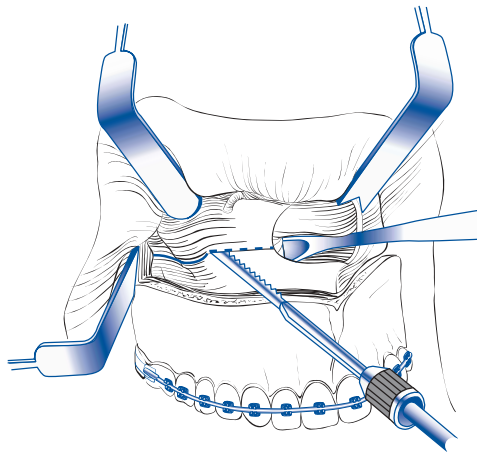

FIGURE 57-10 Lateral wall osteotomy is begun at greatest convexity of the buttress and brought forward to the piriform rim with a periosteal elevator protecting the nasal mucosa and the endotracheal tube.

necessitates maintenance of a slight downward inclination of the septal osteotome. The lateral nasal wall is severed using a thin osteotome directed posteriorly while medial retraction of the nasal mucoperiosteum is accomplished with a periosteal elevator. The osteotome is gently malleted posteriorly for a distance of approximately 20 mm to avoid premature injury to the descending palatine neurovascular bundle that resides in the lateral posterior nasal wall.

After the above osteotomies have been performed, the pterygoid plates are separated from the maxillary tuberosity (Figure 57-13) using a small sharp curved osteotome. This instrument is preferred over the traditional thick pterygomaxillary osteotome because the thin cutting edge limits fracture and promotes precise division of this bony junction.⁵³ The tip of the osteotome is directed as anteriorly, inferiorly, and medially as the tunneled buccal soft tissue allows. A finger placed palatal and posterior to the maxillary tuberosity will facilitate early verification of the complete separation of bone while avoiding trauma to the palatal vascular pedicle. The authors prefer to have this instrument sharpened before each case.

FIGURE 57-11 The saw is then turned inside out and the osteotomy from the buttress to the pterygomaxillary junction is made angling downward as it goes posteriorly.

Downward pressure is placed on the anterior maxilla using the sharp hooks of a Senn retractor to facilitate initial downfracture of the maxilla (Figure 57-14). If moderate pressure does not result in mobilization of the inferior segment, the completeness of the above osteotomies must be suspect. The cement spatula osteotome is used to ensure complete bony severance of the anterior lateral nasal wall and zygomaticomaxillary portions of the osteotomy. The curved osteotome is again placed into the pterygomaxillary junction, malleted gently, and then torqued to mobilize the maxilla. If no significant movement is detected, then the

FIGURE 57-12 Separation of the nasal septum from the septal crest of the maxilla with a special osteotome.

osteotome may be stepped slightly superiorly, directed anteriorly, and malleted until the separation is complete.

When mobility occurs the nasal mucoperiosteum is elevated progressively more posteriorly until the posterior edge of the hard palate is encountered (see Figure 57-14). Portions of the pterygoid plates or perpendicular process of the palatine bone that resist fracture may be completely separated from the maxilla using an osteotome under direct visualization (Figure 57-15). The descending palatine neurovascular bundle is isolated, ligated, and divided.

Significant movement of the posterior maxilla can cause tensile forces on the descending palatine neurovascular components. Superior repositioning of the maxilla may also compress the exposed vessels and nerve between the inferior and superior osseous segments. Severe postoperative bleeding after Le Fort I maxillary osteotomy has been reported.⁵⁴⁻⁵⁷ Attempts to preserve the neurovascular bundle may increase this possibility. Ligation and division of this structure has been shown to have no deleterious influence on perfusion or neurosensory function.^{58,59} The bone of the perpendicular plate of the palatine bone surrounding the neurovascular bundle is

FIGURE 57-13 Pterygomaxillary separation with a small sharp curved osteotome directed medially.

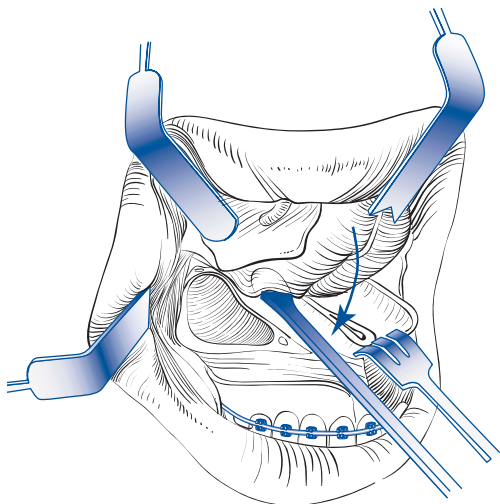

FIGURE 57-14 Down-fracture is accomplished with a sharp-toothed Senn retractor, with simultaneous elevation of nasal mucoperiosteum.

carefully removed using a Woodson elevator, burs, and rongeurs, and the neurovascular bundle is ligated and divided (see Figure 57-15). After down-fracture, complete mobilization of the maxilla is the next objective. A J stripper normally used for periosteal elevation in sagittal osteotomies engages the posterior border of the midline nasal floor at the posterior nasal spine (Figure 57-16), and anterolateral pressure is

FIGURE 57-15 Complete removal of bone around the perpendicular plate of palatine bone. The descending palatine artery is isolated, ligated, and divided.

FIGURE 57-16 Mobilization of the maxilla with a J stripper.

exerted to progressively increase mobility of the maxilla. The goal of these maneuvers is to move the maxilla into the approximate final position with only gentle digital pressure. After mobilization from the cranial base is completed, a reassessment of the surgical move is considered. Based on the movement planned any possible bony interferences posterior to the second molar must be removed before application of maxillomandibular fixation (MMF). When all possible interferences posterior to the second molar have been removed, the maxilla is wired to the mandible with the occlusal splint interposed.

We prefer to have the patient completely paralyzed during the period of maxillary positioning. Condylar positioning while rotating the maxilla and mandible is paramount to success. The physiologic position of the condyles is thought to be a superoanterior orientation relative to the glenoid fossae against the posterior slopes of the articular eminences, with the disk interposed between the condyle and the fossa. The surgeon must position the condyles of the maxillomandibular complex in this upward and forward direction prior to autorotation (Figure 57-17). The importance of this stage of the surgery cannot be overesti-

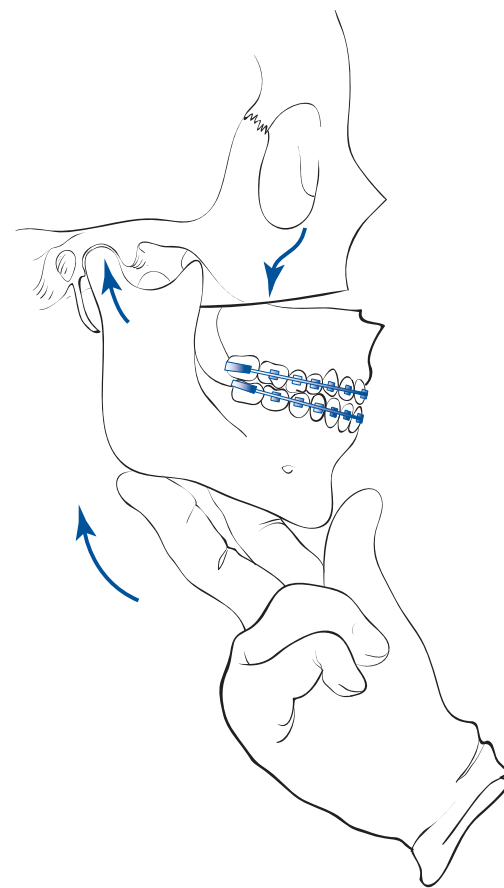

FIGURE 57-17 Manual positioning of the maxillomandibular complex with condyles seated. Note the posterior pivot point that must be removed.

ated. The most likely points of unrecognized bony interferences are in the areas of the pterygoid plates, the maxillary tuberosities, and the perpendicular plate of the palatine bone. It is quite possible to rotate the maxillomandibular complex inappropriately while being unaware of a premature pivot point in these posterior bony areas (Figure 57-18A). This will result in Class II open bite discrepancy once the patient is released from MMF. If a significant period of MMF or training elastics is used postoperatively, this discrepancy may not become apparent for weeks or months (Figure 57-18B). Once these posterior interferences have been removed, the surgeon continues to rotate the entire complex around the temporomandibular joints until the appropriate vertical relationship is achieved as described above. The cartilaginous sep-

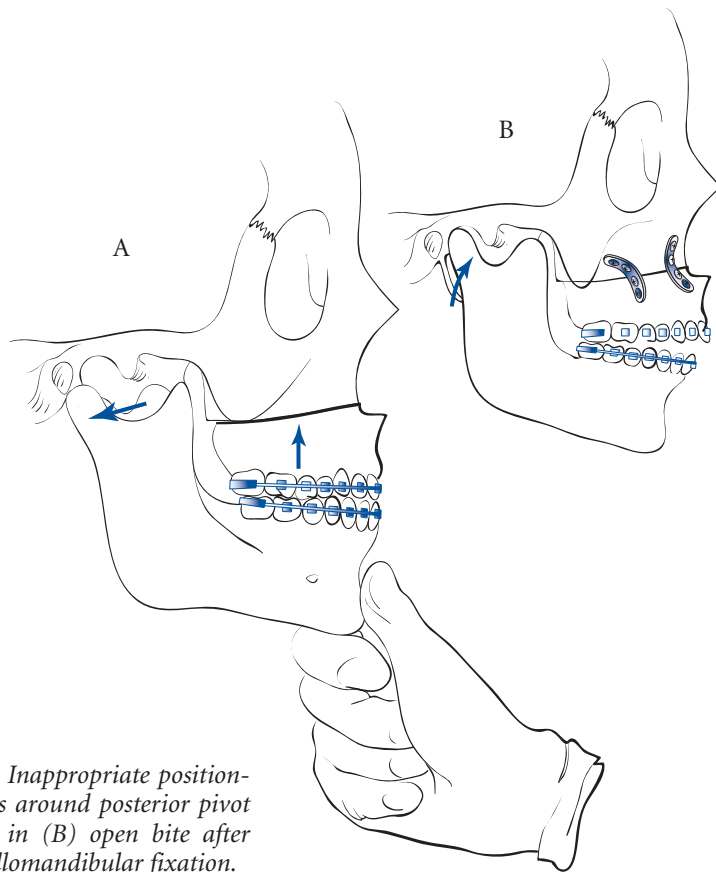

FIGURE 57-18 A, *Inappropriate positioning of the condyles around posterior pivot points will result in (B) open bite after release from maxillomandibular fixation.*

tum and vomer as well as the nasal crest of the maxilla are reduced in height equal to the planned movement of the maxilla. This may entail a submucous resection of the cartilaginous nasal septum to prevent buckling of the septum from pressure as the maxilla is repositioned. A groove can be fashioned in the midline of the nasal floor to accommodate the recontoured septum.

A portion of the inferior edge of the cartilaginous septum should be removed. The tendency is to remove too little because of the irregular inferior contact between septum and maxilla. Even if the maxilla is inferiorly positioned, buckling of the septum may occur because the cartilaginous septum extends anterior and inferior to the anterior nasal spine and therefore can be buckled as the maxilla moves forward even if there is some downward movement (Figure 57-19). All of the maxillary positioning has been pre-determined by the model surgery and

splint construction, except for the vertical. As the maxilla is rotated upward around the condyles, bone is only removed at the point of contact, not a full wedge (Figure

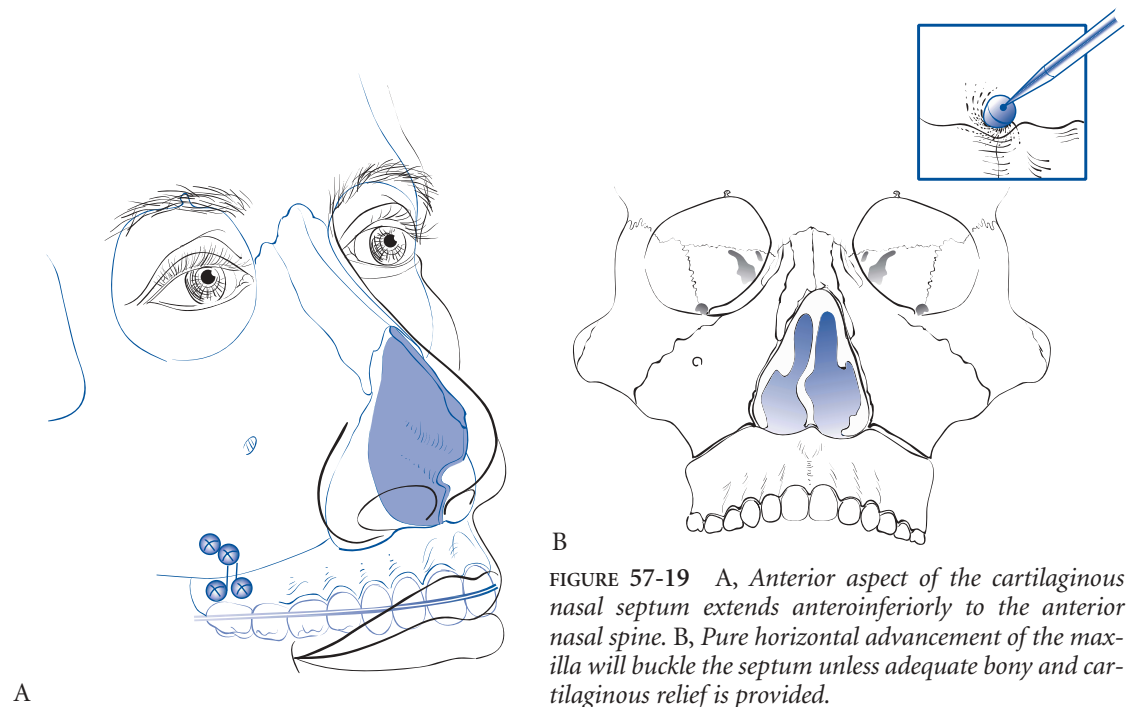

FIGURE 57-19 A, *Anterior aspect of the cartilaginous nasal septum extends anteroinferiorly to the anterior nasal spine. B, Pure horizontal advancement of the maxilla will buckle the septum unless adequate bony and cartilaginous relief is provided.*

57-20). This facilitates ideal bone-to-bone contact and avoids large gaps in between. Once the desired vertical relationship has been achieved based on the measurements described above, the maxilla should be fixed in position with internal rigid fixation. Sequentially eliminating only interfering osseous structures ensures optimal bone contact. This method is preferred over a wedge osteotomy.⁶⁰ Maxillo-mandibular fixation is removed and the mandible is rotated into the splint while held to the maxilla. If the occlusion is correct, the splint is removed and not left in place postoperatively.

Variations in the above basic osteotomy design may enhance osseous contact, facilitate bone graft placement, or aid fixation device application, and result in improved stability of the superiorly, inferiorly, or anteriorly repositioned maxilla. These variations will be described below as they apply to specific maxillary movements. To prevent septal deviation despite adequate bone and cartilage removal, it is often desirable to suture the nasal septum to the anterior nasal spine. This is done by drilling a hole through the anterior nasal spine and passing a 1-0 polyglycolic acid

FIGURE 57-20 Removal of bony walls and slotting of the contact points.

suture through the hole and then through the cartilaginous septum (Figure 57-21). This will also prevent postoperative displacement of the septum during extubation or in the Post-anesthesia Care Unit.

Segmentalization

A wide range of permutations may be undertaken if segmentalization is needed. Three-piece maxillary osteotomy is perhaps the most common. The decisions regarding which of the many options will be used are made by pretreatment and preoperative model surgery. The need for extractions is also determined at this stage. If no extractions are necessary, interdental osteotomies can be safely made between parallel roots of the canines and laterals or canines and premolars. If extractions are decided on by the coordinated efforts of orthodontist and surgeon, they may be done early in treatment or during the osteotomy. A complete discussion of the indications and considerations that influence these decisions is covered elsewhere in this book. However, if there are no specific orthodontic reasons to extract teeth, it has been our experience that it is rarely necessary to extract just for the purpose of

surgery. The most common need for segmentalization is to widen the maxilla and adjust the angulations of the posterior maxillary segments. If the anterior six maxillary teeth fit well with the lower anterior teeth, the interdental osteotomy is performed between the canine and premolar teeth. This places the potential for a periodontal defect at the interdental osteotomy site more posteriorly in the mouth. But if the canines need to be widened along with the posterior seg-

ments, the interdental osteotomy is placed between canine and lateral incisor teeth. We prefer to make this osteotomy with a thin cement spatula osteotome while palpating palatally. The standard circumvestibular incision can be made with conservative tunneling from the incision inferiorly to the alveolar crest on the buccal surface of the maxilla. The osteotome is malletted through until palpated under the palatal mucosa (see Figure 57-8A). With care the osteotomy can be carried superiorly to the level of the horizontal maxillary osteotomy and medially to the horizontal surface of the palate. This should be done before any of the other maxillary osteotomies are done because the maxilla must be stable at the time of malleting. If teeth are to be extracted at the time of osteotomy, an alternative to tunneling is to lay a flap into the gingival sulcus for better access (see Figure 57-8B). However, if this is done, it is recommended that an anterior pedicle be retained for blood supply (see Figure 57-9).

Segmentalization using this or any other technique is more difficult when significantly altered osteotomy designs are used, such as high Le Fort I, II, or III. When the Z osteotomies (see below) are used, interdental segmentalization between canines and laterals is feasible, but more difficult if attempted between canines and premolars.

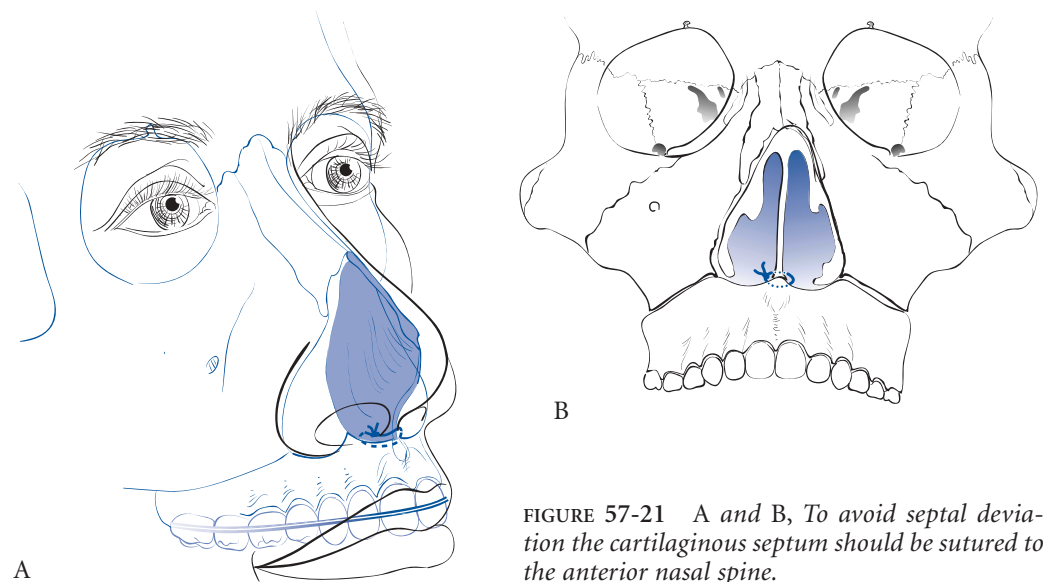

FIGURE 57-21 A and B, To avoid septal deviation the cartilaginous septum should be sutured to the anterior nasal spine.

Following the down-fracture and full mobilization of the maxilla, the remainder of the segmentalization can be performed. The palatal soft tissue is very thin in the midline and the bone is very thick, but the opposite is true 6 to 8 mm lateral to the midline. For that reason two parasagittal osteotomies are made along the floor of the nose using a bur with a rounded tip, such as a Steiger bur (Figure 57-22). The parasagittal cuts are joined with the interdental ones to free the three dentoalveolar segments. If any significant torquing of the anterior segment is to be done, the two parasagittal cuts must be joined across the midline so that there are three dentoalveolar segments and one midpalatal bony fragment. In two-piece osteotomies the two parasagittal cuts are joined with the interdental cut between the central incisors at the incisive canal.

The orthodontic arch wire is cut at the interdental osteotomy sites, and the segments are mobilized appropriately. The segments are wired to the preformed surgical splint. If bone grafting is needed on the palate it must be done before the maxilla is positioned and stabilized vertically. Interdental and buccal bone grafting can be done just before closure of the

FIGURE 57-22 Following down-fracture the maxilla is segmentalized with a rounded end cutting bur such as a Steiger bur by making two parasagittal cuts that join across the midline and connect with the interdental osteotomies.

FIGURE 57-23 The traditional method of gaining access for total maxillary alveolar osteotomy was to make vertical incisions bilaterally. This technique can be used for other segmental osteotomies.

soft tissue wounds. Following splint fixation the orthodontic arch wire can be luted back together with quick curing acrylic if necessary. This avoids the time-consuming practice of tying in a preformed surgical arch wire.

If two-piece maxillary osteotomy is to be performed in the midline, we still prefer to use two parasagittal osteotomies that are brought together at the incisive canal. The interdental osteotomy is also performed with a cement spatula osteotome before the other osteotomies. Four-piece maxillary osteotomy is practically never indicated with a competent orthodontic set-up. If it is attempted, a tunneling technique is recommended in which an anterior pedicle of mucoperiosteum is retained to assist in the perfusion of the anterior segments.

The length of time that the splint is left in place depends on the amount and type of movements made by the various segments. The range of time the splint is left in place would be 3 weeks for smaller movements and up to 8 weeks for greater expansion. The patient is returned to the orthodontist immediately after removal of the splint for fabrication of the appropriate retention and resumption of orthodontic treatment.

Finally if large interdental bone removal is necessary to close large extraction spaces, access may be needed on the palate, especially in the midline. In this case we prefer to retain an anterior labial mucoperiosteal pedicle with a small midline vertical incision to access the anterior nasal spine (Figures 57-23 and 57-24). This allows for a midline palatal incision and conservative circumferential incisions to access the palatal bone removal.

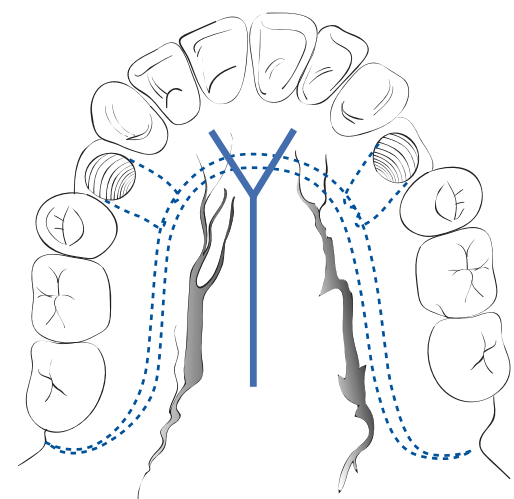

FIGURE 57-24 The traditional total maxillary alveolar osteotomy midline palatal incision with a Y at the anterior aspect can be used with caution.

Superior Repositioning

Lateral maxillary wedge osteotomy prior to maxillary repositioning often leaves large gaps between the bony interfaces as the maxilla is moved superiorly.⁶⁰ Shifting, tilting, or advancing the maxilla may reduce bone-to-bone contact. Sequential removal of osseous contacts avoids this needless loss of bone and provides more secure contact between the maxilla and the cranial base (see Figure 57-20). Therefore, only one horizontal osteotomy is made and no bone is removed until MMF is established and vertical repositioning is begun.

With MMF in place the maxilla and mandible are moved through the arc of rotation as dictated by the seated mandibular condyle (see Figures 57-17 and 57-18). The areas of bone contact can now be seen as the maxilla is positioned superiorly. Just enough bone is removed at the contact points to permit the superior repositioning planned. In many cases this will result in the formation of slots or grooves in the zygomatic buttress wall or elsewhere along the maxillary wall (see Figure 57-20). One must be careful that the grooves do not inhibit the free rotational movement of the maxillo-mandibular complex. This technique is particularly valuable when the maxilla is being shifted laterally or torqued in a transverse direction, which makes prediction of an osteotomy difficult. The maxilla is rigidly fixed and the MMF removed, the mandible autorotated into occlusion, and correct maxillary position confirmed.

Anterior Repositioning

The traditional Le Fort I osteotomy is inclined inferiorly from anterior to posterior in order to avoid the relatively large maxillary cuspid tooth root and placement of the cut inferior to the lateral extent of the zygomatic buttress. The resultant inclined plane may be problematic if this does not coincide with the desired movements.

A variety of straight, stepped, and Z osteotomies can be designed to accommodate the planned moves (Figures 57-25–57-28).^{61–65} If grafting (Figure 57-29) is desirable, the steps or Z osteotomies provide much better grafting sites than the pterygomaxillary fissure.

Inferior Repositioning

Inferior repositioning of the maxilla offers a special challenge in orthognathic surgery because there is a great relapse tendency.^{66–69} Various mechanisms have been advocated for stabilization and fixation of the maxilla after inferior repositioning. There have been a variety of techniques used to stabilize the inferior positioned maxilla, including suspension wires, interosseous wires, bone plates, Steinmann pins, Wessberg pins, and RAPs.^{33,62,65,70–72}

Stabilization of the inferiorly repositioned maxilla may not require bone grafting from a distant site if a series of slanted Z or step osteotomies are used (see Figure 57-25).^{61,65} The angulations of the osteotomies are planned so that the maxilla will slide down the incline plane of the cuts, maintaining bone contact as it is repositioned anteriorly and inferiorly. Depending on the inclination of the anterior versus posterior osteotomies, the max-

illa may be positioned more anteriorly or more inferiorly (see Figures 57-26–57-28).

Most surgeons prefer to use bone grafts and rigid fixation to stabilize the maxilla that has been inferiorly repositioned and has no bone-to-bone contact. Grafts can be secured with bone screws or plates if sufficient bone is available or with wire (see Figure 57-29). Candidates for inferior maxillary repositioning often have paper-thin maxillary bone. Internal rigid fixation with interosseous metal plates is the stabilization method of choice; however, occasionally insufficient bone is available adjacent to the osteotomy sites. In these cases the RAP system can be a crucial alternative (Figure 57-30). The application of this system has been described elsewhere.⁶⁵

Posterior Repositioning

Posteriorly repositioning the maxilla must be approached cautiously due to resultant loss of upper labial and paranasal osseous support for the overlying soft tissue. If the osteotomy is carried through the pterygomaxillary junction, bone must be removed either from the pterygoid plates (with great caution) or the maxillary tuberosity. An alternative is to direct the osteotomy through the maxillary

FIGURE 57-25 A, A Z-shaped osteotomy can be designed in the lateral walls of the piriform rims and the buttresses so that the maxilla may be moved downward and forward (B) without loss of all bony contact.

FIGURE 57-26 A, A Z osteotomy with the posterior cut steeper than the anterior one to increase posterior facial height and to (B) rotate the maxilla downward and forward with adjustment to the occlusal plane.

tuberosity just posterior to the second molar.^{73,74} This will leave tuberosity bone attached to the pterygoid plates, which can be more safely removed. Dangers of the technique include damage to the greater palatine artery distal to its anastomosis with the lesser palatine.

Maxillary horizontal excess may also be addressed by anterior maxillary osteotomy when extractions are indicated or edentulous sites are present. These techniques are discussed in detail later in this chapter.

Stable Fixation for Maxillary Osteotomies

Rigid internal fixation with bone plates and screws has become the standard for maxillary stabilization. Although this technique has eliminated many of the early postoperative stability concerns, the technique is less forgiving than wire fixation. Therefore, intraoperative positioning is even more important. A wide variety of plating systems and sizes are available. Each surgeon will discover his or her preference, but 2.0 mm four-hole plates are used in most cases (Figure 57-31). These will require a little more effort for adaptation than lighter ones, but with

practice can be used just as accurately and with more stability. When used, these plates virtually eliminate postoperative plate fracture or mobility.

Specific Procedures

Total Maxillary Alveolar Osteotomy

The total maxillary alveolar osteotomy was designed to avoid some of the problems seen with the Le Fort I down-fracture

technique; however, it did not fare any better.⁷⁵ Purported advantages including improved nasal airway, improved stability due to better bony contact, improved ability to widen the maxilla, and better maxillary perfusion have not been realized.⁷⁵⁻⁸¹ In several thousand maxillary osteotomies over the past 20 years, we have not found a need for this procedure.

Anterior Maxillary Osteotomy

Numerous techniques have been used to accomplish the anterior maxillary osteotomy. The three major techniques involve the use of one of three vascular pedicles: labial (Figure 57-32), palatal (Figure 57-33), and a combination of these with vertical incisions in both (Figure 57-34). All of these can be successful, and when done properly have few complications; however, what scant literature exists would indicate that the palatal pedicle provides the best vascularity.⁵⁰

Anterior maxillary osteotomies are generally used to treat horizontal maxillary excess when the posterior occlusion is correct or correctable by mandibular surgery. Commonly, anterior maxillary osteotomy with premolar extractions is used for bimaxillary protrusion in which both the anterior maxilla and the anterior mandible are to be retracted (Figure

FIGURE 57-27 A, A Z osteotomy with the posterior cut shallower than the anterior one to increase anterior facial height and to (B) rotate the maxilla down in the front and adjust the occlusal plane to a steeper angle.

FIGURE 57-28 An alternative method for advancement is to create a step (A) in the buttress and place a bone graft (B) in the step after repositioning.

57-35). These procedures are also used for correction of anterior open bite. Occasionally anterior maxillary osteotomy may be coupled with mandibular advancement and anterior mandibular segmental surgery in patients with a severe curve of Spee.

Sequencing the work-up when both jaws are involved requires imagination, because the surgical procedures need to be done systematically so that the surgeon never loses orientation. There are two possible scenarios: (1) the posterior occlusion is not going to be changed because the posterior maxillary and mandibular teeth need not be moved, or (2) mandibular surgery will be performed thereby correcting the posterior occlusion. This a crucial difference because if the posterior occlusion is *not* going to be changed by surgery, then the models must be mounted in *centric occlusion*, not centric relation. If the posterior occlusion will be altered by mandibular surgery, then a new centric relation will be established by the surgery and model surgery can be done as usual. In the first case the maxillary anterior model is cut and repositioned to the best relationship against the uncut mandible in centric occlusion and the remaining maxillary dentition, and then a splint is constructed.

If mandibular surgery is to be done, two mandibular models are mounted, one mandibular model is cut, and the other is left intact to preserve the intermediate phase. The anterior maxilla and the mandible are cut and repositioned together to the final position and a final splint is made. The cut maxilla can then be articulated with the uncut mandible to establish the intermediate position and a second (intermediate) splint is made. The final splint will be wired to the maxilla for a postoperative period so there must be a separate intermediate splint that articu-

lates with the final splint and the mandibular teeth.

Particularly in segmental surgery the model surgery should simulate the actual surgery to provide a clear understanding of the three-dimensional movements necessary to the proper performance of the surgical procedure. Measurement marks should be made at the level of the interproximal spaces and the root tips. Marks should also be made on the palate at the root tips and the maxillary midline. If widening is to occur, transpalatal marks should also be used. The use of intermediate splints in segmental cases is a little different from their use in total arch cases. Since the posterior maxilla is not mobilized, the anterior maxillary positioning is more difficult and can be deceiving. For example, the anterior maxilla can fit into the splint and appear ideal until the mandible is rotated into occlusion. If the mandible does not arc into the ideal occlusion, it is possible that the anterior maxilla is tipped superiorly or inferiorly and must be adjusted. For this reason the mandible should not be wired into MMF but left free to rotate into the maxilla. At surgery, if the mandible is held into intermaxillary fixation during the fixation process for the anterior maxilla, it is possible to pull the condyles out of the fossae

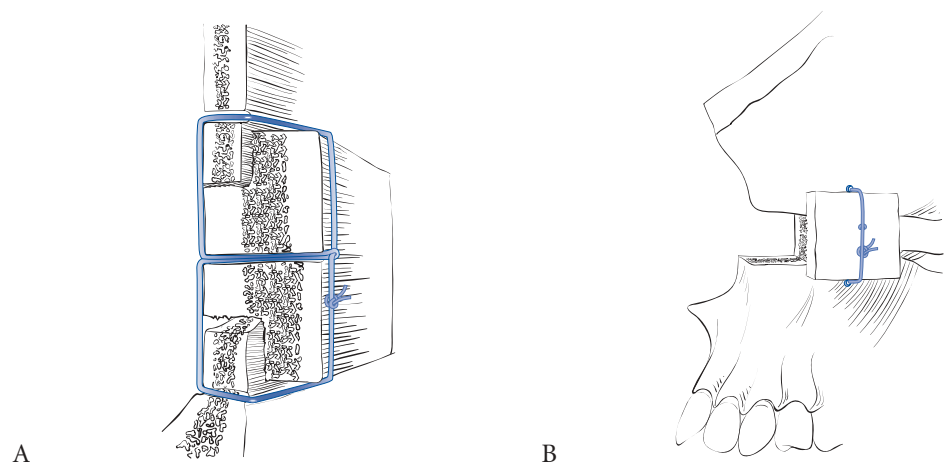

FIGURE 57-29 A, A single hole is placed in the middle of the bone graft and a loop of 28-gauge stainless steel wire is placed through the hole from inside out. The two ends are divided, with one placed through the superior cranial base wall and the other through the inferior maxillary segment. Finally one end is passed through the loop and twisted to the other, much like an Ivy loop. B, Bone graft shown in place.

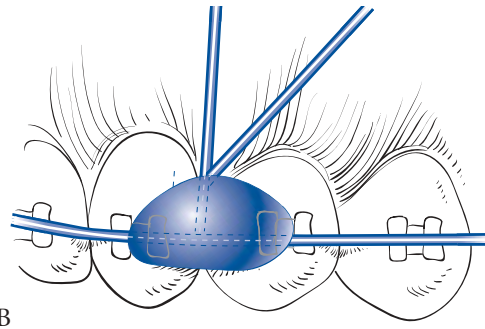

FIGURE 57-30 A, Rigid adjustable pin system. A 0.045 inch orthodontic wire is fabricated on a skull preoperatively and adapted to the newly positioned maxilla intraoperatively so that the wire lies passively, close to the orthodontic appliances or arch bars. B, The acrylic cements the junction of the wire and the orthodontic appliances; the end of the wire is also covered.

with a resultant malocclusion. Therefore, the splint must be ligated to the posterior maxilla first, and the anterior maxilla is then brought into the splint and ligated. If the mandible rotates into the desired occlusion, then the maxilla can be considered to be in the correct place and fixed accordingly. If mandibular surgery is required, it can be initiated at this time.

The choice of surgical technique is made on the basis of access and the areas that will be most difficult to visualize intraoperatively. For example, in cases of open bite in which no teeth are to be

extracted, the anterior segment will be rotated clockwise downward after interdental osteotomies. Access to the interdental area, the midline of the palate, and the anterior nasal spine is not as critical as it is with other surgical movements. This procedure can be done with a circumvestibular incision or with bilateral horizontal incisions in the canine-molar regions and a vertical incision in the midline between the central incisors. On the other hand, if first premolars are to be extracted or have already been, and the anterior maxilla is to be retracted several millimeters, access to

the midpalatal area is essential. The Wunderer technique, in which the palatal soft tissue is elevated posteriorly, gives great access to the palatal bony tissue, but care must be taken to preserve the labial soft tissue pedicle.¹⁸ However, if superior repositioning is required, the access to the junction of the anterior nasal spine and the nasal septum is poor. A vertical incision can be made over the anterior nasal spine, but since this labial flap represents the total blood supply to the anterior maxilla, it is not recommended.

Our choice of procedures for most anterior maxillary osteotomies is a hybrid (see Figure 57-34). The labial incisions are made laterally as per Wunderer with a vertical midline incision to permit access to the anterior nasal spine–nasal septum. However, in place of a full palatal flap, circumdental incisions are made around the necks of the teeth on either side of the interdental osteotomies and a midline incision is made over the midpalatal suture with a small anterior Y if necessary. The Y should be anterior to the interdental bone cut and be as conservative as possible.

Fixation of anterior maxillary osteotomies is as varied as the surgical techniques.⁸² Orthodontic arch wires and cast splints represent two of the extremes

FIGURE 57-31 Bone plating encompasses a wide variety of plates and screws, ranging from very rigid to very malleable. Generally 2.0 mm plates are used in the piriform rims and either 2.0 or 1.5 mm plates in the buttresses.

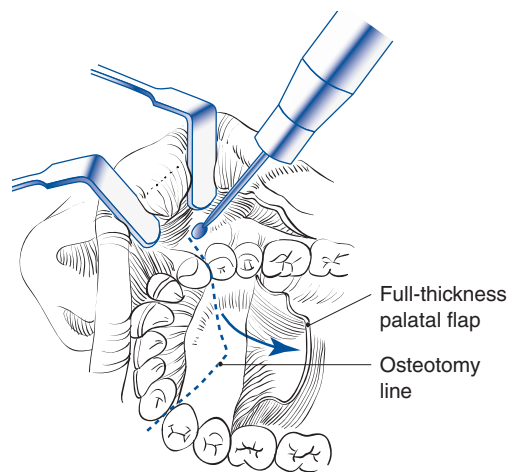

FIGURE 57-32 Labial pedicle for anterior maxillary osteotomy; the palate is flapped open.

FIGURE 57-33 Palatal pedicle for anterior maxillary osteotomy is created with a horizontal labial incision.

FIGURE 57-34 A combination of labial and palatal pedicles can be used for an anterior maxillary osteotomy without extractions.

in techniques used for fixation. Orthodontic appliances, if they are in place, are the handiest to use at least for part of the fixation. However, supplemental fixation may be desirable. An occlusal splint, with skeletal wire in the anterior nasal spine, is helpful in such cases, especially if tension on the free segment is expected. Small plates and screws can be carefully used to fixate the segment. Arch bars have been used and in certain cases may be appropriate, but a lower level of precision can be expected.

The most important guideline is that, at the time of surgery, the anterior maxilla must be mobile enough so that it does not require any significant pressure to move it into the desired position. Fixation can then be instituted by one of the many methods that will hold the segment in the proper position throughout the healing period. Maxillomandibular fixation is almost never required.

Posterior Maxillary Osteotomy

The posterior maxillary osteotomy and its modifications are rarely indicated today.^{19,22,83-88} If open bite or transverse expansion is needed, the Le Fort I down-fracture is much easier, quicker, and more predictable. Posterior maxillary osteotomy is usually indicated as a preprosthetic pro-

FIGURE 57-35 Anterior maxillary osteotomy with first premolars extracted corrects maxillary excess, bimaxillary protrusion, and anterior open bite.

cedure to correct hypereruption of a posterior maxillary dentoalveolar segment. Meticulous model surgery is essential to visualizing the three-dimensional movements and in anticipating osseous interference of the segment. Periapical radiographs are useful for evaluating planned interdental and supra-apical osteotomy sites. Once again the models should be mounted in centric occlusion, not centric relation, unless the mandible is also going to be operated on.

Outpatient anesthesia can be used for isolated posterior segmental procedures. A high palatal vault permits palatal osteotomy transantrally beneath the nasal floor. The soft tissue incision is made horizontally in the maxillary buccal vestibule from the anticipated anterior interdental osteotomy site to the second molar (Figure 57-36). Mucoperiosteal dissection beneath the superior aspect of the incision exposes the lateral maxilla. The pterygomaxillary region is exposed and soft tissue retracted in a tunneling dissection. At the anterior interdental osteotomy site, conservative tunneling of the periosteum exposes the full vertical extent of the dentoalveolus. After retraction of the soft tissue with skin hooks and right-angle retractors, the buccal interdental osteotomy can be outlined

with a small fissure bur in a rotary hand-piece or can be directly completed with a thin cement spatula osteotome.

A horizontal osteotomy is made approximately 5 mm above the roots of the teeth and connected with the anterior interdental cut (see Figure 57-36). The vertical interdental osteotomy should be completed first so that the segment is not mobile while using interdental osteotomes. The palatal osteotomy is accomplished with a small sharp curved osteotome directed at the juncture of the vertical alveolus and horizontal palatal shelf. The surgeon places a finger in the palatal mucosa to detect complete osseous sectioning while minimizing palatal mucosal trauma (Figure 57-37A and B). In cases with high palatal vaults the transantral cut is completed along the entire anteroposterior extent of the planned palatal osteotomy (see Figure 57-37B), except in the area of the descending palatal neurovascular bundle. Next the pterygomaxillary junction is separated with a chisel using a technique similar to that for a total maxillary osteotomy. Patients with low flat palatal vaults are more easily osteotomized through the nasal floor (Figure 57-37C).

The posterior dentoalveolar segment is down-fractured using digital pressure. Anticipated osseous interference may be

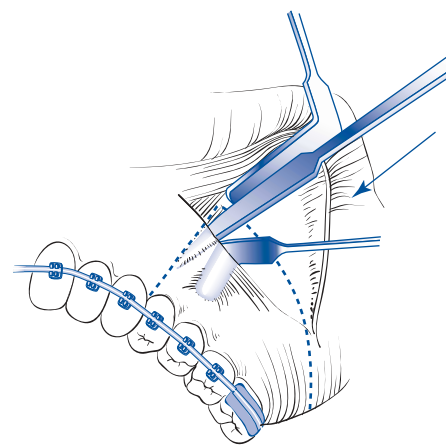

FIGURE 57-36 Posterior maxillary osteotomy. Horizontal vestibular incision with tunneling access to the interdental papilla. The dashed line marks horizontal and interdental osteotomies.

FIGURE 57-37 A, Transantral osteotomy is made at the junction of the horizontal palate and vertical alveolar process. B, Approach for deep vaulted palates. C, Approach for flat shallow palates.

removed using a bur or rongeur. Previously inaccessible medial and posterior walls of the mobile segment are addressed following mobilization and displacement of the posterior segment. Bone removal at the perpendicular plate of the palatine bone and mobilization should continue until the segment can be repositioned with minimal digital force (Figure 57-38). Final contouring is accomplished while holding the splint on the stable portion of the maxilla. The mandible is rotated into its dictated occluding position to ensure that no distortion of the splint has occurred. A slightly thicker splint and transpalatal acrylic or wire reinforcement will add rigidity to prevent inadvertent distortion of the posterior extension of the splint. The segment is ligated to the splint.

The repositioned posterior maxillary segment may be fixated with interosseous wire, suspension wire, stable pin fixation, or bone plates. Osseous grafts are rarely required but may be obtained from local regional sites. Additional stability is attained by luting the orthodontic arch wire back together with quick curing acrylic or by placing a rectangular arch wire across the interdental osteotomy site. Intermaxillary fixation is not required.

If the posterior segment is to be repositioned laterally or medially to any extent, added access is necessary. A midline palatal incision may be made and the palatal tissue reflected laterally (Figure 57-39). Careful dissection ensures the integrity of the greater palatine vasculature. This approach gives access to the sinus and nasal cavity. If the palatal vault is high, the osteotomy is usually carried through the sinus (see Figure 57-37B). If the alveolus is short and the palatal vault shallow, the osteotomy usually crosses the medial sinus wall and passes through the floor of the nose (see Figure 57-37C).

Surgically Assisted Rapid Palatal Expansion: History

The concept of correcting maxillary transverse width discrepancies originated in the United States in 1860 by Angell, who reported it in *Dental Cosmos*. Angell described a widening of the maxillary dental arch by opening the midpalatal suture.⁸⁹ The concept fell into disuse by American practitioners by the early 1900s. Haas re-introduced the concept in 1961 with rapid palatal expansion (RPE, also referred to as rapid maxillary expansion), appliances that effectively corrected arch width discrepancies.⁹⁰ In growing

children nonsurgical RPE results in opening of the midpalatal suture, but stability has been questioned. Timms and Moss, Haas, and Isaacson and Ingram have shown orthodontic RPE to result in alveolar bending, periodontal membrane compression, lateral tooth displacement, and tooth extrusion.⁹¹⁻⁹³ For those reasons Haas believed that overexpansion was very important. Even

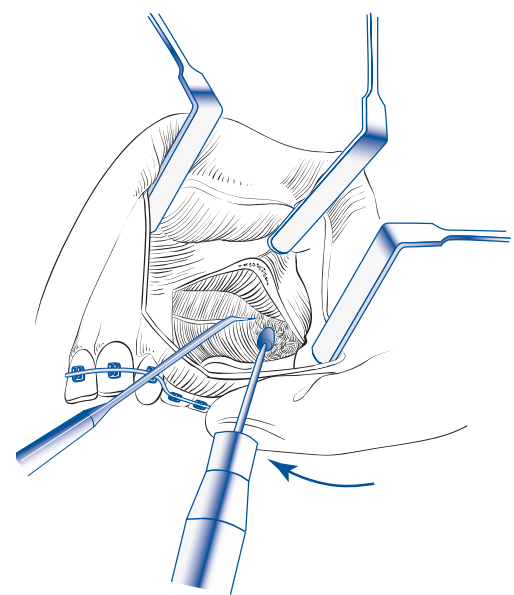

FIGURE 57-38 Bone is removed at the perpendicular plate of the palatine bone using a transantral approach.

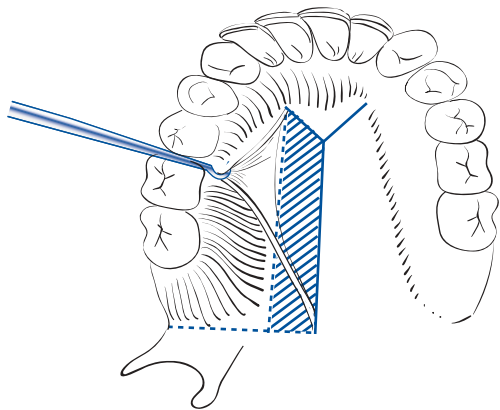

FIGURE 57-39 A midline palatal incision gives access for the removal of bone as the posterior maxillary segment is moved medially.

with 50% overexpansion, nonsurgical RPE has been associated with relapse and subsequent failure in adults, but has been relatively successful in children and adolescents.⁹¹⁻⁹³

Although historically the midpalatal suture was thought to be the area of resistance to expansion, Isaacson and Ingram have shown that the major site of resistance is not the midpalatal suture but the remaining maxillary articulations.⁹³ Lines as well as Bell and Epker demonstrated that increased facial skeletal resistance to expansion was at the zygomaticotemporal, zygomaticofrontal, and zygomaticomaxillary sutures.^{94,95} Wertz theorized that the resistance was due to the zygomatic arches.⁹⁶ Identification of these areas of resistance in the craniofacial skeleton stimulated the development of various maxillary osteotomies to expand the maxilla in conjunction with orthodontic appliances.⁹⁶ Published surgical techniques report the removal of the bony resistance of the maxilla in order to symmetrically expand the hemimaxillas with short-term orthopedic forces.^{94,95,97-101} Lehman and colleagues have also demonstrated expansion with an RPE appliance.⁹⁷ Kennedy and colleagues reported a significant increase in the amount of lateral movement in animals that had osteotomies prior to orthodontic RPE.⁹⁸

Reported results vary with technique and the timing of placement of an active orthopedic expansion device, but all note the expansion to be more stable than orthodontic RPE alone.

The role of surgery with RPE is to release the areas of resistance in the maxillas before RPE. Whether RPE will be done alone or in conjunction with surgery will depend on the patient's age and the condition of the midpalatal suture, but not the maxillomandibular relation. Lines found surgically assisted rapid palatal expansion (SARPE) to be extremely valuable in young patients (growing children) exhibiting maxillary collapse, maxillary retrusion, and pseudo-Class III malocclusions.⁹⁴

SARPE is distraction osteogenesis of the maxilla in a transverse plane. The benefits of its use are gradual callous distraction that allows the soft tissues to accommodate, and greater long-term stability.

When maxillary expansion and total maxillary osteotomy are needed, two treatment regimens are possible: SARPE as a first stage followed by a one-piece maxillary osteotomy at a later date or multiple-piece maxillary osteotomy in the normal orthognathic sequence. The four factors that must be considered when determining which method is preferred are arch length discrepancy, arch morphology, vertical dimension, and ectopic eruption of posterior teeth.

Arch Length Discrepancy In cases of arch length deficiency, a SARPE increases arch circumference sufficiently, especially in the anterior, to permit alignment of crowded teeth and avoid extraction of premolars or excessive tipping of incisors. SARPE is also beneficial when minimal changes in the sagittal dimension are necessary because of the nasolabial angle and lip-to-tooth considerations.

Arch Morphology The majority of cases of transverse deficiency characteristically exhibit a narrow tapering arch form with

the discrepancy pronounced in the canine region. To achieve a functional occlusion, the intercanine width must be increased and the anterior segment flattened for a normal elliptical arch morphology. If nonextraction orthodontic therapy is desired, a SARPE is the treatment of choice. A three- or four-piece segmental maxillary surgical procedure may be less ideal, particularly because of potential periodontal problems and possible vascular compromise.

If the discrepancy is minimal and extraction of the first premolars is desired, a three-piece segmental maxillary procedure is indicated, but only after the canines are orthodontically moved posteriorly to provide an increased width. The inherent problem is relapse of the buccally displaced canines. This procedure is indicated if there is no transverse discrepancy in the canine region but significant constriction in the premolar-molar region.

Vertical Dimension The vertical dimension is of particular concern in patients who exhibit anterior open bites. Segmental orthodontics is suggested, with no attempt to level the arch, using a three- or four-piece maxillary procedure to level the arch and at the same time correct the bilateral absolute transverse maxillary deficiency.

Ectopic Eruption of One or Two Posterior Teeth If ectopic eruption is serious enough that it cannot be treated with orthodontic therapy, a segmental osteotomy with expansion may be done.

The stability of SARPE has been reported.^{99,102} In one reported study on long-term stability of SARPE, the surgical results remained stable with only 6.4 to 7.5% relapse in the canine, premolar, and molar regions.⁹⁹ This stability exceeds that of multiple-piece Le Fort osteotomies.^{100,102}

Surgically Assisted Rapid Palatal Expansion: Surgical Technique

Bilateral mucoperiosteal incisions are made from the piriform rims to zygomatic

buttresses (Figure 57-40A). Bilateral osteotomies are then made from the piriform rims to low in the pterygomaxillary junction (see Figure 57-40A). A simple anteroposterior osteotomy from the piriform rim to the pterygomaxillary junction is suggested for SARPE. More complicated designs appear to be advantageous in two-dimensional drawings, but in fact are meaningless when applied to three-dimensional geometric structures such as the maxilla.¹⁰³ The theory put forth by Betts and colleagues shows a sloped cut from the piriform to the buttress.¹⁰³ The supposition is that as the maxilla is expanded, it will “ride down” this slope. This concept appears valid in a two-dimensional drawing; however, three-dimensionally, if the osteotomy is made flat from lateral to medial, as expansion occurs, then the bone at the piriform slides laterally over the flat surface lateral to it and the bone of the buttress slides laterally over the flat surface lateral to it. Therefore, if the lateral maxillary wall saw cuts are made straight in perpendicular to the midsagittal plane from lateral to medial, then the angulation of the cut from anterior to posterior does not affect the vertical position of the segments as they are expanded. This can be easily demonstrated on a dry skull.

Osteotomies are made of the anterior 1.5 cm of the lateral nasal wall because this is the thickest portion of the anterior nasal wall. Separation of the hemimaxillas is performed by driving a spatula osteotome between the central incisors parallel to the palate for approximately 1 to 1.5 cm (Figure 57-40B–D). The expansion device is turned until separation is noted between the central incisor teeth (Figure 57-41). Both segments are mobilized by prying until equal mobility is seen bilaterally. Mobilization is continued until approximately 1.5 to 2.0 mm is opened between central incisors.

Some authors recommend a subtotal Le Fort I osteotomy with a horizontal

FIGURE 57-40 Surgically assisted rapid palatal expansion. A, Bilateral horizontal mucoperiosteal incisions are made, followed by bilateral osteotomies from the piriform rims to pterygomaxillary junctions. B–D, Division of hemimaxillae is accomplished by inserting an osteotome in the midline.

osteotomy, vertical midline osteotomy, and pterygoid and septal separation.¹⁰³ Shetty and colleagues demonstrated, with a photoelastic model, that the mid-palatal and pterygomaxillary articulations were the primary anatomic sites of resistance to expansion forces.¹⁰⁴ The article by Shetty and colleagues in 1994 report performing only incomplete cuts of the lateral maxillary wall, from second bicuspid to second molar. It is unclear whether these findings would be as significant with complete cuts from the piriform to the pterygomaxillary fissure. Need for separation of the pterygomaxillary junction is therefore a point of debate. However, since our results have

FIGURE 57-41 Surgically assisted rapid palatal expansion. Expansion device is turned to separate hemimaxillas.

shown minimal relapse without pterygo-maxillary disjunction, we do not perform this maneuver in most cases.⁹⁹

If two sources of potential hemorrhage (manipulation of the pterygomaxillary junction and separation of the nasal septum from the nasal crest of the maxilla) are avoided, this procedure can be done as an office-based procedure, on an outpatient basis, and under intravenous sedation. Steroids are routinely used but antibiotics are not necessary. A 5-day post-operative rest period is observed, after which the expansion appliance is turned according to specific instructions until the desired expansion is achieved.

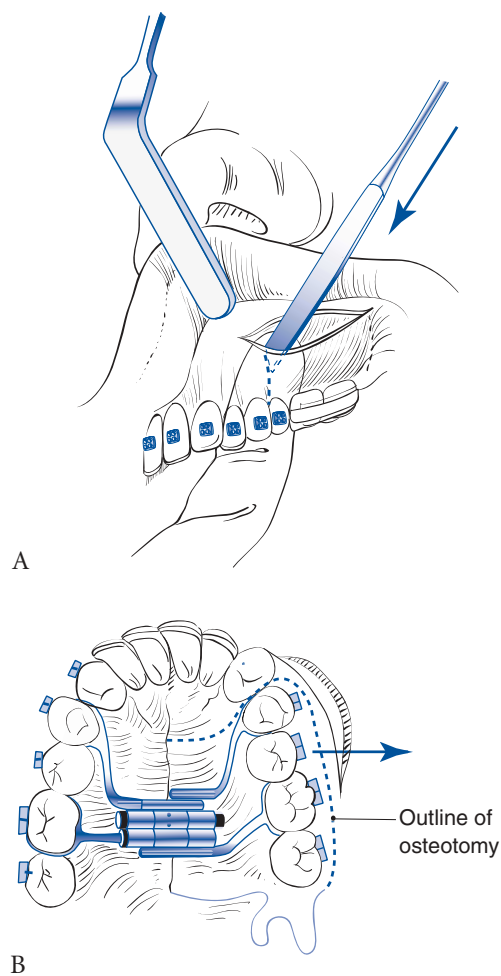

FIGURE 57-42 Unilateral surgically assisted rapid palatal expansion. A, Osteotomy is driven to midpalatal suture. B, Horizontal osteotomy is completed in the same manner as bilateral osteotomy.

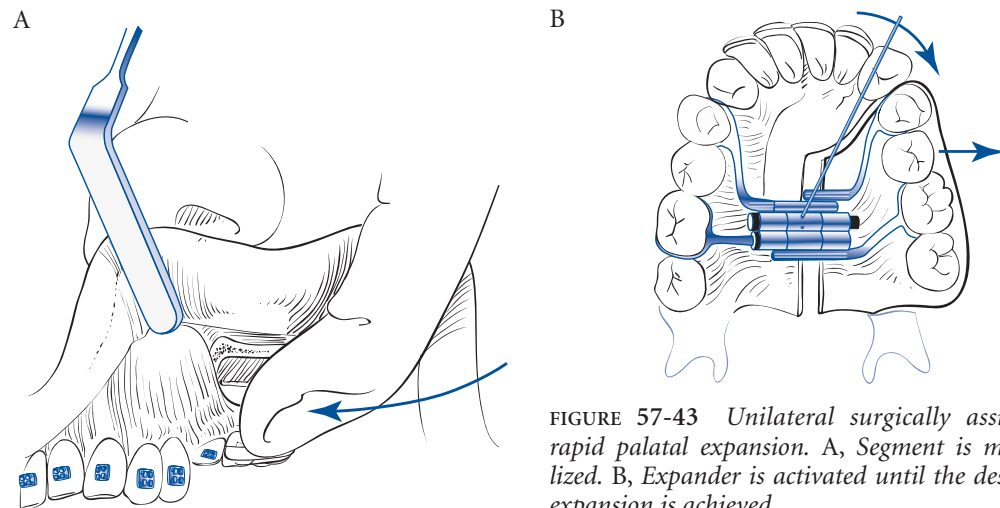

FIGURE 57-43 Unilateral surgically assisted rapid palatal expansion. A, Segment is mobilized. B, Expander is activated until the desired expansion is achieved.

Unilateral SARPE can be achieved by completing a vertical interdental osteotomy between the appropriate teeth and connecting that with a horizontal osteotomy extending posteriorly to the pterygomaxillary junction. If the entire hemimaxilla is to be mobilized, it is performed in the same way as described for a bilateral case, only unilaterally. If a widening of only the posterior part of the hemimaxilla

is desired, the interdental osteotomy must be completed all the way to the midline suture (Figure 57-42). The segment is mobilized (Figure 57-43A) and expanded in the same manner as the bilateral procedure (Figure 57-43B).

Zygomatic Osteotomy

In patients with severe midface deficiency it may be favorable to enhance the prominence

FIGURE 57-44 Zygomatic osteotomy. A, Parasagittal vertical osteotomy cuts through the root of the zygoma. B, With out-fracturing and placement of graft material for transverse augmentation of the malar eminence. C, Mushroom-shaped graft placement for anteroposterior and transverse augmentation of the malar eminence.

of the zygomas. Also, esthetically, high cheekbones have always been popular, and with a growing public awareness of surgical capabilities an increasing demand has surfaced for procedures to enhance this area. Numerous methods have been developed to augment the malar eminences, most involving grafts or implants. Autologous grafts are disappointing because of resorption and the need for a donor site. Allogeneic transplants such as lyophilized cartilage have been used with some success but are prone to migration. Presently our choice for malar augmentation is with alloplastic implants (porous polyethylene).

However, when alloplasts are contraindicated, the zygomatic osteotomy may be useful. The zygomatic osteotomy is approached through an intraoral incision. A reciprocating saw is used to make a parasagittal osteotomy through the zygoma just adjacent to the root of the structure (Figure 57-44A and B). This is done as close to the lateral orbital rim as possible. The zygoma is out-fractured gently so that an interpositional material can be placed to hold it in position. The interpositional material can be stabilized in any traditional method, since it is not difficult to fixate this area. This technique does not give anterior projection unless the interpositional material is fashioned to project forward (Figure 57-44C).

Modified Le Fort Osteotomies

Osteotomies that extend the traditional Le Fort I have been called by many names including modified Le Fort I, II, III; high Le Fort I; and pyramidal, middle, intermediary, quadrangular, and maxillary-malar-infraorbital osteotomies (Figure 57-45A–C). We have used them all and have described them previously.¹⁰⁵ This group of osteotomies is severely limited regarding expansion, and rotational and torquing movements. Therefore, with the success of porous polyethylene implants to the malar, infraorbital, lateral orbital, and paranasal regions, we rarely see a need for these more invasive osteotomies (Figure 57-46A–C).

Management of Facial Asymmetry

Peter D. Waite, MPH, DDS, MD

Scott D. Urban, DMD, MD

In the 1960s surgical treatment of orthognathic deformities developed when satisfactory results were unobtainable by orthodontics alone. Mild cases of jaw deformities and malocclusion can sometimes be camouflaged by dental treatment and growth modification.¹ Severe malocclusion is often beyond the envelope of orthodontic treatment; therefore, surgical procedures of the maxilla and mandible have been developed. Just as some malocclusions are beyond orthodontics alone, some orthognathic deformities are beyond surgery directed at a single jaw, that is, the maxilla or the mandible. Although a single osteotomy might improve function and esthetics, bimaxillary surgery or double-jaw surgery is often indicated for large anteroposterior discrepancies, open bite, and most asymmetries.²⁻⁵ As orthognathic surgery has been refined, it has become evident that some problems are beyond treatment of a single jaw. The novice might assume that single-jaw surgery is better—simple and less complicated—but the final outcome is often a compromise and unstable. Bimaxillary surgery allows a much greater degree of flexibility with regard to three-dimensional treatment.

In the 1960s and 1970s surgeons attempted to limit orthognathic surgery to one jaw, usually the mandible. Ramus osteotomies with maxillary osteotomies were complex, technically difficult, time consuming, unstable, and associated with

higher morbidity.⁶ It is impossible to correct a canted maxilla without adjusting the mandibular plane of occlusion. Even simple midline discrepancies resulting from unilateral tooth loss can be quickly improved by mild rotational changes in the facial skeleton.

This chapter focuses on the unique nature of asymmetric orthognathic deformities as an indication for bimaxillary surgery, which is really nothing more than a combination of two procedures. The most important aspect of bimaxillary surgery is not the ability to do simultaneous maxillary and mandibular procedures, but to understand the indications and treatment plan and how to maintain a stable reference during surgery.

Little has been written on orthognathic asymmetries as an indication for bimaxillary surgery. Poor treatment planning and poor surgical reference are common mistakes. Asymmetries require three-dimensional changes and complex skeletal movements with adjunctive soft tissue symmetry. The current discussion includes etiology amenable to orthognathic procedures, diagnostic imaging, treatment planning, and surgery.

Facial symmetry has a high correlation with attractiveness. Even a slight asymmetry is quickly noticed by the human eye. Greater degrees of asymmetry are correlated with clinical depression, neurosis, inferiority complex, poor self-esteem, and gen-

eral poor-quality-of-life health problems.⁷ Mandibular asymmetry is a significant dysfunction and difficult to correct.

Etiology

There are multiple causes of mandibular and facial asymmetry, but the differential can be separated into three classes: congenital, developmental, and acquired.^{8,9} *Congenital* anomalies are conditions acquired during in utero development and can be further subdivided into malformations, deformities, and disruptions. Malformations are the result of an intrinsically abnormal developmental process in embryogenesis. Unilateral cleft lip is an example of a malformation.⁹ Deformities are an abnormal form or position of a part of the body caused by a nondisruptive mechanical force during the fetal period.⁹ Mandibular deformation may result from a prolonged sharply laterally flexed position of the head with the shoulder pressed against the mandible during late intrauterine growth. Disruptions are morphologic defects resulting from a breakdown of an otherwise normal developmental process.⁹ Rare facial clefting and limb amputation from an amniotic band are good examples of disruption.⁹ *Developmental* anomalies are conditions arising during postuterine growth through adulthood. *Acquired* anomalies are conditions arising from either trauma or pathology.

Congenital Anomalies

Hemifacial Microsomia

Hemifacial microsomia (HFM) is a craniofacial malformation of the first and second branchial arches presenting with asymmetric unilateral or bilateral hypoplasia of the orbit(s), maxilla, mandible, ear, cranial nerves, and soft tissue (Figure 58-1).¹⁰ Current evidence supports the theory that hemifacial microsomia results from a defect in the proliferation and migration of embryonic neural crest cells.^{11,12} Other theories have included hemorrhage of the stapedia artery during fetal development, which ultimately leads to impaired unilateral facial growth.^{13,14} However, the true etiologic factors still remain unknown.

Two important factors need to be considered in the treatment planning of HFM: (1) the facial growth potential and/or restriction and its effect on surrounding structures and (2) the degree of hypoplasia involving the glenoid fossa, mandibular condyle, and ramus unit.^{15,16} Classifying the extent of the HFM deformity

FIGURE 58-1 A 16-year-old female with mild hemifacial microsomia type I. Note the canted maxilla, dental deviation, and facial asymmetry.

can provide clarity in determining ideal reconstruction and accurate prognosis. The Pruzansky HFM classification,¹⁷ modified by Kaban and colleagues,¹⁸ currently provides a clinically useful framework to help guide the treatment plan based on the presence or absence of critical structures.^{18,19}

HFM type I deformity can be summarized as a generalized mild hypoplastic state involving the muscles of mastication, the glenoid fossa, and the mandibular condyle and ramus unit. The temporomandibular joint (TMJ) functions with normal rotation and restricted translation. Patients present with mild mandibular retrognathia and facial asymmetry. Because there is satisfactory TMJ occlusal function and mild dysmorphology, surgical therapy is usually not indicated.

HFM type IIA deformity involves a hypoplastic cone-shaped condylar head. The condyle is located medial and anterior to a hypoplastic glenoid fossa. TMJ function is often satisfactory. Again, surgical intervention of the TMJ is usually not indicated.

HFM type IIB deformity involves a moderate to severe hypoplasia of the glenoid fossa, condyle, and mandibular ramus. Unlike the type IIA deformity, these patients have no articulation between the temporal bone and a condyle. However, manual manipulation reveals a posterior “stop” of the condyle contacting the glenoid fossa.²⁰

A patient with HFM type III has a complete absence of the mandibular ramus and condyle. No manual condylar seating or posterior stop is present. These patients present with severe mandibular dysmorphology and often require TMJ surgical reconstruction (Figure 58-2).²⁰

The treatment of HFM is controversial. The treatment philosophy of interceptive orthodontics and surgical treatment in growing children is based upon the theory that HFM is a progressive deformity.¹⁵ Conversely, a treatment protocol based on

FIGURE 58-2 A 14-year-old female with severe hemifacial microsomia type III, which is associated with facial clefting and a total absence of condyle.

the theory that HFM is not progressive in nature is well described by Posnick.¹⁶

Cleft Lip and Cleft Palate

Patients with a cleft lip and cleft palate often present with a bilateral or unilateral midface deficiency resulting in augmentation and involving the paranasal, nasal, infraorbital, and zygomatic regions as well as the occlusal level.²¹ However, the degree and location of maxillofacial growth deficiency in children with clefts is largely dependent on the location and type of cleft lip/cleft palate repair and the age of the child at the time of repair.²²⁻²⁴ Most studies show that children with a repaired cleft lip/cleft palate have decreased vertical and horizontal maxillary growth and decreased vertical growth of the ramus and steep mandibular plane angle.²⁵⁻²⁷ Ross has shown that approximately 25% of patients with a repaired cleft lip or cleft palate have a midface deficiency and class III malocclusion that require skeletal surgery.²⁸

Plagiocephaly

Plagiocephaly is derived from the Greek word *plagios*, which refers to the twisted shape of the skull when viewed cranially-caudally. The etiology is often a unilateral synostosis of the coronal or lambdoid

suture. Unilateral synostosis of the coronal suture results in an asymmetric parallelogram-shaped forehead and brow. The affected side is flattened, and the contralateral side may show compensatory bulging or bossing. In addition, synostosis of the coronal suture often indirectly affects the lower facial morphology. The root of the nose is deviated to the involved side, and the chin is often deviated to the side opposite of the flattened forehead. The mandible is normally developed but may exhibit secondary dysmorphology.^{29,30}

Congenital Hemifacial Hyperplasia

Congenital hemifacial hyperplasia is a rare unilateral enlargement of the craniofacial soft and/or bony tissues. Although the term *hemihypertrophy* has commonly been used, it is inappropriate because the condition refers to hemihyperplasia.³¹ Pollock and colleagues have hypothesized that the reason for the asymmetric facial development is abnormal neural crest migration.³² Yoshimoto and colleagues have found increased proliferative activity of osteoblasts in a patient with congenital hemifacial hyperplasia and have hypothesized that fibroblast growth factor and its receptor signal transduction axis in osteoblasts may be selectively involved, leading to the progression of hemifacial overgrowth.³³

Developmental Anomalies

Intrinsic Jaw-Growth Deformities

Facial Hemiatrophy Facial hemiatrophy (Parry-Romberg syndrome) is characterized by a progressive unilateral facial loss of skin, soft tissues, cartilage, and bony tissue (Figure 58-3). Usually, the left side is affected rather than the right. Associated abnormalities include jacksonian epilepsy, cutaneous dyspigmentations, and ipsilateral alopecia.³¹

The syndrome usually starts during the first two decades of life and completes progression within 2 to 15 years.^{34–36} The etiology of facial hemiatrophy remains largely unknown, but associations with Lyme disease, ablation of the superior cervical sympathetic ganglia, localized scleroderma, Rasmussen encephalitis, and systemic lupus erythematosus have been found.^{37–41} Alterations in the peripheral trophic sympathetic system is one of the more emphasized theories.³¹ Treatments have included silicone injections, alloplastic implants, microfat injections, and microvascular free tissue transfer.^{42–44}

Hemimandibular Hyperplasia/Elongation Another condition resulting in facial asymmetry is hemimandibular hyperplasia. Hemimandibular hyperplasia is characterized by a diffuse enlargement of the condyle, the condylar neck, and the mandibular ramus and body.⁴⁵ In 1986 Obwegeser and Makek described the deformity as hemimandibular hyper-

plasia or hemimandibular elongation.⁴⁶ In 1996 Chen and colleagues proposed that all cases of hemimandibular hyperplasia and hemimandibular elongation actually represent variations of condylar overgrowth.⁴⁷ They proposed that if condylar overgrowth is not arrested, it can progress into hemimandibular hyperplasia and hemimandibular elongation. In spite of the differences in nomenclature, no etiologic factor has been established. Condylar growth patterns can be evaluated by serial clinical comparisons, cephalometric tracings, and bone scanning with technetium 99m phosphate. However, no ideal method has been found to assess whether condylar overgrowth is “inactive.” Therapy is guided by the patient’s age and condylar growth activity. Treatment modalities have ranged from condylectomy to orthopedic maxillary management. However, strong consideration should be given to refraining from surgery until growth activity has ceased.⁴⁵

Secondary Growth Deformities

Sternocleidomastoid torticollis is a condition thought to result from a birth trauma-induced hematoma of the sternocleidomastoid muscle that fibroses over time and leads to muscular contraction. However, the precise etiologic factors are still considered unknown. If the condition is not corrected with proper physiotherapy for the neck/sternocleidomastoid muscle or surgical therapy, malformed facial development may occur ipsilateral to the side affected by the torticollis.^{48,49}

Duchenne’s muscular dystrophy and cerebral palsy often result in areas of decreased muscle tone, which can affect the development of facial morphology by limiting the amount of bone formation at sites of muscle attachment and function. Consequently, facial asymmetry/dysmorphology can be a finding with Duchenne’s muscular dystrophy and cerebral palsy.⁵⁰

FIGURE 58-3 *Right facial hemiatrophy (Parry-Romberg syndrome). At the time this photograph was taken, the patient had undergone skin and bone grafting.*

Acquired Facial Asymmetries

Condylar Trauma

A frequent cause of facial asymmetry in the growing child is trauma to the mandibular condyle (Figures 58-4 and 58-5).⁵¹ Trauma-induced injury to the condyle can lead to a hemarthrosis, which can result in scarring and restricted translation of the condyle. Proffit and Turvey described this as a functional ankylosis or soft tissue extracapsular ankylosis.⁵² Bony ankylosis of the condyle to the skull base can also occur from an intracapsular hemarthrosis.

Consequently, traumatic-induced scarring or bony ankylosis of the TMJ can result in relative degrees of restricted skeletal growth. In other words, the greater the degree of translational restriction, the greater the facial deformity. Thus, a frequently entertained question is whether open reduction and internal fixation of the condylar fracture are required to stabilize the condylar cartilaginous growth center. Studies in immature primates and children have revealed that the displaced condylar segment undergoes resorption and that a new condyle and the overlying cartilage are regenerated. Thus, there is nothing intrinsically important about the condylar head tissue as a mandibular

FIGURE 58-4 This adult male sustained a fracture of the condyle as a teenager resulting in abnormal growth.

growth center. Because the condylar head in children is generated spontaneously, the necessity of open reduction and internal fixation of the displaced condylar segment is eliminated. Moreover, the resulting scar and possible soft tissue and hard tissue restriction from open reduction could outweigh the benefits of surgical and anatomic condylar alignment. Thus, open reduction of condylar fractures in children should be avoided.⁵²⁻⁵⁴

Juvenile Idiopathic Arthritis

Facial asymmetry can be a finding in patients affected with juvenile idiopathic arthritis (JIA) of the TMJ.⁵⁵ JIA is a disease characterized by chronic inflammation of one or more joints affecting children up to the age of 18 years. The TMJ is frequently involved and can lead to facial growth disturbance including facial asymmetry.⁵⁵ TMJ involvement can be asymmetrical or asymptomatic and may not be evident clinically.^{56,57} However, symptomatic TMJ involvement may not be associated with facial growth disturbances, and, conversely, facial growth disturbance may be present without TMJ symptoms.⁵⁶

Both polyarticular- and pauciarticular-onset JIA have been found to have a negative impact on the form, function, and esthetics of the face; however, the effects are more pronounced with polyarticular JIA.^{58,59} Characteristic facial features of patients with JIA include a small mandible, Class II malocclusion, and anterior open bite. Patients with polyarticular JIA with TMJ involvement tend to have small short faces with underdeveloped mandibles.⁶⁰

Currently there is no effective therapeutic means to eliminate the progression of the disease and its effect on facial development; however, methotrexate therapy has been shown to minimize TMJ destruction and craniofacial dysmorphology in patients affected with polyarticular JIA.⁶¹ Corticosteroids have been used in the treatment of JIA, but their therapeutic value is still controversial.

FIGURE 58-5 Panoramic radiograph of the patient in Figure 58-4 demonstrates condylar asymmetry.

Degenerative Joint Disease

Degenerative joint disease (DJD) is considered an end-stage result of progressive internal derangement of the TMJ. Usually, patients have bilateral involvement of the TMJ; however, unilateral involvement is not uncommon. The “wear and tear” effect of DJD on the TMJ results in condylar-glenoid erosion and decreased condylar ramus height. Clinically, patients often present with increasing preauricular crepitus, a limited mandibular range of motion, pain, and an anterior or open bite.⁶²

Clinical Assessment

Principles

The method of evaluating the patient with a dental facial condition begins with ascertaining the patient’s chief complaint. Then, as the medical history of the present illness unfolds, the answers to pertinent questions regarding a history of facial trauma, arthritis, and congenital malformations, for example, are obtained.

A physical examination of the head and neck should include the following⁶³:

1. Visual inspection of the entire face including facial subunits for symmetry
2. Palpation of the face to differentiate between soft and hard tissue defects

3. Comparison of dental and facial midlines with each other and with the central facial axis
4. Inspection for gonial angle symmetry and differences in antegonial notching
5. Analysis of the relationship between the upper lip and the maxillary central incisors
6. Inspection for malocclusion, occlusal canting, inclination of anterior teeth, dental crowning, open bites, maximal interincisal opening, and mandibular deviation with opening
7. Examination of the TMJ function

After the patient's chief complaint, history of present illness, past medical history, physical examination, radiographs and articulator mounted diagnostic casts have been obtained and evaluated, a problem list and corresponding treatment plan can then be constructed.

Radiography

Panoramic Radiographs The panoramic radiograph can provide information regarding the relative height of the mandibular condyle and ramus. Degenerative changes or asymmetric morphology can be identified with a comparative vertical measurement of the condylar head apex to the sigmoid notch base, and the sigmoid notch base to the mandibular angle.⁶³

Posteroanterior Cephalometric Radiographs The posteroanterior cephalometric radiograph enables one to understand the extent of the deformity relative to the cranial base. By tracing soft and hard tissue features and then placing a true vertical and horizontal midline axis, one can visualize deviations of the dental and skeletal midline, occlusal cants, and vertical asymmetries.⁶³

Lateral Cephalometric Radiographs A lateral cephalometric radiograph can provide clues of vertical differences by the

lack of superimposition (eg, two separate radiographic mandibular inferior borders). However, to determine the relative significance of the differences in dentofacial superimposition, one must know whether the external auditory canals are level with the patient's natural head position. Only a single cephalometric ear rod should be used if the patient's auditory canals are not level.⁶³

Computed Tomography

Computed tomography (CT) can provide two-dimensional localized views of the facial skeleton, or it can be developed further into three-dimensional views that can provide excellent detail necessary for the proper diagnosis and treatment of a complex facial dysmorphism (Figure 58-6).

Stereolithographic Modeling

Three-dimensional CT scans can provide information to allow the fabrication of an actual three-dimensional skeletal model. These models can help one make surgical predictions; however, because of their expense, these models are mainly used for complex dentofacial and craniofacial deformities.⁶⁴

Technetium 99m Phosphate Bone Scans

Radionuclide skeletal scintigraphy has been shown to be a sensitive technique for identifying mandibular overgrowth in the patient with a facial deformity. However, scan findings are nonspecific and may be the result of a variety of bone and soft tissue abnormalities, including soft and hard tissue carcinomas, sarcomas, metastatic disease, hematologic disease, infections, inflammatory states, metabolic diseases, and trauma.⁶⁵ In patients with facial asymmetry mandibular overgrowth, nucleotide uptake is not symmetric bilaterally. In these cases, patients present with an increased nucleotide activity on the affected side. However, caution must be taken when evaluating an area of

FIGURE 58-6 Three-dimensional computed tomographic scan of asymmetric skull.

increased uptake not to mistake condylar overgrowth for other conditions (ie, arthritis, TMJ disorders, trauma) that can mimic nucleotide uptake activity.⁶⁶ Additional techniques of fusing single-photon emission CT images to high-resolution structural CT images have been shown to provide a further precise anatomic delineation of bone activity.⁶⁷

Surgical Treatment

Asymmetry may not always be obvious to the patient and family. Correct treatment begins with proper diagnosis. One should evaluate the face in all dimensions, carefully analyzing vertical and horizontal dimensions corresponding to facial subunits. Failure of the surgeon to recognize asymmetry until after surgery is often viewed by the patient as an excuse for poor treatment. In general, treatment planning of facial asymmetry is much the same as for any orthognathic case, except that more emphasis is placed on the frontal view.

Cephalometrics may be grossly inaccurate owing to ear rod positioning. Posteroanterior cephalometric radiographs are good simple screening tools but, standard computerized CT scans are much more accurate. CT data can be converted by computer-aided design/computer-aided manufacturing (CAD/CAM) imaging into an actual acrylic model. This

model can be used for model surgery, implant fabrication, and distraction osteogenesis design.

Ultimately, the clinical examination is the most important diagnostic tool. Body posture, mannerisms, and hairstyle hide facial asymmetry and may mislead the treatment plan.

In a University of North Carolina study of 495 patients with facial asymmetry, the mandible was most often affected. Upper facial asymmetry was found only in 5%, but a chin deviation was present in 75% of all cases. Chin deviation is most often to the left, indicating a tendency for increased right-sided growth.⁶⁸ People notice chin deviation.

Delayed Treatment

Treatment of asymmetry in preadolescent children is extremely complex, and the results are not always predictable. Studies of growth modification with functional appliance have been problematic because of a various treatment designs with poor treatment group composition, poor control group composition, and difficulties with randomization. The topic is often discussed in orthodontic pediatric textbooks. Although noninvasive techniques do not harm the patient, most craniofacial asymmetry syndromes, condylar deformities, and traumatic injuries at an early age do require surgery. Bite-block therapy can be helpful in controlling the plane of occlusion but rarely prevents surgery. Bite-block therapy is mainly directed as an intervention for secondary growth deformities.

Maintenance of TMJ Function

Mild asymmetry in a growing patient with functional condyles should receive early interceptive orthodontics, and the patient should be allowed to finish growing before surgery is performed. Jaw movement is important following condylar fracture. Physical therapy and rehabilitation stimulates condylar and mandibular growth. Poor function results in a more asymmet-

ric mandible and secondary skull base. Asymmetry of the skull base correlates with maxillary midface asymmetry.

Post-traumatic mandibular hyperplasia is less frequently seen than growth retardation. Mandibular hyperplasia is usually apparent after adolescent growth, whereas delayed growth is often present early in life. Regardless of the true etiology, it is important to establish a surgical treatment plan with the most esthetic, functional, and stable result. Orthognathic asymmetries should be treated after growth is complete, and often require combined maxillary and mandibular surgery.

Orthodontic Considerations

Human facial symmetry has long been a critical factor for attractiveness. It is also well documented that true symmetry is not normal.^{69,70}

For the average orthodontic patient, minor asymmetries become a concern only as an esthetic issue. Severe asymmetries often result in crossbite, malocclusion, cheek biting, poor mastication, condylar dysfunction, myositis, tendonitis, and chronic pain. From a diagnostic standpoint, patients with asymmetries differ from the typical orthodontic patient in several ways. The clinical examination and records should generate enough information to accurately diagnose and formulate the best possible treatment plan. This includes multiple photographs, lateral and posteroanterior cephalometric radiographs, and face-bow-mounted dental models.⁶²⁻⁷¹

Facial structures may be evaluated against a grid formed by the midsagittal plane and several perpendicular lines, according to the area being evaluated (eg, interpupillary, subnasal, stomion). A tongue blade or Fox plane can be used to determine whether a cant is present in the occlusal plane. Unilateral vertical maxillary excess and mandibular asymmetries are usually associated with an occlusal plane

cant.⁶³ This is why most asymmetries cannot be treated with single-jaw surgery.

Typical orthodontic diagnostic records rely heavily on a profile view. The lateral approach comes from the traditional diagnosis based on cephalometric radiographs; however, patients are more aware of their esthetic presentation from the frontal view. Additional diagnostic records may include a posteroanterior cephalometric radiograph, a submentovertex radiograph, and an accurate face-bow transfer with casts mounted on a semiadjustable articulator.⁶⁵⁻⁷³

The orthodontic management of patients with asymmetries does not differ a great deal from that for a typical orthognathic patient. Good communication and a team approach during all phases of treatment are essential. Once the diagnosis and treatment plan are established, the presurgical orthodontic phase is initiated. Basic principles of presurgical orthodontics must be observed. All tooth movements that may compromise stability must be avoided, especially if the intended movement may be more easily accomplished with the movement of a bony segment during surgery, that is, transverse expansion. Dentoalveolar decompensation in the upper arch must take into account the postsurgical position of the upper incisor. Maxillary anteroposterior movements as well as posterior impactions have the greatest effect on the upper incisors with regard to anteroposterior positioning and torque, respectively. Dentoalveolar decompensations in the lower arch must observe the anatomic limits of the symphysis. One must observe that the morphogenetic pattern of patients with maxillomandibular discrepancies results in specific abnormal bony architectures. It is for this reason that cephalometric norms should not be used. There should be no compromise in the presurgical orthodontic treatment plan as it would severely limit the overall outcome. Do not hesitate to extract teeth if necessary. Impressions and early model

surgery are helpful and confirm that the presurgical goals are correct and/or have been achieved. Common problems include improper buccal root torque in the upper arch, improper arch coordination (especially when anteroposterior movements are planned), and a lack of overjet (which would hinder placement of buccal segments in an ideal Class I occlusion).

The decision to extract teeth is often difficult. The first question that must be asked is whether there is severe crowding. The answer is based primarily on the planned position for the upper and lower incisors well positioned in basal bone. The upper incisors' relationships to the sella-nasion (SN) (104°), palatal plane (104°), and nasion-A point (NA) line (4 mm and 22°) are good indicators of whether these teeth need to be decompensated. It must be kept in mind that posterior impaction of the maxilla decreases the torque of the upper incisors. In addition, large unilateral vertical changes such as impaction downgrafting on one side also swing and rotate the midlines of the maxillary teeth. However, when this is anticipated, the upper incisors should be maintained slightly proclined. As a surgical objective, the position of the upper incisor and that of a point relative to the nasion perpendicularly can be used as reasonable cephalometric references. Therefore, dental crowding and the desired position for the upper incisors within basal bone of the maxilla ultimately determine the need for extractions. Upper second bicuspid are the teeth of choice for extraction when minimal incisor decompensation is required. Maxillary first bicuspid are extracted when the upper incisors require greater degrees of decompensation, such as in Class III malocclusions.

If mild crowding is present (up to 4 mm) and no dentoalveolar decompensation is needed, a nonextraction approach is acceptable, and some interproximal reduction may be required. If decompensation of the incisors is required, the

cephalometric correction must be factored into the crowding assessment. For every 3° of change in the angle between the lower incisor and the mandibular plane, one must add or subtract 2.5 mm to the measured clinical crowding. In patients with Class II malocclusion, cephalometric correction most often adds to the clinical crowding since the lower incisor typically requires more upright positioning. In patients with Class III malocclusion, cephalometric correction usually alleviates crowding. In other words, cephalometric correction takes into account the goals for the lower incisor in the crowding assessment; moreover, it helps one decide which teeth should be extracted. When the measured crowding in the lower arch is moderate (5–9 mm), second bicuspid should be extracted. The result is the alignment and complete closure of the extraction sites. This should be achieved with the lower incisor in the ideal position. When crowding is severe (> 10 mm) after cephalometric correction, first bicuspid should be extracted to allow alignment and proper positioning of the lower incisor. The rationale is as follows: When two bicuspid are extracted, an average of 14 mm of space is created. If the total crowding is 10 mm including cephalometric correction, then 4 mm of space are left. These 4 mm are used by forward movement of the posterior teeth as lost anchorage during the alignment and retraction of the lower anterior tooth.

Maximum decompensation is often required with minimal clinical crowding, therefore requiring that the first bicuspid be extracted. If crowding exceeds 14 mm, extractions alone are not sufficient to alleviate crowding and achieve an ideal position for the lower incisors. Interproximal reduction may help to create another 3 to 4 mm of space.

Patients with hyperdivergent faces with an asymmetry require differential maxillary impaction. Such cases need a flattening of the curve of Spee on both

arches prior to surgery. The curve of Spee is often different from left to right. Flattening this curve allows for maximum intercuspation to be achieved between the anterior teeth and bicuspid, with minimum posterior open bites. If the posterior maxilla is intentionally overimpacted when relapse is expected, the result is a posterior open bite, and no vertical elastics are placed distal to the bicuspid for the first 8 weeks after surgery. Intercuspation should be accomplished. In the patient with facial asymmetry, one side may be more open than the other. It is usually the hypoplastic side that remains slightly open, and teeth can be extruded postsurgically. An open bite of 2 mm is acceptable and sometimes desirable as settling and some relapse occur after surgery. After surgery no orthodontic forces should be in the direction of the potential surgical relapse.

Patients with hypodivergent asymmetric faces typically require mandibular advancement and an increase of the lower anterior facial height. The original malocclusion is often characterized by an excessive overbite, overjet, and curve of Spee. The upper curve of Spee should be flattened and the ideal position of the upper incisors achieved. The degree of curve of Spee may be different from side to side. No attempt should be made to level the lower curve of Spee because forward movement of the mandible to an ideal overbite and overjet automatically increases the lower facial height. If the lower mandibular plane angle has been maintained during advancement, this may result in a posterior open bite at the bicuspid or molars. The interocclusal space leads to leveling of the mandibular curve of Spee with minimal effort after surgery. A flexible braided wire is used in the lower arch as vertical intercuspation elastics are applied to extrude the lower posterior teeth. A class II or class III vector may be incorporated to achieve optimal occlusion. The upper arch should be stabilized by a heavy rectangular wire. Postsurgical orthodontic procedures

usually are completed within 6 to 8 months of surgery if all other phases of treatment are successful. Vertical elastics may be directed by the orthodontist depending on the occlusion and the unique differences of the hyperplastic or hypoplastic side of the face. Severe orthognathic asymmetries are often difficult from an orthodontic standpoint owing to the presence of unilateral differences of a hyperplastic presentation and a contralateral hypoplastic dental compensation.

Surgical Approach and Techniques

In rare cases asymmetries may be treated in a single jaw. Generally, asymmetric growth causes compensation in the teeth, alveolus, and other jaw. Furthermore, this compensation is different from side to side and requires slightly different orthodontic mechanics. Facial asymmetry may be improved esthetically by an inferior border ostectomy, augmentation, and genioplasty. The esthetic impact of asymmetry involves both hard and soft tissue. The zygoma and periorbital and nasal structures may be asymmetric. Even adjacent soft tissues, such as the salivary glands, muscles, and adipose tissue, can be different in quantity from side to side. The patient should be well informed regarding the limitations and surgical expectations. Rarely can asymmetric deformities be corrected completely.

Most patients notice horizontal or transverse discrepancies more often than vertical asymmetries. Maxillary dental midline, chin, and nasal deviations are obvious clinically. Facial length is less apparent. In severe cases, such as hemifacial microsomia or other syndromes, soft tissue augmentation and even free vascularized tissue may be necessary.

The oral and maxillofacial surgeon should make a note of minor anatomic asymmetry. Orbital, nasal, and upper lip position; maxillary midline; smile arch; amount of gingival show per side; cheek

mass; dimples; mandibular dental midlines; mandibular deviations on opening; TMJ articulation; translation; gonial angles; and cervical anatomy should be documented. The surgical procedure should be selected based on the etiology and a concern for stability. For example, when correcting a maxillary cant, vertical impaction is more stable than is vertical downgrafting. Often the discrepancy can be corrected by a combination of both impaction and downgrafting. Severe asymmetries with a short ramus height may require an extraoral inverted L osteotomy with bone grafting. This technique releases the mandibular sling and provides good access to the hypotrophic ramus, excellent bone grafting access, and accurate rigid fixation. Vertical changes of < 6 to 8 mm may be treated by intraoral sagittal split osteotomies. Rotational movements of the mandible produce proximal segment flaring on the advancing side and ramus collapse on the other. Proximal segment flaring may require modification (see Chapter 56, "Principles of Mandibular Orthognathic Surgery."). Some surgeons prefer a vertical oblique ramus osteotomy combined with a unilateral sagittal split ramus osteotomy. This combination surgery usually requires intermaxillary fixation, which may be beneficial in asymmetric cases. With current techniques, monocortical plate fixation can be achieved with a vertical ramus osteotomy. On the other hand, intermaxillary fixation is often necessary and even beneficial because alignment of the segments with rigid fixation is not always possible and the soft tissue pulls back to the original asymmetric position. A treatment plan should be established with an accurate clinical examination, cephalometric analysis, and model surgery. The surgical procedure should be executed efficiently, deftly, and with minimal morbidity. The aforementioned issues of relapse, stability, and mode of fixation should be established prior to surgery and discussed with the patient.

The first, and perhaps most important, treatment plan decision the surgeon encounters involves the upper incisor position. The choice of maxillary incisor position is key and essentially determines the three-dimensional position of everything else. The surgeon must correct maxillary incisor midlines, proclination, occlusal plane, smile arch, dental/gingival show, and lip support. An intermediate splint can be valuable in positioning the maxilla, assuming an accurate face-bow transfer and model surgery have been performed. One should not be a slave to an intermediate splint for it is only one method of aligning the asymmetry. Surgical experience and appreciation of esthetic symmetry are often more valuable.

The maxilla must be placed in the proper and most symmetric position. Consider the occlusion in relation to the unsplit mandible and ask yourself, Does that look reasonable according to the treatment plan? The maxillary position can best be measured using a combination of an external pin, Fox plane, lip position, and internal reference marks. The intermediate splint helps one place and hold the maxilla in the correct position during rigid fixation. The concept of an intermediate splint is based on proper condylar position. Functional condylar position in an awake upright person is not the same as it is in a supine paralyzed patient. Furthermore, asymmetric problems often originate from abnormal condylar (TMJ) disorders. Many patients with facial asymmetry do not have symmetric condylar rotation and therefore exhibit a great deal of muscular compensation with posturing. If an intermediate splint does not seem to position the maxilla properly in all three dimensions, the surgeon should consider other references for facial symmetry. Nothing can replace surgical experience. The mandible is usually cut first but is not split until after maxillary surgery and fixation. This prevents excessive force on the new maxillary position and seems to

expedite the process. Some surgeons complete and fixate the mandibular osteotomy before maxillary surgery. This requires a predetermination of both mandibular and maxillary positions.

Mandibular ramus surgery is often difficult in cases of asymmetry because the ramus and body of the mandible are deformed and hypoplastic and the range of motion limited. Limited surgical access and a smaller soft tissue envelope create a difficult challenge. If the mandible is cut first but not split, the osteotomies are made and a moist sponge is placed while the maxillary surgery is completed. The mandible is later split and moved to the proper position with the maxilla and held in the proper occlusion by an occlusal wafer or splint with intermaxillary fixation. Rigid fixation of the mandible can be achieved with either bicortical position screws or monocortical plates, assuming the condylar position is correct. In large horizontal rotations of the mandible, bicortical screws cannot be placed as true compression screws (lag screws) without torquing the condyle. Modifications of the lingual cortical plate and selective grinding of the bone can be helpful in increasing the bony apposition. In most cases monocortical plates seem to provide adequate stability without compression of the nerve or torquing of the condyle.

Surgical mobilization is a key point in bimaxillary surgery. The mandible and maxilla should be free enough to be positioned passively without pulling the soft tissue. This is a significant point to be considered because the positioning can create a tight masseteric sling and limited periosteal tissue. If the segments are “stretched” into position, one cannot expect long-term stability. A balance between an excessive stripping of the vascularity and a restricted connective tissue envelope must be achieved. Therefore, in cases of severe hypoplastic asymmetry with only rudimentary condyle, one should consider condylar reconstruction

or extraoral procedures of the ramus. In some situations distraction osteogenesis may even be helpful in growing more bone and essentially expanding tissue.

Adjunctive simultaneous soft tissue procedures can be considered after successful positioning of the maxillo-mandibular dental component by secure rigid fixation. Alignment of the chin, nose, and malar complex should be performed after the functional anatomy of the maxilla and mandible is established. Simultaneous surgery has multiple advantages, but may not always be feasible.

The following case is an example of a patient with facial asymmetry resulting from trauma who required combination maxillary and mandibular surgery (Figure 58-7). She was a 20-year-old female with a chief complaint of difficulty eating and chewing; she had chronic myofascial pain and masticatory dysfunction. She had sustained a jaw fracture as a young child and had not received treatment. The young lady experienced gradual facial asymmetry and sought orthodontic treatment. Such a case cannot be treated properly with orthodontics alone; neither can it be corrected in a single jaw.

Her physical examination revealed a healthy young woman in no acute distress but with an obvious facial deformity.

The basal view often better demonstrates the deformity, as does having the patient bite on a tongue blade (Figure 58-8). She was normocephalic (although she had a short face), asymmetric, and had deviation of the jaw to her right (Figure 58-9). The TMJ articulated and translated well without clicking or popping. The maximum incisal opening was 56 mm, with a deviation to the right. The mandibular midline was 7 mm to the right, the overjet was 5 mm, the overbite was 2 mm, and there was excessive lower dental show. She had a right buccal crossbite, an anterior crossbite, maxillary hypoplasia, a canted maxilla, and a short mandibular condyle (Figure 58-10).

The presurgical work-up included a three-dimensional CT scan, cephalometric and panoramic radiography, and face-bow mounting for an accurate intermediate splint and model surgery (Figures 58-11–58-13). The Erickson table was used to measure the vertical change and to fabricate an intermediate splint to assist in positioning the maxilla from the stable mandible (Figures 58-14 and 58-15). The surgical plan was a Le Fort I advancement of 3 to 4 mm and a downgrafting of 4 to 5 mm on the right side (Figure 58-16). The osteotomy gap was bone grafted with

banked tibial bone that was mortised and fixated. This was determined with a model surgery to level the cant of the maxilla. A Steinmann pin was placed at the nasal bone for an external vertical reference. This technique is valuable in establishing the correct facial dimension. In addition, a Fox occlusal plane was used to evaluate the leveling of the maxilla in relation to the infraorbital rims during surgery (Figure 58-17). Multiple methods of evaluating symmetry are helpful in achieving a good result. Intermediate splints, internal/external reference marks,

FIGURE 58-11 This three-dimensional computed tomogram clearly identifies the asymmetry.

and careful clinical inspection from different perspectives are all valuable surgical skills in simultaneous jaw surgery for the patient with facial asymmetry. The unsplit mandible is also a key reference for determining the change in maxillary position. In this case, after the maxilla was correctly positioned and leveled, the mandible was split and set to the plane of occlusion. A bilateral sagittal split osteotomy of the mandible was cut prior to the Le Fort I procedure but was not split. This seems to be a common sequence for most surgeons. Consideration was given to a vertical oblique osteotomy on the left, but the rotation seemed favorable and the fixation more stable. Most patients with facial asymmetry are hypoplastic and need lower facial advancement not reduction. A horizontal geniotomy was performed to advance the chin point 4 mm and level the deviation. After the orthognathic phase of surgery, the tube was switched to the mouth by the transpharyngeal route. This technique is efficient and is commonly used for simultaneous rhinoplasty. A standard internal rhinoplasty was performed to narrow the nose, refine the tip, and reduce the dorsum. Often facial asymmetry affects multiple facial subunits. The nose may appear asymmetric or deviated in relation to the mouth and chin. Great

FIGURE 58-13 A face-bow transfer is valuable but sometimes difficult in cases of severe asymmetry owing to an abnormal external auditory canal.

attention must be given to creating middle face symmetry.

At 3 months the postoperative results were satisfactory and the patient was very happy (Figure 58-18). The occlusion was well aligned and finishing orthodontics were completed without difficulty. This case demonstrates well the principles discussed above.

An example of mild developmental asymmetry is demonstrated in the follow-

FIGURE 58-14 Mounted dental models on an Erickson platform with reference marks help one determine the amount of change and fabrication of an intermediate splint. Note the amount of midline discrepancy.

ing case. Such a case can be challenging for the orthodontist/surgical team because the orthodontic preparation may be different for right and left sides; the asymmetry is mild and it is tempting to undertreat the problem with single-jaw surgery. This patient was a 17-year-old female with an open bite and right laterognathia. She had posterior vertical maxillary excess mild crowding, Class III molar relation, dento-facial asymmetry, and a pseudomandibular prognathism (Figures 58–19 58–22). She complained of lip incompetence, difficulty chewing and biting food, nasal obstruction, and xerostomia. Her father had a history of mandibular prognathism and orthognathic surgery.

This patient denied previous trauma to her facial bones. The orbital rims were symmetric, but the right ear was slightly lower. The TMJs articulated well, and there was no myofascial pain. The mandibular midline was 4 mm to the right, as was the chin. She had 4 to 5 mm of gingival show with a high smile. There was no overjet and 4 mm of open bite. She had a mild transverse deficiency of the posterior maxilla.

The treatment plan began with an extraction of teeth no. 1, 16, 17, 18, 32, 4, 13, 21, and 28 prior to presurgical orthodontics. Orthodontics was performed to level alignment and to decompensate in

FIGURE 58-15 Lateral view of mounted models.

preparation for a two-piece Le Fort I osteotomy, bilateral sagittal osteotomy, genioplasty, and rhinoplasty. Presurgical records included surgical mounted models, a face-bow transfer, and detailed radiographs. A CT scan was not obtained.

A sagittal split osteotomy was cut but not split until after the maxilla was positioned. The maxilla was impacted 4 mm posteriorly and widened by a segmental osteotomy between the central incisors. An intermediate splint was used to

FIGURE 58-17 A prosthetic Fox plane can be used as a final reference to evaluate the leveling of the maxilla in reference to the infraorbital rim.

FIGURE 58-18 A, Postoperative lateral view with animation. B, Postoperative frontal view with animation.

position the maxilla. The maxilla was rigidly fixated with a resorbable mesh. Internal and external references were used to properly position the maxilla, as were the predetermined intermediate splint and model surgery. The mandible was then completed and rotated slightly by the sagittal split osteotomy. The chin point was moved to the left and advanced with a horizontal genioplasty. The endotracheal tube was changed to the oral route, and rhinoplasty performed to improve facial harmony and symmetry. The surgery was performed without complications.

The postoperative course was without complications. At 1 month the splint was

removed and the occlusion was satisfactory (Figures 58-23 and 58-24). At 1 year the patient's occlusion was good, the open bite stable, and facial symmetry excellent (Figures 58-25–58-28).

Summary

Correction of orthognathic deformities often requires surgery of both the maxilla and the mandible. Combining osteotomies of the maxilla and the mandible is more complicated than single-jaw surgery and is perhaps associated with increased morbidity, but the surgical options and results are better. Double-jaw surgery does *not* result in twice the morbidity of single-jaw

FIGURE 58-20 The frontal view of dentition demonstrates an open bite and midline asymmetry.

FIGURE 58-21 Initial cephalometric radiograph.

surgery. The indications for bimaxillary surgery are severe deformities untreatable in one jaw, deformities of both jaws, unfavorable movement prone to relapse, and complex three-dimensional movements for which single-jaw surgery would be a functional/cosmetic compromise. Dentofacial asymmetry may develop from a primary cause but presents with secondary compensation in the hard and soft tissues of the face. Such asymmetry is a good indication for bimaxillary surgery.

Current surgical techniques have reduced the morbidity and length of stay in the hospital and have improved the outcome. This chapter presented combined maxillary and mandibular osteotomies with a special emphasis on asymmetries as an indication. The concept of comprehensive facial analysis and treatment was represented in the cases demonstrated. If correction of mild asymmetries is attempted with single-jaw surgery, the results are suboptimal and disappointing.

Acknowledgment

We would like to thank Dr. Andre Ferreira for orthodontic support.

Soft Tissue Changes Associated with Orthognathic Surgery

Norman J. Betts, DDS, MS

Sean P. Edwards, DDS, MD

While few patients and clinicians question the functional benefits of orthognathic surgery, the esthetic results that accompany surgery of the bony foundation of the face are equally powerful, if not more so. It is therefore incumbent upon the surgeon to include a component of soft tissue changes in the surgical treatment plan while working to achieve a stable, functional dentoskeletal unit.

Fundamental to such treatment planning is a sound knowledge of the behavior of the soft tissues of the face in response to both orthodontic and surgical changes. Close collaboration between surgeon and orthodontist is essential for this to occur.

The soft tissue response to orthognathic surgery will be discussed in this chapter. In addition, the surgical procedures and techniques used to control the soft tissue changes will be presented and evaluated in order to help the surgeon understand, control, and maximize the beneficial aspects of the facial soft tissue response to surgery.

Historical Perspective

The orthodontic literature contains the origins of predicting changes in the soft tissues of the face following the treatment of dentofacial deformities. Orthognathic

surgery initially was used to correct skeletofacial deformities and the resultant functional problems, often at the expense of the facial soft tissue esthetics. In time, a greater concern for the esthetic aspects of surgery developed, such that facial soft tissue prediction became an integral part of preoperative planning and postoperative outcome assessment.

Early studies produced average ratios, which related designated hard and soft tissue landmarks. The ratios were of use for predicting the response of the soft tissues to various skeletal and dental changes. These ratios are averages, however, and investigators realized that individual variability was significant. It was surmised that facial soft tissue response to orthodontics and surgery was multifactorial in nature. As a result, more elaborate statistical analyses were employed, with varying degrees of success, to elucidate the factors governing the soft tissue response to surgery. Consequently, prediction equations were developed that would help in preoperative surgical planning and postoperative outcome assessment.

Recently, much emphasis has been placed on developing procedures that assist the surgeon in controlling the soft tissue response to surgery. By using procedures

such as the alar cinch suture and V-Y closure, the surgeon can minimize or eliminate unesthetic soft tissue changes and may optimize positive esthetic changes.

Facial Esthetics in Society

Physical appearance is critically important in our society.¹⁻³ Perception of oneself and the perceptions of others are both essential to self-esteem. The most significant aspect of one's self-image is facial appearance. As a result, dentofacial and skeletofacial deformities have a significant psychological and social impact on those afflicted. Further, the correction of these deformities can have an equally significant impact on self-esteem and personality.

General Considerations

Much has been written about soft tissue changes associated with orthognathic surgery, and each paper has its strengths and weaknesses. Variation in design, heterogeneity of study design, surgical technique, and patient populations do not allow for direct comparison. To make some objective comparisons between methodologically different studies, we identified a set of characteristics for the theoretically ideal study of the soft tissue changes associated with orthognathic

surgery (Table 59-1). These criteria should help the reader to evaluate individual investigations. This technique for assessing the previous literature is helpful and should be considered for use in other areas of scientific investigation.⁴

Most of the studies dealing with this subject provide ratios of soft to hard tissue movement. Ratios are averages. Averages apply well to groups but often fail to account for individual variation within the group. Further, these ratios only describe the relationship of two specific points. It is highly improbable that consistently accurate predictions of soft tissue change can be accomplished with only simple correlations. The complex behavior of the facial soft tissue drape is much more realistically described by the interaction of several factors within the skeletal framework. This

may explain some of the extreme variability that many authors have encountered.⁵⁻⁹ At best, ratios serve to give a general appreciation of the expected outcome.⁹ Some authors have stated that ratios are just as efficacious in predicting the soft tissue response to osseous surgery as multiple regression and stepwise regression analysis.^{6,9} This may be a result of several factors such as lack of inclusion of important variables (eg, the method of soft tissue closure and osseous contouring) into their database; a mixed sample population (race, age, or sex); small numbers of patients; or inability to limit the sample to specific vectors of osseous movement.^{4,6,8,9}

Recent investigations have shown improved predictive ability when patients were grouped by vector-specific movements of the osseous segments.^{4,10}

Orthodontic Considerations

Tooth position and alveolar morphology result from the sum of applied forces during their development. These applied forces derive from the cheeks, lips, and tongue and parafunctional habits. Obviously, skeletal imbalances are accompanied by soft tissue imbalances. The result is dental compensation for skeletal malocclusions. Orthodontic correction of these compensatory changes will often result in a worsening of the malocclusion preoperatively, and the jaw-to-jaw discrepancy will appear clinically more severe.^{11,12} Thus, initial treatment planning should consider these changes, and final surgical treatment plans should be based on records obtained as close to surgery as possible. When evaluating ratio studies, it becomes apparent that the position of the incisor teeth does not always accurately reflect the osseous movement. This is because of postoperative orthodontic tooth movement. The molar teeth or bony landmarks such as the anterior nasal spine (ANS) undergo less postoperative change and may more accurately describe the osseous surgical movement. Therefore, these landmarks should produce a more accurate ratio or prediction.⁹

Cephalometric Considerations

The use of a standardized cephalometric technique is essential to the study of this subject. The components of a standardized cephalometric technique are using the same cephalometer, with the same source-object and object-film distances, and positioning the patient in a natural head position with the teeth in centric relation and soft tissues in repose. The cephalogram obtained from the standardized cephalometric technique must allow visualization of the complete soft tissue profile. Relaxation of the soft tissues may be difficult to produce and reproduce. Relaxed lip posture is especially difficult to achieve in patients with excessive interlabial gap. Straining to close the gap by contracting the mentalis muscles flattens

Table 59-1 Theoretical Ideal Characteristics of a Study to Investigate the Soft Tissue Changes Associated with Orthognathic Surgery

1. Prospective
2. Adequate sample size
3. Randomized treatments (if treatments differ within the sample)
4. Nongrowing patients
5. No previous trauma to the osseous structures of the face
6. Exclusion of patients with congenital defects or syndromes (eg, cleft patients)
7. Elimination of the confounding effects of pre- and postoperative orthodontic tooth movement
8. Constant presence or absence of orthodontic appliances
9. Same cephalostat used for all cephalograms with identical source-subject and subject-film distances
10. Soft tissues in repose for all cephalograms
11. Superimposition of cephalograms on the nearest osseous structure not affected by surgery or on a stable reference line
12. Use of a tracing template to assist in landmark identification
13. Evaluation of both profile and full facial soft tissue changes, or 3-D analysis
14. No concomitant or prior soft tissue surgery
15. Exclusion of segmental surgical procedures
16. One vector of movement (or grouped in study)
17. No concomitant osseous surgery on another portion of the facial skeleton
18. Homogeneity of the soft tissue incisions and closure techniques
19. No hard tissue contouring (eg, recontouring of ANS)
20. Use of rigid osseous fixation
21. Uniform follow-up intervals
22. Follow-up time of at least 6 months (1 year is preferable)
23. Error analysis of measurement and landmark identification

ANS = anterior nasal spine.
Adapted from Betts et al.⁴

the labiomental fold and distorts the overall contour of the chin. It is important that patients be instructed to keep their lips in repose for the cephalogram.¹³

To minimize measurement error during cephalometric analysis, landmarks or planes approximating the structures being evaluated must be superimposed. This superimposition should be on landmarks not modified or changed during the surgical procedure.^{9,14} Another contributing factor to measurement error is orthodontic tooth movement between the times of comparison. Orthodontic changes can be minimized by obtaining the preoperative cephalogram within a month of the planned surgical procedure,^{6,9} and performing minimal postoperative orthodontics.⁹ Also, the presence, or absence, of orthodontic appliances must be constant during the study period. The presence of orthodontic appliances influences lip posture, and their placement or removal will change the soft tissue drape.⁴

Landmark identification is simplified and becomes more accurate when templates are used.^{9,10,14} This is especially valid for soft tissue landmarks.¹¹ Soft tissue landmarks are often arbitrary and located on gently curving contours. These landmarks can therefore move vertically over the surface of the tissue after surgically induced change.^{8,12} If tracing templates are used, these points can be more accurately located.

Soft Tissue Considerations

The ability to predict the hard and soft tissue changes prior to an orthognathic surgical procedure is critical to the treatment planning process. With the refinement of surgical procedures and the advent of rigid fixation techniques, the surgeon is able to accurately reposition and retain the osseous components in a planned position. However, the change in soft tissue morphology after combined orthodontic and surgical therapy depends on several

factors. These include surgical procedure,^{6,15-19} method of wound closure,^{6,9,15,16,18,19} the new spatial arrangement of the skeletal and dental elements,¹⁹ the adaptive qualities of the soft tissues,¹⁹ growth,^{17,20} orthodontic vectors of tooth movement,^{17,19} lip thickness,^{5,6,17,21-23} lip tonus,⁹ lip area, lip contact (competence), lip strength, interlabial gap, amount of overjet, amount of fatty tissue and musculature, and postoperative edema.¹⁷

Because of swelling, tissue redistribution, and functional adaptation, long-term follow-up is needed to assess soft tissue changes after surgical procedures. Most authors suggest that the soft tissues stabilize after 6 months.^{15,17,19,21,22} Others suggest that at least 12 months are required.^{11,24} Hack and colleagues found evidence of continued soft tissue settling several years after surgery.²⁵ Surgical technique and method of wound closure have been shown to affect soft tissue relationships.^{6,9,15,16,18,19,26-28} For example, the horizontal incision in the upper labial vestibule commonly used to gain access to the maxilla for the Le Fort I osteotomy causes shortening of the lip with loss of vermilion and a decrease in lip thickness,¹⁶ whereas vertical incisions with a tunneling approach and palatal flap for the same surgical procedure show minimal postoperative lip changes.¹⁹ Betts and colleagues, investigating the soft tissue response to maxillary surgery, noted that soft tissue changes may be more affected by the type and position of the soft tissue incision and methods used in closure than by the surgically induced hard tissue change.⁴

Changes in facial esthetics and occlusion following orthognathic surgery depend highly on the stability achieved following surgery. Simply put, the soft tissue will mirror changes in the bony foundation should skeletal relapse occur.

Many authors have shown that thin lips move more predictably than thick lips.^{5,6,10,17,22,23} Two theories have been advanced to explain this discovery. First, the actual bulk of a thick lip may have a

tendency to absorb a large amount of bony advancement without a perceptible change in soft tissue contour. Second, “dead space” under the lip may absorb the first portion of a bony advancement before the soft tissue is affected (eg, with severe maxillary retrognathia).^{5,6,10,17,22,23}

The general trend noted in the literature is that the horizontal changes in the soft tissues are often predictable, whereas the vertical changes are unpredictable. This may be because of smaller movements in the vertical plane and the use of soft and hard tissue landmarks better suited for horizontal assessment. Also, hard tissue change is less predictable and less stable in the vertical dimension.

The cephalometric landmarks shown in Figure 59-1 will be used to describe the relationships between the soft and hard tissue changes presented in the rest of this chapter.

Orthodontic Incisor Retraction

Most orthodontic changes will be reflected in changes in the position and posture of the lips. Early studies in the orthodontic literature stressed that the soft tissue profile was closely related to skeletal and dental structures.²⁹ More recent work has demonstrated that a direct relationship between hard and soft tissue changes may not always exist.^{20,30} Simply put, the position of the lips is not solely determined by tooth position. The effects of growth and development, large ANB angle (angle formed by A point, nasion, and B point), positional relationship of the upper incisor on the lower lip (overbite and overjet), and adipose tissue are other factors that confuse the issue and may contribute to the great individual variability observed.^{14,31}

The changes in the soft tissues associated with orthodontic incisor movements are seen in Table 59-2.

Review of the literature indicates that with incisor retraction, the upper lip rotates backward around subnasale,¹⁸ with an associated reduction in the prominence of the lips relative to their adjacent sulci.³²

Also, upper lip thickness increases with maxillary incisor retraction (1 mm with 3 mm of incisor retraction,³³ 1 mm with 1.5 mm of incisor retraction³⁴). Correlation analysis discloses that upper lip response is related not only to the upper incisor retraction, but also to lower incisor movement, mandibular rotation, and the position of the lower lip.

The lower lip moves less predictably with retraction of the incisors than does the upper lip.³² Several theories have been advanced to explain this phenomenon. Hershey has theorized that this is because the lower lip is much more self-supporting

and not as dependent upon underlying incisor support.³² Other investigators feel that this is explained by combined upper and lower incisor effects on the lower-lip positioning (note the $-1:1$ effect of upper incisor retraction to lower-lip retraction).³⁵ They feel that the upper teeth, not the lower, establish the curve of the lower lip. Therefore, if the upper incisor is retracted more than the lower incisor, the lower lip may displace more posteriorly than the lower incisor ($-1.56:1$,³⁵ $-1.22:1$ ³²). Another theory is that many factors contribute to the final position of the lower lip. This theory is supported by

correlation analysis, which indicates that mandibular rotation had a greater influence on lower lip response than did incisor movement. Stepwise regression analysis lends further support to this theory by revealing a complex interaction between dental movement, mandibular rotation, and the perioral soft tissues, as well as a complex relationship within the soft tissues themselves.

Maxillary Surgical Procedures

Most soft tissue change after Le Fort I surgery is manifested in the nasal and labial structures.³⁶⁻³⁸

Nasal Structures

Movement of the maxilla affects the lower aspect of the nasal dorsum.^{5,6,21,36-39} The general trend is a widening of the alar base in all patients regardless of the vector of maxillary movement. An associated shortening of the columellar height, alar height and nasal tip projection has been observed, and the nasolabial angle decreases or remains constant in most cases (Figure 59-2).⁴

Different movements of the maxilla have distinct effects on the nasal and labial morphology (Table 59-3). Superior repositioning of the maxilla causes elevation of the nasal tip,^{40,41} widening of the alar bases,^{4,41} and a decrease in the nasolabial angle.⁴⁰ Inferior maxillary repositioning produces loss of nasal tip support, downward movement of the columella and alar bases, thinning of the lip, and an increase in the nasolabial angle. Anterior repositioning of the maxilla has a profound effect on the nose and upper lip, resulting in advancement of the upper lip, subnasale and pronasale, thinning of the lip,¹⁶ widening of the alar bases, and an increase in the supratip break if the ANS is left intact.^{8,36-38} The nasal tip advances approximately one-half the distance of subnasale.²¹ This may be a result of widening at the alar base, which reduces nasal tip protrusion.⁴

FIGURE 59-2 The general trends of postsurgical changes in the nasal and labial soft tissues expressed in a nonvector format (the arrows are not specific for length, but are specific for direction). Generally, the alar base of the nose widened and the nasal tip decreased in height in relation to the adjacent soft tissues. The philtral columns of the lip widened and became longer, and the nasolabial angle decreased. Adapted from Betts NJ. Changes in the nasal and labial soft tissues after surgical repositioning of the maxilla. [master's thesis] Ann Arbor (MI): University of Michigan; 1990.

Preoperative alar-base width of the nose is important in final postsurgical outcome. Narrow noses were observed to widen more at the alar base than did broad noses.^{4,26} Important nasal changes have been documented as a result of rotation of the maxilla.^{9,42} A counterclockwise rotation of the occlusal plane raises the nasal tip, while a clockwise rotation of the occlusal plane decreases the superior movement of nasal tip.^{6,42}

Labial Structure

Maxillary surgery has a significant impact on upper lip morphology and position. The upper lip is attached to the nose and this prevents a 1:1 soft tissue change.⁴³ The upper lip widens and lengthens at the philtral columns after maxillary surgery.⁴ Shortening of the upper lip with a loss of exposed vermilion can occur if a V-Y closure technique is not employed at the time of surgery.^{16,28}

Anterior Segmental Repositioning

The soft tissue changes associated with the maxillary segmental setback osteotomy include an increase in the nasolabial angle because of posterior lip rotation around subnasale,⁴³⁻⁴⁶ lengthening of the upper lip, decrease in interlabial gap,⁴⁶ and uncurling and retraction of the lower lip with associated decrease in the depth of the inferior labial sulcus (Table 59-4).⁴⁵

H = horizontal; Ia = incisor A point; Is = incision superius; Ls = labrale superius.

Anterior Repositioning

Maxillary anterior repositioning has the greatest effect on the nose and upper lip. This movement precipitates advancement of the upper lip, subnasale, and nose,^{6,36-38} slight shortening of the upper lip, thinning of the lip (approximately 2 mm),^{10,36-38,47} widening of the alar bases,³⁶⁻³⁸ and a deepening of the supratip depression if the ANS is left intact.^{21,23,36-38,48} A progressive increase in the horizontal soft tissue displacement is seen from the tip of the nose to the free end of the upper lip.³⁷ A concomitant decrease in nasolabial angle is observed with only slight changes in the lower lip.^{5,18} Leaving the ANS intact has a favorable effect on the forward displacement of the upper lip and especially the base of the nose (subnasale).²⁴ The ratios derived from previous investigations can be found in Table 59-5.

A significant difference between the ratio of horizontal change of upper incisor to vermilion border of the upper lip in previous studies (0.6:1)^{6,21,22} compared with the ratio reported by Carlotti and colleagues (0.9:1)⁴⁸ is a result of the use of the alar cinch suture and V-Y closure during the surgical procedure. The ratio reduces with larger advancements because of soft tissue stretching.⁴⁸ If the ANS is left intact, the nasolabial angle may remain relatively unchanged. The nasal tip rises slightly so subnasale migrates forward along with the upper lip.¹⁵

Superior Repositioning

Superior repositioning of the maxilla causes elevation of the nasal tip,^{21,36-38} widening of the alar bases (2–4 mm),^{23,26,36-38} and a decrease in the nasolabial angle (Table 59-6).³⁶⁻³⁸ These nasal changes occur without change in angulation of the upper lip.^{6,8} The upper lip closely follows the movement of the maxillary incisor in the horizontal plane. The lip follows superiorly approximately 40% of the vertical maxillary change. This lip shortening is accentuated with combined anterior and superior maxillary movements.²³ The amount of vertical soft tissue change increases progressively from the nasal tip to stomion superius, with loss of vermilion if a V-Y closure is not used.^{6,8} However, Phillips found that the vermilion border of the upper and lower lips decreased slightly in the lateral portion of the lip, even with a V-Y closure.²⁶ Interestingly, when superimposition is done on maxillary landmarks, the soft tissues of the lip migrate downward in relation to the maxilla. This may be because of the connection of the upper lip to the nose.^{6,8}

Inferior Repositioning

Maxillary inferior repositioning produces loss of nasal tip support, downward repositioning of the columella and alar bases, thinning of the lip, and an increase in the nasolabial angle.³⁶⁻³⁸ Lengthening and thinning of the upper lip is also observed.¹⁸

Posterior Repositioning

Maxillary setback procedures result in loss of nasal tip support because of posterior movement of the ANS and the bony support area around the piriform aperture.³⁷ The lip rotates posteriorly and superiorly about subnasale with increasing nasolabial angle^{8,49} and thickens slightly (Table 59-7).⁴⁹

Multidirectional Maxillary Movements

Most maxillary movements are multidirectional (anterior and superior, anterior and inferior, posterior and superior, posterior and inferior, etc). The expected soft tissue changes would be a combination of the expected changes from the pure vectors of movement (Figures 59-3–59-5).

Mandibular Surgical Procedures

Generally the soft tissues of the mandible follow the hard tissues closely. The exception is the lower lip. Because of its contact with the upper incisor and upper lip, its movement is often variable and unpredictable.

Anterior Segmental Posterior Repositioning

The lower lip follows the lower incisor posteriorly, which causes a flattening of the labiomental fold. There is less posterior displacement of the soft tissues as the chin is approached. No effective change is observed at the chin (Table 59-8).⁴³

Anterior Repositioning

The soft tissue changes associated with mandibular advancement surgery are limited to the structures below the superior labial sulcus. There is little change in the upper lip^{43,50-52} and none above the ANS.⁵³ The lower lip advancement is variable, and the lip often lengthens.⁵³ The lower labial sulcus and chin adhere to the bony structure of the mandible. Consequently, they follow the underlying osseous tissues closely, advancing more than the lower lip does (Figure 59-6). This leads to an opening of the labiomental

fold. As with maxillary and genial surgeries, the vertical changes are variable.

A correlation between the vertical change in menton and the angle and depth of the labiomental fold has been elucidated. As menton moves caudally, the angle opens and the depth decreases.⁵⁰

Facial height is also affected by mandibular advancement. In low-angle, Angle Class II cases, facial height increases slightly with advancement, but in high-angle, Angle Class II cases, a large increase in facial height occurs with advancement. Further, soft tissue changes may be more

pronounced with advancements in low-angle cases (Table 59-9).⁵⁴

The position of the lower lip is affected by the upper incisor, the lower incisor, and its contact with the upper lip. The anterosuperior position of the upper one-half of the lower lip touches the upper incisor in Angle Class II, non-open-bite cases and is usually folded forward. As the mandible is advanced, the chin and lower labial sulcus come forward, but the superior portion of the lower lip does not, since it was already folded forward by its contact with the upper incisor. This causes an opening of the labiomental fold and may explain why the ratio of advancement at labrale inferius to the incisor inferius is reduced.^{18,43,53} Consequently during treatment planning, the lower lip must be righted to a relatively normal position before it is advanced in order to approximate its true postsurgical position.

Dolce and colleagues, with 2 years of follow-up, suggest that these changes are more stable when rigid fixation techniques are employed.⁵⁵ Long-term, more horizontal relapse can be expected at the level of the lip and the lower labial sulcus than at the level of pogonion.⁵⁶ As Johnston⁵⁷ and Mobarak⁵⁴ point out, the lack of correlation between surgical hard tissue movements and the soft tissue changes long-term make prediction of lasting changes difficult to predict.

Posterior Repositioning

Mandibular setback surgery has no effects on subnasale or the tissues superior to subnasale. However, a slight posterior displacement of the upper lip, with lengthening,^{18,58,59} and a slight increase in the nasolabial angle is observed.⁶⁰ The soft tissues follow the mandible posteriorly, with the chin following most closely, followed by the inferior labial sulcus and the lower lip. The lower lip shortens, becomes more protrusive by curling out, and the labiomental fold deepens and becomes more acute (Figure 59-7).^{7,58-60} Vertical changes of the soft tissues of the lips are related to hard tissue vertical changes. During

with increased area.⁶¹ The vertical soft tissue changes correlate poorly with hard tissue movements (Table 59-10).⁶¹ As with mandibular advancements, long-term soft tissue changes have been found to correlate relatively poorly with the initial surgical bony changes, though in the short term they do change predictably.⁶²

Autorotation

During autorotation of the mandible, the soft tissues follow the osseous landmarks on approximately a 1:1 basis,^{6,8} except the lower lip, which falls slightly lingual to the arc of rotation.^{6,8,15} A slight increase in the labiomental angle is often observed,⁶ as is a slight thickening of the lips as the vertical facial height decreases (Table 59-11).⁴³

FIGURE 59-5 Overlay of average hard and soft tissue changes of advancement, impaction and advancement, downgraft in vector format. Average advancement (see legend above) as defined by the mean direction and mean amount of change, is indicated by arrows (downgraft) and lines with dots (impaction). Note that subnasale moves in the direction of the anterior nasal spine and A point. Adapted from Betts NJ. Changes in the nasal and labial soft tissues after surgical repositioning of the maxilla [master's thesis] Ann Arbor (MI): University of Michigan; 1990.

Genial Segment Surgical Procedures

The symphysis has been exposed both intraorally and extraorally for osteotomy of the inferior border of the mandible to advance, retract, widen, narrow, lengthen, or shorten the chin.⁴⁵ The majority of change seen after genioplasty is in the soft tissue of the chin, and less effect is seen in the labial sulcus and lower lip.⁶³ Early studies describing the soft tissue changes associated with genial surgery had several problems. They included few cases, related short-term results, and superimposed the cephalograms on the cranial base. Superimposition of the cephalograms should occur on the areas of the mandible not changed with surgery,^{13,64,65} because concomitant maxillary and mandibular

surgery may invalidate chin measurements calculated from superimpositions on the cranial base.⁶⁶⁻⁶⁸

Anterior Repositioning: Bony

Early attempts at advancement genioplasty used nonpedicled free grafts or onlay bone

grafts. However, these procedures were later abandoned because of excessive resorption and poor predictability. Consequently, the surgical emphasis shifted to the horizontal osteotomy of the anterior mandible.

At first a degloving incision was used to expose the anterior mandible.^{67,69,70} However, several investigators demonstrated that minimal soft tissue stripping gave a more predictable hard and soft tissue response because of less bone resorption of the advanced segment.^{13,45,65,66,71,72} No bony remodeling of gnathion or menton was observed. However, bone resorption could be demonstrated near the osteotomy (the anterosuperior and posteroinferior aspects of the advanced genial segment).^{66,67,69,70,72-74} Bony apposition occurred at B point and the inferior border osteotomy (Figure 59-8).⁶⁷ These same studies demonstrated that when the technique of minimal soft tissue stripping was used, the soft tissues followed the hard tissues closely without chin droop.^{13,45,65,66,68} There was also a small but negligible effect on the labiomental sulcus,^{66,68} an increase in submental length, an improved relationship of lower lip to tooth,⁶⁶ less soft tissue thinning,⁶⁸ and an improved neck-chin angle.

The soft tissue changes following horizontal advancement genioplasty depend on the magnitude and direction of the positional change of the genial segment, the design of the mucosal and osseous incisions, the amount of soft tissue stripping, and other concomitant jaw movements (Table 59-12).^{13,66,67,69,70}

The advantages of osseous genial surgery are preservation of the normal chin contour,⁷⁵ improved predictability of the soft tissue response,⁴⁵ stability,^{45,68} versatility,⁴⁵ and preservation of blood supply to osteotomized segments.⁷⁵

Those patients who had both vertical reduction and advancement genioplasties showed slightly larger soft tissue advancement than those who had advancement genioplasty only (0.93:1 vs 0.81:1). This may be explained by bunching of the soft tissues. When the soft tissues are bunched (vertical reduction more than advancement), the soft tissues advance more than when the soft tissues are stretched (advancement only).^{66,76}

Tulasne suggested that the overlapping bone flap genioplasty gives a more natural contour to the lower face and a better balance between the lower lip, chin, and submental

region than does the sliding genioplasty associated with a wedge osteotomy.⁷⁷ However, it is associated with a large amount of bony resorption, especially in adolescent patients.

Predictions of lower and genial soft tissue changes when a genioplasty is added

to a mandibular advancement are notoriously variable.⁷⁸ However, the use of rigid internal fixation for the mandibular advancement makes the soft tissue changes in the chin and lip more durable in the long term.⁵⁵

Anterior Repositioning: Alloplastic

Early attempts at advancement genioplasty included the use of alloplastic implants. Unfortunately, long-term follow-up revealed several unforeseen complications. For this reason, advancement genioplasty with alloplastic implants has fallen out of favor. The disadvantages of alloplastic materials include resorption or deformation of the underlying symphyseal bone with possible devitalization of the mandibular anterior teeth,^{12,18,47,79–81} migration of the implant,^{45,69,79} extrusion of the implant,⁷⁹ infection (especially with Proplast),^{45,69} and a less predictable soft tissue to hard tissue ratio.^{45,69} In addition, alloplastic materials do not address excessive or reduced chin height.⁶⁹ Newer materials have been developed that reduce the incidence of these

complications, making alloplastic augmentation a more viable option.

If alloplastic implants are used they should be placed subperiosteally, low on the inferior border below the mentalis muscle, and over dense cortical bone. See Table 59-13 for soft tissue changes with alloplastic chin implants. Alloplastic implants should not be used in the correction of severe deformities but can be used in patients with a mild to moderate deformity.^{13,47,80} A periodic radiographic examination of the implant is recommended to monitor bony resorption.^{47,81}

Posterior Repositioning

Early attempts at reducing horizontal excess of the genial segment of the mandible by bony recontouring caused very little improvement of the soft tissue profile.⁶⁴ This technique has been abandoned. The soft tissue changes associated with setback genioplasty are less well correlated with the hard tissue movements than during advancement genioplasty (Table 59-14).

result.⁸² It is also important to realize that setback genioplasty will make undesirable changes in the neck-chin proportion. In a patient with a poor neck-chin proportion, this procedure is contraindicated.

Vertical Repositioning: Superior and Inferior

The soft tissues follow the hard tissues very closely in augmentation genioplasty. However, this is not the case for vertical reduction (inferior border osteotomy or sandwich osteotomy) genioplasty (Table 59-15).

Special Circumstances

Distraction Osteogenesis

Since its first use in the human mandible by McCarthy and colleagues, this surgical technique has exploded in popularity.⁸³ Its use does not lend itself well to soft tissue predictions of the sort used for orthognathic surgery for various reasons, and few efforts have been made in this regard. Difficulties derive from the fact that most patients are still growing when subjected to the technique, that the principle of gradual distraction of a bone is probably accompanied by a component of soft tissue growth, so-called distraction histogenesis, and that very little is known about the dimensional stability of these bony changes. Efforts in this regard have examined soft tissue profile changes associated with maxillary distraction.^{84,85}

However, the technique allows for real-time adjustment of the change within the context of desired occlusion for most

applications, thereby not requiring precise predictions as for conventional orthognathic surgery. The topic will be of great interest, and the stability of the changes only more so as its use for the treatment of obstructive sleep apnea in adults becomes more prevalent.

Overall, the changes observed are comparable to those for maxillary advancement via the Le Fort I osteotomy with a decrease in midfacial concavity, increases in nasal tip projection, advancement of the lip, and closing of the nasolabial angle (Table 59-16).^{84,85}

Bimaxillary Advancement Surgery for Obstructive Sleep Apnea

The 5-year incidence of obstructive sleep apnea (OSA) in adult populations in the United States has been estimated to be

7.5% for moderately severe cases and 16% for less severe cases.⁸⁶ While orthognathic surgery has traditionally been applied to correct stomatognathic deformities and dysfunction, it also has been shown to be a powerful tool in correcting obstructive sleep apnea.^{87,88}

Little work has been done to describe the facial changes associated with this surgery, which differs from traditional orthognathic surgery in several ways. Patients presenting for maxillomandibular advancement surgery for OSA tend to be older, in their fourth and fifth decades of life.⁸⁹ They tend to be obese and have a thicker, laxer soft tissue envelope with which to “absorb” these bony changes. They will often present without skeletal imbalances that we traditionally seek to correct. Further, advancements of this sort are generally larger than those seen in the typical orthognathic surgery population, usually ranging from 10 to 12 mm. The goals of this surgery are very different. Here we seek to maximize the skeletal advancement to the benefit of the airway but often to the detriment of the soft tissue profile. Treatment planning then aims to minimize any untoward changes to the profile. Most patients seem to approve or be neutral with respect to their facial changes.⁹⁰ Prognathic patients are more likely to disapprove of

their new profile.⁹⁰ Adjunctive measures such as ANS reshaping may help minimize upper lip and nasal tip rotation, but little can be done to minimize the effects of surgery at the chin (Table 59-17).

In terms of ratios of change in this population, only one study has been reported to date.⁹¹ This overall lack of data does not permit a comparison to traditional orthognathic changes.

Poor Surgical Esthetic Results and Techniques of Soft Tissue Control

Maxilla

The secondary soft tissue changes found with maxillary surgery include widening of the alar bases,^{36-38,48,92} upturning of the nasal tip, flattening and thinning of the upper lip,^{19,36-38,48,92} downturning of the commissures of the mouth,^{36-38,48,92} and opening of the nasolabial angle. These changes are similar to those found in the aging face and are generally perceived as unesthetic.³⁶⁻³⁸ Other potentially unesthetic changes include loss of normal lip pout and a decrease in visible vermilion.^{19,48,92}

Several investigators have suggested that the etiology of these soft tissue changes is attributable to three factors: (1) elevation of the periosteum and muscle attachments adjacent to the nose without adequate replacement, (2) postsurgical edema, and (3) increased bony support in advancement cases.^{24,41}

The importance of muscle repositioning following superior repositioning of the maxilla was stressed by many investigators.^{24,48,92,93} They state that the muscles detached during stripping of the periosteum required for maxillary surgery shorten and retract laterally. The muscles reattach in this position if they are not reapproximated at the time of surgery. The lateral movement of the muscles and subcutaneous tissues causes the alar base to flare and the upper lip to thin.

The loss of visible vermilion may be a result of other causes. These include a rolling under of the vermilion of the upper lip secondary to an incision made high in the vestibule with associated scarring and retraction^{24,48,92} and inclusion of large amounts of tissue during closure.²⁴ This loss of vermilion is especially unattractive in those individuals with already thin lips⁴⁰ and is more pronounced with posterior and superior repositioning of the maxilla.

Postsurgical widening of the alar base after the maxillary Le Fort I procedure may be a favorable outcome in a patient with vertical maxillary hyperplasia and thin slit-like nares.¹⁵ However, if a wide preoperative alar base is present, these same changes become undesirable,^{24,41} especially with anterior or superior repositioning of the maxilla⁹⁴ (Figure 59-9A–D). Before techniques to control nasal width were developed, Bell and Proffit suggested that at the time of preoperative assessment, patients with a wide nose be warned that a rhinoplasty may be indicated.⁴⁰

Techniques to Control the Soft Tissues

To control the soft tissue changes associated with maxillary surgery, the surgeon must first be aware of any preexisting deformity, the anticipated soft tissue adaptation to the surgical procedure being planned, and the importance of the effects of orofacial muscles on form, function, and esthetics. Once this has occurred the soft tissues can be manipulated to advantage by the surgeon.^{4,93}

Several surgical techniques have been suggested to help control the detrimental soft tissue changes associated with maxillary surgery. They include the V-Y closure, the alar cinch suture, a combination of the alar cinch suture and the V-Y closure, contouring of the ANS, septum reduction, and the double V-Y closure.

Table 59-17 Soft Tissue Changes Associated with Maxillomandibular Advancement for OSA

Anatomic Structure	Ratio	Landmarks	Author(s)
Nasal tip (H)	0.16:1	Pn: Is	Louis et al ⁹¹
Superior labial sulcus (H)	0.39:1	Sn: Is	
Upper lip (H)	0.80:1	SLS: Is	
Nasal tip (V)	0.16:1	Pn: Is	
Superior labial sulcus (V)	0.16:1	Sn: Is	
Upper lip (V)	0.16:1	SLS: Is	

H = horizontal; Is = incision superius; Pn = pronasale; SLS = superior labial sulcus; Sn = subnasale; V = vertical.

FIGURE 59-9 Unesthetic widening of the alar base and downturning of the corners of the mouth in a patient with an already wide nose. This patient was treated with a maxillary procedure without an alar cinch or V-Y closure. A, Preoperative full facial view. B, Postoperative full facial view. C, Preoperative smiling full facial view. D, Postoperative smiling full facial view. Reproduced with permission from Betts NJ, Fonseca RJ. *Soft tissue changes associated with orthognathic surgery*. In: Bell WH, editor. *Modern practice in orthognathic and reconstructive surgery*. Vol 3. Philadelphia (PA): W.B. Saunders; 1992. p. 2197.

V-Y Closure There is always an antero-posterior thinning of the upper lip (especially with maxillary advancement) and a loss of vermilion (especially with maxillary impaction) unless a V-Y closure is used (Figure 59-10A–C).

The upper lip, when closed in a V-Y fashion, follows the hard tissues forward at more nearly a 1:1 ratio, with prevention of upper lip thinning and loss of the vermilion.^{10,15,48,93}

The V-Y closure is accomplished during closure of the maxillary vestibular incision.

The mid portion of the incision is identified and retracted anteriorly with a single skin hook. One centimeter of the incision is closed in an anteroposterior direction. Using a separate suture mucosa, periosteum and interposed muscular tissue is engaged by the needle

FIGURE 59-10 Unfavorable change in the vermilion of the upper lip following maxillary impaction surgery in a patient with a preexisting thin vermilion. A, Preoperative state. Note preexisting minimal vermilion exposure. B, Postoperative state. C, Close-up view of the postoperative state. Note that the loss of vermilion is more pronounced in the lateral portions of the lip than in the medial portion. Reproduced with permission from Betts NJ, Fonseca RJ. *Soft tissue changes associated with orthognathic surgery*. In: Bell WH, editor. *Modern practice in orthognathic and reconstructive surgery*. Vol 3. Philadelphia (PA): W.B. Saunders; 1992. p. 2198.

on either side of the incision and sutured in a continuous fashion. The superior aspect of the incision is gradually advanced toward the midline by taking smaller bites of tissue in the upper margin of the incision and larger bites in the lower margin (Figure 59-11A and B). Both sides of the incision are closed in a similar fashion to the midline suture. Often, following this type of closure, the lip will look rather full and short in the midline. Within the next several days, the lip will lengthen and become more normal in appearance.⁹³

Alar Cinch Collins and Epker identified patients who may develop undesirable nasal esthetic changes as those who have normal or wide frontonasal esthetics prior to surgery and will undergo a superior or anterior surgical repositioning of the maxilla.⁹⁴ These observations led to the development of techniques designed to control the alar base width after maxillary surgery. Bell and Proffit described adjunctive techniques to ensure an esthetic reconstruction of the alar base in maxillary impaction cases.⁴⁰ These included (1) reduction of the anterior extent of the piriform rim, (2) reduction of the ANS, and (3) trimming of the height of the anterior nasal floor. A different technique for correcting the flat and flaring nose was described by Millard.⁹⁵ This served as a model for the later development of the alar cinch techniques.⁹⁴ The original cinch suture was passed from the fibroadipose tissue on one side of the alar base to the other and was tied to a predetermined width (Figure 59-12A–E).

This technique was then modified to a figure-eight suture that was passed from lateral to medial, catching the fibroadipose tissue of the alar base (Figure 59-12F–H).^{24,41} Schendel and Delarre suggest that the suture should be passed not through the fibroadipose tissue but through the transverse nasalis muscles of the nose.⁹²

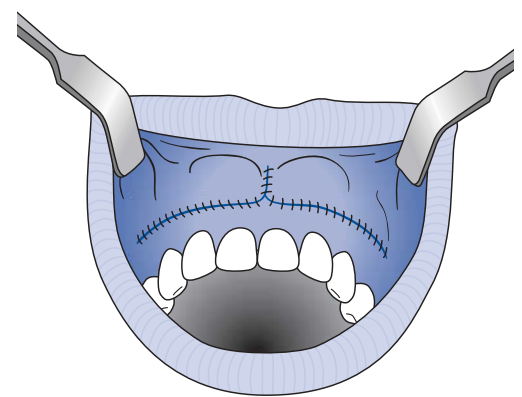

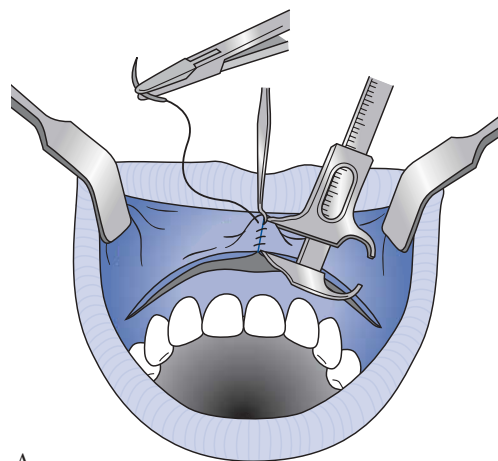

Past observations have suggested that the alar cinch suture does not control the alar base width^{4,96} and may even cause fur-

ther widening of the alar base. Subsequently, another technique of alar cinch suturing was suggested. In this technique, a hole is placed in the ANS and the suture is passed through the soft tissues at the base of the nose and back to the ANS bilaterally and individually tied (Figure 59-12I–L).¹⁵

A measurement of the greatest alar width must be taken on the patient and

recorded in the chart preoperatively. This number should be available during surgery so that reference to it can be made at the time of nasolabial muscle reconstruction.

Combination of Alar Cinch and V-Y Closure Several investigators indicated that the best control of the alar base in patients having maxillary superior or anterior repositioning could be achieved by using the V-Y closure and the alar cinch suture together.^{15,36–38,41,92,93} Their objective was to quantify the alar base width changes with and without the alar base cinch suture. All patients had a V-Y closure. They

FIGURE 59-11 A, The V-Y closure is accomplished during closure of the maxillary vestibular incision. The midportion of the incision is identified and retracted anteriorly with a single skin hook. One centimeter of the incision is closed in an anteroposterior direction. B, Using a separate suture mucosa, periosteum and interposed muscular tissue are engaged by the needle on either side of the incision and sutured in a continuous fashion. The superior aspect of the incision is gradually advanced toward the midline by taking smaller bites of tissue in the upper margin of the incision and larger bites in the lower margin. Both sides of the incision are closed in similar fashion to the midline suture. Photographs reproduced with permission and illustrations adapted from Milles M, Betts NJ. Techniques to preserve or modify lip form during orthognathic surgery. *Atlas Oral Maxillofac Surg Clin North Am* 2000;8:71–9.

FIGURE 59-12 A, Alar base cinch suture. The upper lip is grasped between the forefinger and thumb, with the forefinger placed directly on the junction of the ala with the face. B, The lip is inverted and the tissue lying over the forefinger is grasped with a forceps. The lip is released and the tissue grasped in the forceps is manipulated to ensure that the alar base moves properly. If appropriate movement is not observed, the process must be repeated until correct needle placement is ensured. C–E, A nonresorbable suture (ie, 2-0 Prolene) is passed from the fibroadipose tissue (or transverse nasalis muscle) on one side of the alar base to the other and is tied to a predetermined width. (CONTINUED ON NEXT PAGE)

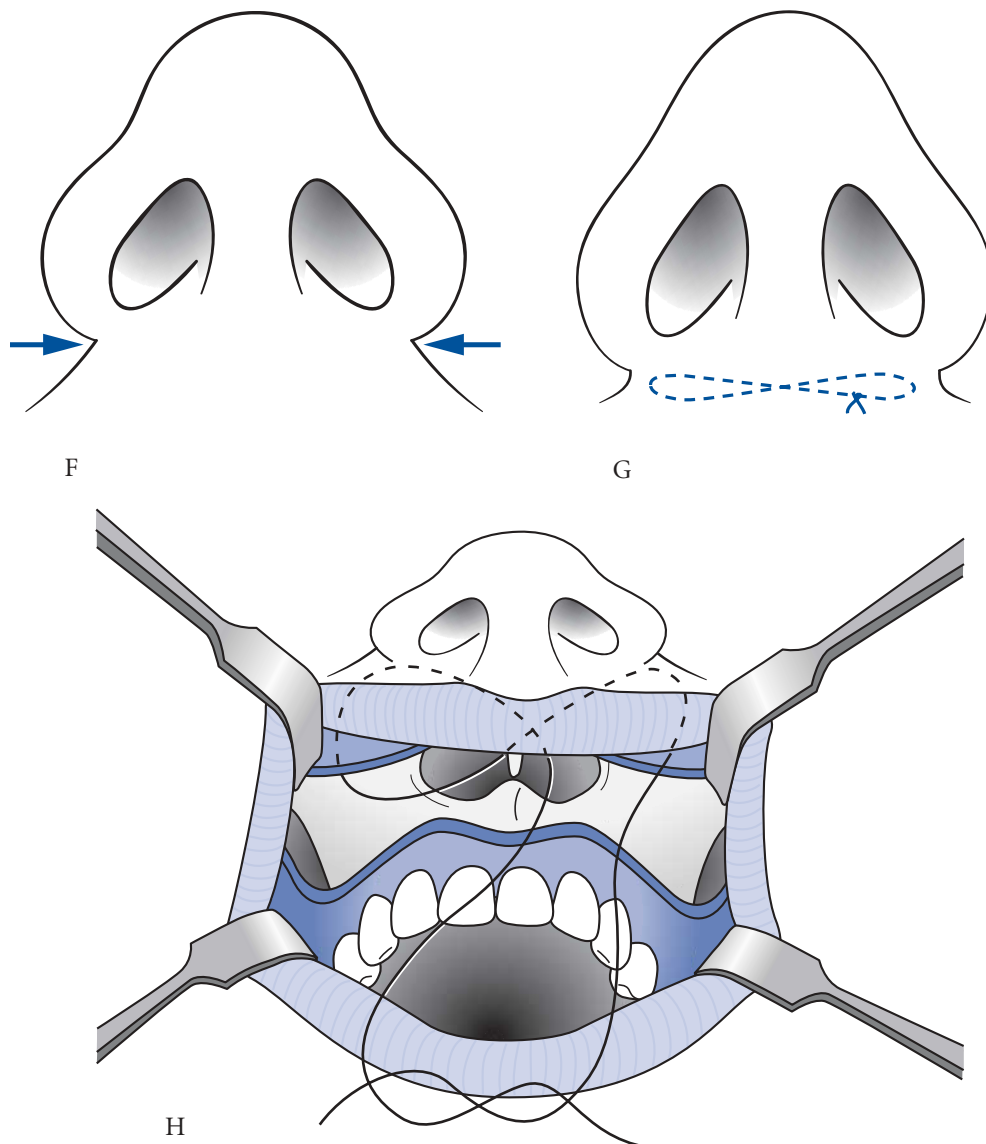

FIGURE 59-12 (CONTINUED) F–H, The figure-eight alar cinch suture technique. Following the initial steps described above, the suture is passed in a lateral to medial direction through the fibroadipose tissue on one side, and in the identical fashion (lateral to medial direction) on the other side of the nose. It is then tied in the midline to a predetermined width. (CONTINUED ON NEXT PAGE)

found that the alar bases widened in all patients and widening was lessened when the alar cinch suture was used. The alar base widened an average of 2.9% with the alar cinch suture and 10.8% without it.⁴¹

The effects of simultaneous placement of an alar cinch suture and a V-Y closure are successfully repositioning the lip muscles in a predictable manner,⁹³ preventing shortening of the lip in impaction cases,^{41,93} maintaining the normal lip pout,⁹³ preventing loss of vermilion,^{41,48,93}

maintaining the anteroposterior thickness of the lip,⁴¹ decreasing the widening of the alar base,^{41,48,93} and preventing drooping of the corners of the mouth⁹³ (Figure 59-13A–E). The ability of the figure of eight alar cinch suture combined with a V-Y advancement closure to reconstruct the patient to their preoperative soft tissue state was recently demonstrated in a prospective investigation with long-term follow-up. This study was performed in a surgical model (surgically assisted maxil-

lary expansion) that stressed the soft tissue closure technique and did not confound the soft tissue changes with vertical or anteroposterior vectors of maxillary movement. A figure-eight alar cinch suture combined with a V-Y advancement closure predictably reconstructed the patient's preoperative soft tissue state. Suturing the alar bases independently to the nasal septum (combined with a V-Y closure) was less effective but still superior to a V-Y closure alone.⁹⁷

Contouring the ANS Reduction of the ANS is indicated in patients undergoing large advancements or impactions of the maxilla who already have good nasal tip projection (Figure 59-14).²¹ The hard tissue changes in the position of the ANS affect primarily the soft tissue landmarks subnasale and pronasale.⁴

This technique should not be used in patients who have poor preoperative nasal tip projection. The nasal tip will rise if the ANS is left intact when advancing or impacting the maxilla. ANS reduction is also contraindicated in patients who are having a maxillary setback procedure. The result could lead to a “polybeak” deformity or drooping of the columella (Figure 59-15A–D).

Septoplasty The cartilaginous nasal septum should be reduced during maxillary impactions of greater than 3 mm to prevent postoperative deviation or buckling of the septum.^{40,46} This is done by reflecting the septal perichondrium and removing the appropriate amount of cartilage from the inferior aspect of the nasal septum with a scissor or scalpel blade (Figure 59-16A and B). The same amount of septum should be removed as the maxilla is impacted. This technique can be combined with reduction of the maxillary nasal crest. Prudence must be exercised as overreduction of the septum can result in either a saddle nose deformity or a polybeak deformity depending on the location of the excessive cartilage resection.¹⁵

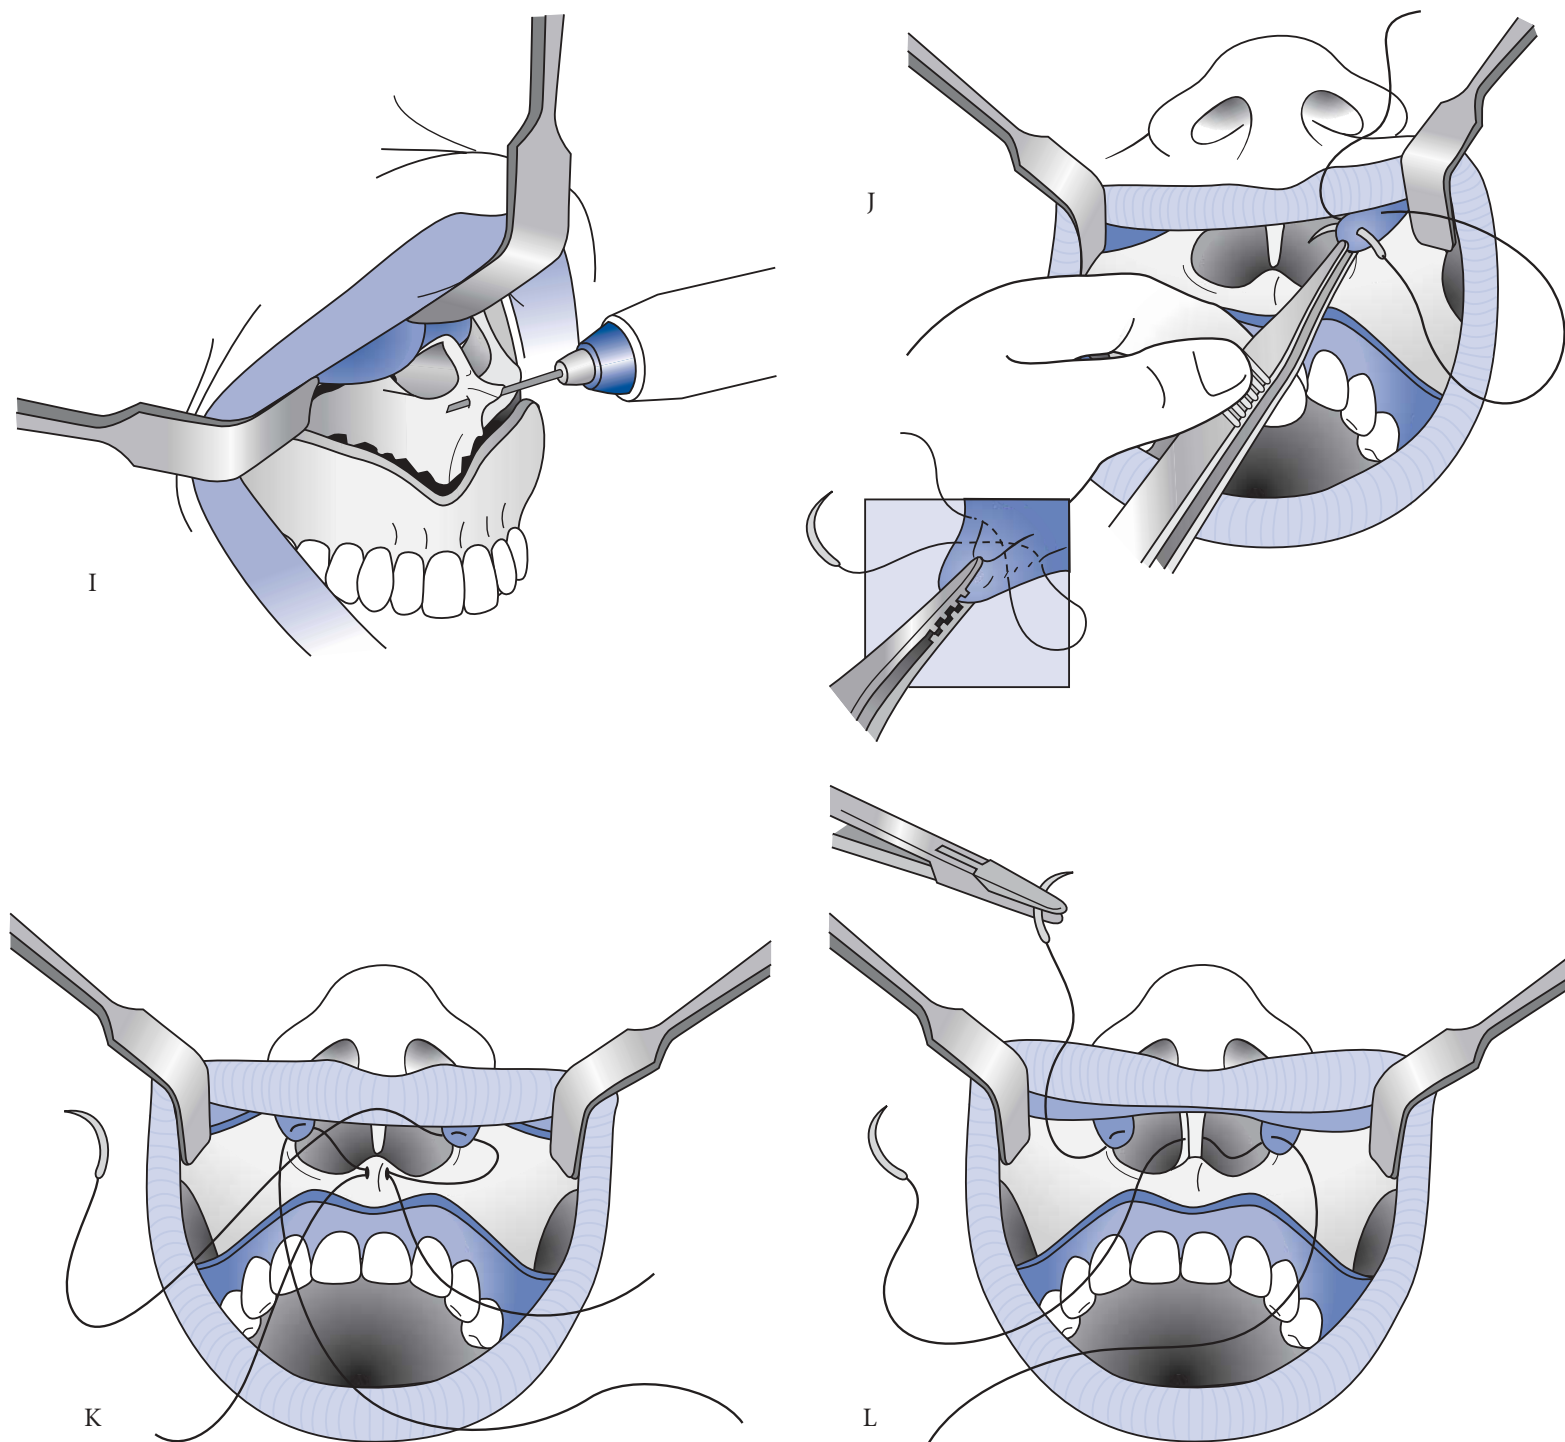

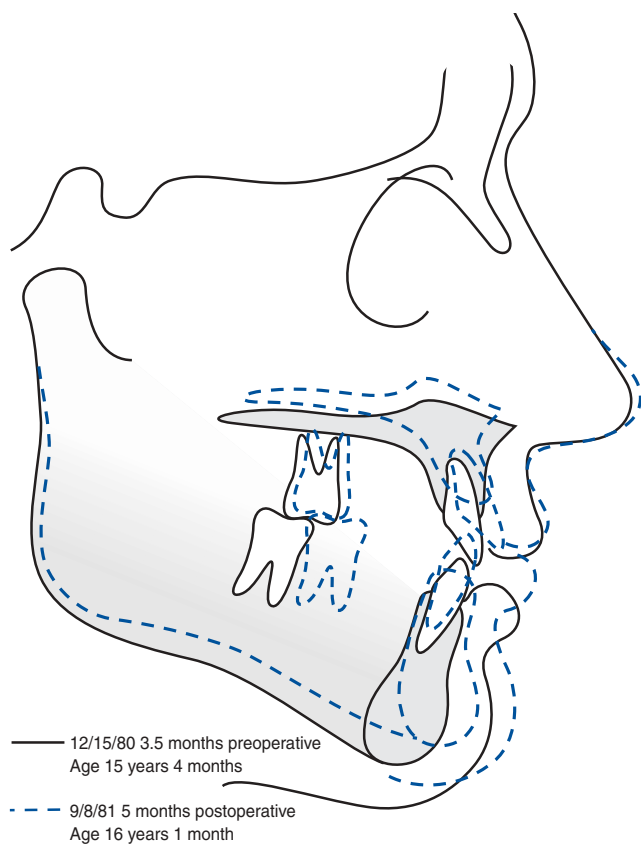

FIGURE 59-12 (CONTINUED) I–K, The dual-suture alar cinch technique. Before identifying the appropriate tissues described above, a hole is drilled in the ANS. Individual sutures are placed through the fibroadipose tissues, then through the hole below ANS and tied to a predetermined width for each nostril. L, Modification of this technique. Instead of the sutures being placed through the ANS, the individual sutures are passed through the anterior caudal septum. Adapted from Betts NJ. Techniques to control nasal features. *Atlas Oral Maxillofac Surg Clin North Am* 2000;8:53–69.

Double V-Y Closure The double V-Y closure was first proposed by Lassus for thickening of the thin lip (Figure 59-17A and B).⁹⁸ Hackney and colleagues com-

pared muscle reorientation using an alar cinch suture in conjunction with a simple closure technique, a single V-Y closure technique, and a double V-Y closure tech-

nique.⁹⁹ They observed that all three methods of closure yielded a significant increase in alar base width, and the double V-Y closure preserved the vermilion

FIGURE 59-13 Favorable soft tissue changes after maxillary impaction surgery and mandibular autorotation in a patient with an already wide alar base by use of an alar cinch suture and a V-Y closure. A, Data from pre- and postoperative cephalograms. Patient 3.5 months preoperation at age 15 years, 4 months (solid line); patient at age 16 years, 1 month postoperation (dotted line). FIGURE 59-14 Reduction of the anterior nasal spine during a maxillary osteotomy. This procedure is indicated in patients undergoing large advancements or impactions of the maxilla who already have good nasal tip projection. This procedure is contraindicated in patients who have poor preoperative nasal tip projection or are having a maxillary setback procedure. Adapted from Betts NJ. *Techniques to control nasal features. Atlas Oral Maxillofac Surg Clin North Am* 2000;8:53–69.

(especially in the lateral portion of the lip) with less variability than with the other two techniques of closure. The true

indication for this procedure is the patient who preoperatively has a thin lateral vermillion.¹⁰⁰

Mandible

When contemplating a mandibular setback osteotomy the surgeon must carefully assess the patient's submentocervical morphology. If a patient has a short submental length and poor submentocervical proportion, mandibular setback may worsen this, resulting in a "double chin." If this complication is a possibility, the surgeon may elect to combine the mandibular setback procedure with an advancement genioplasty or submentocervical liposuction (if adipose tissue is present).

Chin

Incorrect planning, vestibular scarring, excessive detachment of soft tissue from the chin, suprahyoid myotomy, improper closure of the soft tissue incision, hematoma formation, genial remodeling, and excessive bone resorption may compromise the results of chin surgery.⁶⁶

Bone resorption is related to the amount of soft tissue dissection and therefore is more pronounced in nonpedicled genioplasties.⁶⁹ Adolescent patients also have more bone resorption after genioplasty procedures.⁷⁷

FIGURE 59-15 Poor esthetic outcome in a patient who had overzealous reduction of anterior nasal spine (ANS) after a maxillary advancement procedure. A, Preoperative full facial view. B, Postoperative full facial view. C, Preoperative profile view. D, Postoperative profile view. FIGURE 59-16 A, Septal reduction during maxillary impaction osteotomy. The cartilaginous nasal septum should be reduced during maxillary impactions of greater than 3 mm to prevent postoperative deviation or buckling of the septum. This is done by incising the nasal mucosa and reflecting the septal perichondrium and removing the appropriate amount of cartilage with a scissor or scalpel blade. The same amount of septum should be removed as the maxilla is impacted. This technique can be combined with reduction of the maxillary nasal crest. B, Clinical example. A adapted from and B reproduced with permission from Betts NJ. *Techniques to control nasal features.* *Atlas Oral Maxillofac Surg Clin North Am* 2000;8:53–69.

Chin ptosis or “witch’s chin” (Figure 59-18A–C) is an unesthetic complication secondary to the degloving dissection of the chin or to lack of reattachment of the mentalis muscle at the time of surgery. This may lead to an inferior tissue slide causing excess interlabial incompetence and exposure of the lower teeth secondary to lower lip ptosis and redundant tissue in the submental area.^{45,68,70}

Several investigators have demonstrated that using a procedure that minimizes soft tissue stripping may produce a more predictable hard and soft tissue response in the osteotomized segment.^{44,45,65,66,68,71} Therefore, the surgeon should attempt to maintain as much soft tissue pedicle on the labial and lingual aspects of the mandible as possible. In addition to a predictable soft to hard tissue ratio, preserva-

tion of the soft tissue pedicle ensures a greater blood supply to the osteotomized segment, less bony resorption, and a decreased risk of infection.^{64,71}

During closure, the mentalis muscles must be reapproximated to prevent ptosis of the chin. An incision out into the unattached tissues of the lip can help prevent postoperative wound dehiscence and facilitate muscle reapproximation.

C, Close-up of the chin in repose. Reproduced with permission from Betts NJ, Fonseca RJ. Soft tissue changes associated with orthognathic surgery. In: Bell WH, editor. *Modern practice in orthognathic and reconstructive surgery*. Vol 3. Philadelphia (PA): W.B. Saunders; 1992. p. 2203.

A chin dressing fabricated from elastic tape should be placed at the end of the surgical procedure to stabilize the soft tissues and prevent hematoma formation. These dressings are typically worn for 5 to 7 days postoperatively.

Secondary Revision of Poor Surgical Results

The best method of treatment for a poor soft tissue outcome is prevention. The deformity should be recognized, the soft

tissue effects of the surgical procedure should be anticipated, and the correct interceptive procedures instituted. However, if a secondary procedure is required, the same techniques described in the preceding sections can be used. Revision surgery is more difficult than control of the soft tissues at the time the original surgery because of scarring and change in normal anatomic relationships.^{24,45} Rosen suggests that these secondary procedures be attempted only after the final soft tis-

sue drape has been established and the residual defect has been identified.²³

Other procedures for revising a poor surgical outcome are submental lipectomy, nasal wedge resection (Weir excisions) (Figure 59-19),²³ and rhinoplasty.

Prevention and Management of Complications in Orthognathic Surgery

Joseph E. Van Sickels, DDS

Complications of orthognathic surgery can be divided into several broad and overlapping categories. Whether surgery of the maxilla or mandible is done, regional anatomy, amount of movement, number of segments needed, and type of fixation employed all influence the types of problems observed. Difficulties encountered can fall into one or more of the following areas: vascular, neural, infectious, fracture management, occlusal changes, joint dysfunction, dental, and miscellaneous complications.

The approach to complications used in this chapter is divided into two areas: prevention and management. Prevention can be summarized as preoperative evaluation and treatment planning. Many of the less than desired results can be traced to errors in preoperative clinical examination, models, or records. Patients with unusual anatomy may dictate departure from established treatment modalities, but their care should be planned in advance.

Vascular Complications

Hemorrhage in the Maxilla

Acute Injuries Severe hemorrhage has been documented with maxillary and mandibular surgery and can have both

immediate and secondary effects.¹⁻⁷ Massive hemorrhage is rare whether acutely or in the postoperative period, but is possible with maxillary surgery. The vessels most at risk of injury during maxillary surgery are the internal maxillary artery, the posterior superior alveolar artery, and the greater palatine artery.

Massive blood loss can occur secondary to injury to the internal carotid artery and the internal jugular vein. When fracturing the pterygoid plates it is possible to fracture the base of the skull by vigorously manipulating chisels or directing chisels against the plates.^{8,9} This can result in direct or indirect damage to major vessels in the neck or skull. When approaching maxillary surgery one should remember that vessels may be directly injured during osteotome placement or indirectly through shattering the pterygoid plates. Efforts should be made to properly direct osteotomes in the pterygoid plates and to down-fracture the maxilla without excessive force. If the maxilla is extremely difficult to mobilize, the posterior cut may be directed into the tuberosity and away from the pterygoid plates (Figure 60-1).¹⁰ Patients who are undergoing a maxillary osteotomy to correct malposition of their maxilla following trauma may present special considera-

tions. The previous midface trauma may have resulted in fractures at the base of the skull. Manipulations to mobilize the maxilla may result in the osteotomy following the previous fracture lines.

Generally when brisk bleeding is encountered during surgery, the osteotomy should be completed, the maxilla down-fractured, and the site assessed for the bleeding source. Alternatively, the region may need to be packed to control blood loss, and then the osteotomy completed. The best opportunity to identify a

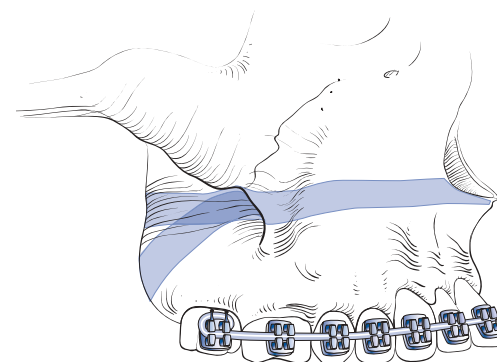

FIGURE 60-1 The posterior cut is directed into the tuberosity behind the second molar when the maxilla is difficult to mobilize. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1466.

bleeding vessel is when it is first cut. Ligature clips are applied or electrocautery is used if the vessel is easily seen. When hemorrhage obscures the field, packing followed by attempts to directly occlude the vessel should be attempted. The last option is to pack resorbable materials in the region under pressure, with tamponade of the bleeding source.

The carotid artery may be susceptible to both direct and indirect insult during the operation. Thrombosis of the internal carotid artery after orthognathic surgery may occur because of excessive extension of the head and neck.¹¹ Mortality associated with thrombosis of the internal carotid has been estimated at 40%, with an additional 52% of the patients being left with a serious neurologic deficit. Extension of the head and neck serves to stretch and partially fix the carotid artery against the cervical vertebrae, and contralateral rotation of the head results in further stretch of the artery. Positioning the patient in this manner places the internal carotid at risk for direct or indirect trauma.

Delayed Hemorrhage Delayed hemorrhage following a Le Fort I maxillary osteotomy may occur as early as the night of surgery to as late as 9 days postoperatively. The vessels most frequently involved are the greater palatine artery, the internal maxillary, and the pterygoid venous plexus of veins.⁶

Suggestions to reduce this type of injury include careful placement and orientation of the pterygomaxillary osteotome in the suture and angling the osteotomy inferior from the zygomaticomaxillary crest toward the pterygoid plates.¹² The mean distance from the most inferior junction of the maxilla and the pterygoid plates to the internal maxillary artery in the pterygopalatine fossa is 25 mm. With an average length of an osteotome of 15 mm, assuming normal anatomy, the margin of safety to separate

the entire pterygomaxillary junction is 10 mm. However, patients with dentofacial and craniofacial anomalies can have anatomic variation from these normative data. The internal maxillary artery and its branches are most vulnerable to damage in their course through the pterygopalatine fossa and fissure when the maxillary tuberosity is separated from the pterygoid plates with an osteotome.

The posterior superior alveolar and the greater palatine arteries may be severed during the Le Fort I procedure because they lie in the bony walls, although the posterior superior alveolar artery is not thought to present a significant problem for bleeding. It is generally recommended that the greater palatine arteries be preserved by gently removing bone that surrounds the vessels (Figure 60-2). However, if bleeding is encountered, the vessel should be ligated rather than letting it retract and bleed. Preserving the vessels maximizes the blood supply to segmented

maxilla and minimizes neural deficits to the palate.

There are several treatment options for the patient with postoperative hemorrhage after maxillary surgery, and they vary with the degree and severity of the bleeding. The most obvious sign of this type of problem is hemorrhage coming from both nares.³ When a patient is initially seen with postoperative bleeding, intermaxillary fixation (IMF), if present, should be removed. The patient's general physical status should be assessed and appropriate bleeding and coagulation studies ordered. Abnormal parameters warrant correction and possible consultations. With a good light source present, the nose should be suctioned to reveal whether a bleeding site is arterial or venous in nature. If adequate assessment is not possible, the nose should be anesthetized and decongested with a local anesthetic and a vasoconstrictor. Local anesthetic injections in the nose and

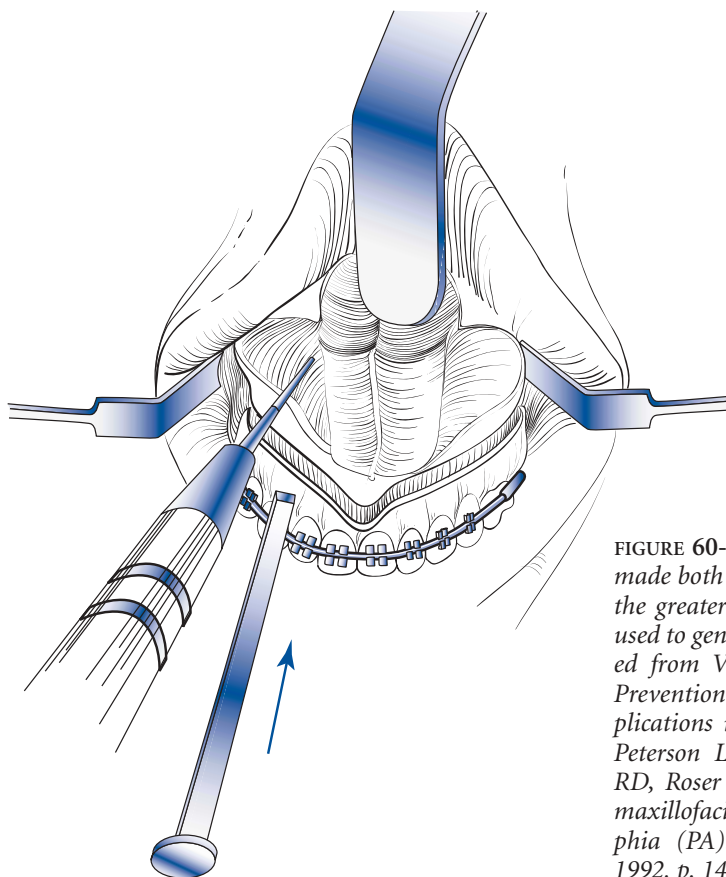

FIGURE 60-2 Using a bur, a groove is made both medially and laterally up to the greater palatine artery. A chisel is used to gently fracture the bone. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1466.

around the greater palatine foramen are helpful in stopping or slowing postoperative hemorrhage.

If the bleeding is minor in nature, it may be possible to treat the patient with bed rest. Anterior and posterior packing for 3 to 5 days combined with bed rest can be used for recurrent bleeding or for a patient not responding to initial therapy. For a patient who does not respond to these therapies or in whom the bleeding is severe or persistent, exploration of the surgical site and direct ligation or packing of problematic regions is suggested. An angiogram may be necessary. Additional operative techniques may be employed depending on clinical examination or angiographic findings. These include packing of the maxillary sinus and angiographic embolization of the specific vessel. Ligation of the external carotid artery might be considered in extreme emergencies; however, with collateral circulation, bleeding may still occur after this vessel is ligated.

Hemorrhage in the Mandible

Vascular Injury As with maxillary surgery, major vessels can be injured with mandibular procedures. Occlusion of the internal carotid has been described following a sagittal split osteotomy.¹³ Major central nervous system morbidity can occur following this injury.

Vascular injuries are due to indirect trauma either through forceful placement of a retractor placed on the lingual surface of the ramus of the mandible or the use of a mallet and chisel on the medial aspect of the mandible. Medical and surgical management of carotid artery thrombosis is beyond the scope of this text. Prevention is relatively easy. Placement of retractors and chisels on the medial posterior aspect of the mandible should be used with caution. It is preferable to limit dissection and subsequent chisel placement just distal to the lingula.

Hemorrhage with Sagittal Split Osteotomy Early reports noted numerous incidences of excessive bleeding with the sagittal split osteotomy.¹⁴ Vessels injured were the internal maxillary artery, the facial artery, and the inferior alveolar artery. These injuries were attributed to inexperience, excessive tissue stripping, and lack of sophisticated instrumentation. Excessive hemorrhage remains a problem with the sagittal split osteotomy although to a much lesser degree. In a series of 256 sagittal osteotomies the incidence of hemorrhage was 1.2% (3 cases).¹⁵ This included 2 cases of injury to the inferior alveolar artery and 1 to the anterior facial artery.

Hemorrhage occurring secondary to vascular injury on the medial or lateral aspects of the mandible with a sagittal split osteotomy can be controlled in a number of ways. The simplest involves packing, clamping, or injecting epinephrine (1:100,000) into vessel walls. Caution should be used when applying electrocautery in close proximity to the inferior alveolar nerve. When necessary, bipolar cautery is suggested. Extraoral dissections to control bleeding sources are seldom necessary.

Hemorrhage with Other Ramal Procedures In a study of the intraoral vertical subcondylar osteotomies there was a low incidence of damage to the maxillary artery.¹⁶ The masseteric artery may be injured by carrying a saw cut too far into the sigmoid notch. The inferior alveolar artery may also be injured with a vertical subcondylar osteotomy, which is usually caused by bringing the vertical cut of the ramus too far anteriorly to the posterior border of the mandible.

Access to the bleeding vessel is difficult given the approach. Fortunately in most instances, intraoperative bleeding along the ramal cut or in the sigmoid notch can be controlled by tamponade. Late sequelae such as an aneurysm may require embolization.

Loss of Vascularity

Segmental Procedures The results of vascular compromise vary between maxillary and mandibular procedures. Complications, ranging from fibrosis of pulpal tissues and periodontal defects to loss of segments, tend to increase with the number of segments. The most frequent cause of complications associated with the maxilla is interruption of the blood supply.¹⁷ Additional causes may include lack of segment stabilization, patient factors, inadequate preoperative evaluations, poor follow-up, and multiple segments.¹⁷ Patients who are heavy smokers or who have other systemic reasons for small vessel disease may mandate an altered treatment plan.

Several suggestions have been proposed to avoid vascular complications with segmental procedures. Preoperative planning to ensure adequate space between teeth, model surgery that minimizes the amount of bone removed, and careful examination of periapical radiographs prior to surgery are part of the planning that goes on prior to arriving in the operating room. Intraoperative management includes careful cutting between segments and the use of chisels and irrigated burs to complete cuts. These steps will minimize the amount of heat generated and decrease the chance of creating bone or tooth defects. Release of soft tissue adjacent to osteotomy sites and gentle mobilization of segments to avoid tearing and cutting of flaps is essential. Splints with palatal bars used for stabilization should not impinge on the palatal pedicle that serves as the major blood supply to maxillary segments. Special considerations must be given to the patient who has had previous palatal surgery or multiple segmental procedures or is a cleft palate patient. In these instances standard flap designs may not be adequate.

Complications such as periodontal defects, pulpal necrosis, and delayed union

are more commonly seen in the anterior region of the mandible but may be associated with any segmental operation. Mandibular segmental procedures require detailed planning of soft tissue incisions and careful elevation of soft tissue pedicles. In order to minimize intraoperative complications, the vascular supply to involved segments must be optimized by designing as large a flap as possible to the involved segment, maintaining maximal soft tissue attachment to the segment to be mobilized, avoiding stripping the lingual mucoperiosteal pedicle, and making the bony cut as apical as possible to include as much muscle as possible.

Aseptic Necrosis Major loss of soft and hard tissue of the maxilla is rare and is most often due to a compromised blood supply. This can be caused by a kinked pedicle in the palate or tearing of flaps. Isolated cases of loss of the entire maxilla or segments have been reported (Figure 60-3).¹⁷ More subtle complications secondary to vascular

FIGURE 60-3 Necrosis of the soft and hard tissues has occurred in the left lateral/cuspid region after a Le Fort I osteotomy. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1468.

compromise range from flattening of the papilla and loss of the gingiva to periodontal defects in areas of osteotomy cuts.

Aseptic vascular necrosis of the proximal segment with a sagittal split osteotomy has been attributed to excessive stripping of the segments.¹⁸ Loss of bone secondary to aseptic necrosis has resulted in disfigurement of patients. As early as 1974 Grammer and colleagues noted in animals the death of large areas of bone in the proximal fragment secondary to elevation of the mucoperiosteal pedicle.¹⁹ They proposed that devitalized bone usually revascularized. However, when revascularization does not occur, a substantial loss of bone from the mandibular ramus can occur, especially in the gonial angle region. In 1977 Epker presented modifications of the sagittal split and discussed a technique in which the amount of dissection of the masseter was greatly decreased.²⁰ Adoption of this technique has greatly minimized the incidence of avascular necrosis after a sagittal split osteotomy. Rigid fixation of segments, which allows early revascularization, has also minimized the incidence of aseptic necrosis.

Early publications suggested that an advancement genioplasty could be done successfully by repositioning the lower border of the mandible as a free graft. However, when this is done, resorption of the advanced segment occurs to varying degrees and results in slight to almost complete loss of the genial segment. Leaving the lingual and the buccal pedicles intact minimizes resorption and gives a more predictable chin contour. Therefore, efforts should be made to preserve the largest pedicle possible. Large genial advancements may mandate more release of lingual soft tissue to achieve the desired results. However, with an adequate labial pedicle and rigid fixation, bone loss should not be appreciable.

The intraoral vertical subcondylar osteotomy is the mandibular procedure where the proximal segment is at most risk

due to release of periosteal attachments. One study reported 2 out of 42 patients with necrosis of the distal tip of the proximal segment.²¹ The surgical technique involved stripping the entire lateral and medial surfaces of the mandible up to the mandibular neck. With more recent modifications of the technique where a pedicle of medial pterygoid muscle attached to the posterior and medial aspect of the proximal segment is maintained, necrosis of the proximal tip has not been a problem.²²

Nonunion or Delayed Union of the Maxilla

Nonunion of the maxilla may be due to both local and systemic factors. The blood supply may be compromised by poor surgical planning or may be questionable because of previous surgery, as in cleft palate patients. Scarring in large advancements may make it difficult to passively reposition a maxilla. Patients may have parafunctional activity or excessive bite forces. In those patients in whom the maxilla has been moved superior and posterior, there may be insufficient bone interface to allow healing. Patients with systemic conditions that interfere with healing, such as diabetes and smoking, require individual case planning to minimize complications.

When an unstable maxilla is anticipated, bone plates may be combined with auxiliary forms of stabilization. In most cases this includes skeletal wires and a period of IMF from 1 to 6 weeks. With inferior positioning of the maxilla, bone plates and bone grafts can be combined with adjustable pins (Figure 60-4). When these are used the patient is not kept in IMF for more than 1 week. Bone gaps greater than 5 mm should be grafted. If the maxilla has good bone contacts in multiple regions, isolated defects may be filled with alloplastic material. Large bone gaps in multiple regions require autogenous grafts.

After surgery the major sign of a problem is mobility of the maxilla when the

FIGURE 60-4 The maxilla is inferiorly positioned using bone grafts, plates, and adjustable pins. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1469.

patient occludes. Treatment of a mobile maxilla may be divided into early and late management. The use of IMF is controversial. If the patient is not in fixation a short period of fixation may help. On the other hand, if the patient is in IMF, removing it may allow consolidation. This is particularly important in the patient who has parafunctional activities. Additionally, flat plane splints may be used to distribute occlusal force more evenly. For minor problems selective occlusal equilibration may resolve premature contacts, contributing to movement of the maxilla. Patients should be placed on a soft diet. Heavy elastics should be discontinued, because with function they put intermittent strong forces on the maxilla. For patients with posterior relapse, light short class III elastics can help prevent further movement and may allow osseous consolidation. However, all elastics must be used judiciously as they may aggravate a problem. If a patient ends up with a minor Class III malocclusion, it is usually easier to manage than a nonunion maxilla.

Late management involves returning the patient to surgery for autogenous bone grafting and very rigid stabilization of the maxilla. This would include large bone plates, bone grafts, auxiliary techniques, and possibly alloplastic materials. Reoperation should be approached aggressively by completely mobilizing the maxilla and removing fibrous tissue.

Nonunion or Delayed Union of the Mandible

Nonunion or delayed union of the mandible may be due to avascular necrosis, insufficient bone contact, instability of the fixation appliances, or instability of bone fragments. It has been seen with sagittal split and vertical subcondylar osteotomies.

Vertical ramal osteotomies have special considerations, not only because a great deal of tissue may be stripped from the segments but also because the fragments may not lie in close apposition or be stabilized. Any large parafunctional movement of the jaws or trauma in the early phases after surgery may lead to nonunion (Figure 60-5).

FIGURE 60-5 A and B, Patient whose plates gave way 2 weeks after surgery when vigorous manipulation of her jaw was attempted.

Large advancements are of a greater concern than small advancements. For advancements of greater than 7 mm, additional plates may be needed to maintain stability (Figure 60-6). Alternatively, skeletal wires and a brief period of IMF have been shown to give increased stability.²³

Delayed union of a sagittal split osteotomy can be treated by a period of IMF. Alternatively, the patient may need a second operation and additional plates or screws. Nonunion mandible following a vertical subcondylar osteotomy may be more of a problem with edentulous patients or when a very short vertical cut is used (Figure 60-7). A second operation, approaching the fragment from an extraoral approach to align and rigidly fix it, may be necessary.

Dental and Periodontal Injuries

Dental and periodontal injuries can be secondary to both vascular and nonvascular

FIGURE 60-6 Large advancement of the mandible with monocortical plates and bicortical screws.

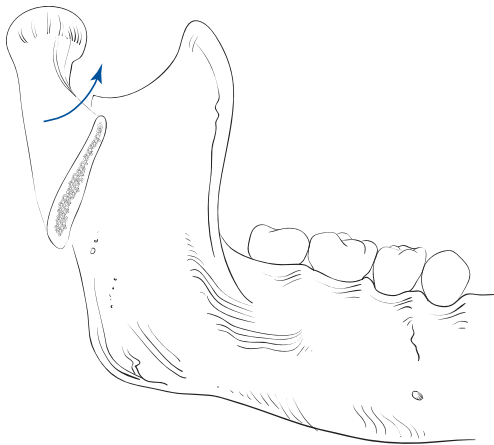

FIGURE 60-7 Severe condylar rotation is common with a short subcondylar osteotomy. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic Surgery*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1470.

causes and are most frequently related to planning or technical errors made at the time of surgery (Figure 60-8). Segmental procedures in the maxilla and mandible may cause a number of problems, including cut teeth, loss of teeth, need for postoperative root canals, and periodontal defects.

Preoperative orthodontic mechanics can be used to maximize a space between root apices in a planned osteotomy site.

FIGURE 60-8 Injured root surface adjacent to an interdental cut.

Periapical radiographs should be studied to note the direction of the root apices. A minimum space of 3 mm is advocated when placing osteotomy cuts between teeth, and 5 mm is recommended above the apices to avoid injury to pulp.²⁴ Precise model surgery can greatly reduce the frequency of dentoalveolar injury. Surgery should be planned so that a minimal amount of bone is removed between segments. Manipulation and prying of segments should be done toward the apices of the teeth rather than at the gingival margin to minimize tears in the mucosa and subsequent periodontal defects. Segments should be tipped apart whenever possible. Copious irrigation of fine fissure burs should be used when cutting through the outer cortex in the maxilla. This is followed by gentle and progressive chisel placement in the region to separate the segments. When a bony palatal island is used, release of tissue should occur under the island rather than from the alveolar segments. After segments are gently separated, small amounts of bone may be judiciously removed. When larger wedges of bone are planned for removal, always remove less bone than was planned. When segments do not fit together, they can be gently trimmed. Defects seen following excessive removal of bone usually fill with scar tissue.

In the mandible it is necessary to cut both the buccal and lingual plates, leaving only a small amount of lingual cortical plate near the cervical portion of teeth to be separated by a chisel. Use of saws is recommended to cut through the mandible, with careful palpation on the lingual surface. Owing to the dense lingual cortex, chisels are much more dangerous in the mandible than in the maxilla where they could shatter the lingual cortex or tear the lingual pedicle region. For these reasons chisels should be used cautiously following a saw cut, and segments should be pried apart with minimal tapping through to the lingual surface.

Fistulas

Postoperative fistulas in the oronasal and oroantral regions generally result from soft tissue injury at the time of surgery. Fistulas have been reported with isolated segmental as well as total maxillary osteotomies.²⁵ This may occur as a result of rotary instruments, saws, or osteotomies that perforate the palatal mucosa at the time the segmental osteotomies are completed. Impingement of soft tissue in the segmental osteotomy site during segment repositioning and fixation may also result in tissue necrosis and fistula formation. Tearing of palatal mucosa at the time of attempted tissue stretching may also result in non-healing defects. This is most common when a bony osteotomy is made in the midline of the maxilla while attempting to stretch the midpalatal tissue (Figure 60-9).

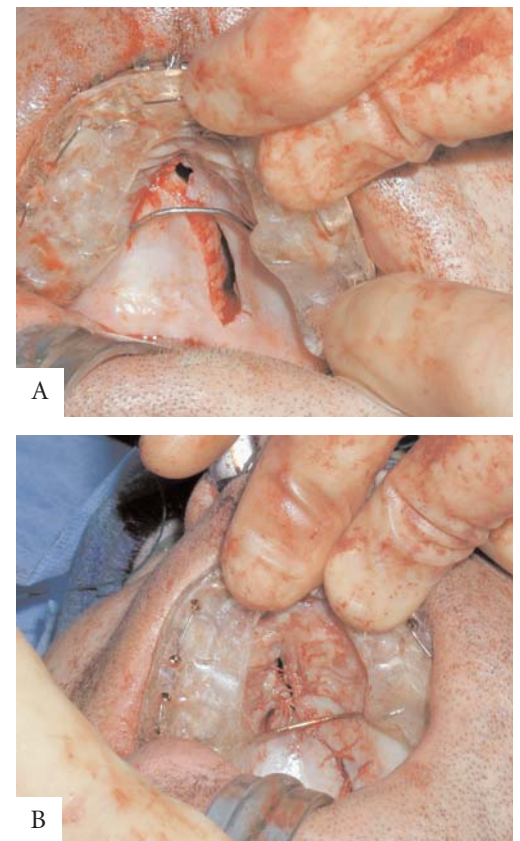

FIGURE 60-9 A, Oronasal communication has been created during a Le Fort I osteotomy with palatal sectioning. B, Sutures placed at the time of surgery, with good oral hygiene, resulted in spontaneous closure at 8 weeks.

Careful soft tissue manipulation at the time of surgery in an attempt to prevent tissue perforation is the best method for prevention of fistula formation. When expansion is needed, the palatal mucosa can be incised with two parallel incisions just medial to the greater palatine foramen; bony separation then occurs in the midpalatal area.²⁵ The tissue can stretch and expand in an area well away from the bony separation. An alternative technique involves making parasagittal cuts in the nasal floor immediately adjacent to the lateral nasal wall. The osteotomy can thus be made over tissue that is thicker and somewhat more elastic.²⁶ If a small tear is noted following a bony cut, care should be taken to release the palatal tissue from above prior to expansion of segments.

When a fistula is noted postoperatively, several measures can be pursued that may allow the fistula to close spontaneously. Preventing sinus or nasal infections is essential. This includes antibiotic therapy, decongestants, and nasal drainage. Construction of an appliance that will obturate the fistula without placing pressure on the overlying tissue will generally help in closure by reducing food contamination. Careful attention must be given to the construction of any appliance used to obturate a fistula in the immediate postoperative period. Excess pressure on the palatal mucosa may result in decreased vascularity, resulting in further loss of soft tissue and associated bone. If local measures, appropriate medical therapy, and fistula obturation have been unsuccessful, surgical closure of the fistula will be required.

When considering closure of a fistula, it is important to ensure that at least 6 months have elapsed to allow for revascularization of the maxillary segment. Carefully managed fistulas will continue to close for 8 to 12 weeks. If this therapy is not successful, a soft tissue flap should be raised from an area farthest from segments with the least potential for decreased vascularity. Timing varies, but the maxilla

should be revascularized by 6 months. If a large segment of the maxilla was involved in the initial hypovascular state, distant flaps should be considered. Choices include a buccal fat pad or a tongue flap, among others.

Management of Tissue after Vascular Compromise

Doppler flowmetry of the maxillary gingiva can be used to detect subtle decreases in the maxillary gingival blood flow following a Le Fort I osteotomy.²⁷ However, its use is limited to clinical studies at the present time. Clinically, blanched followed by cyanotic attached gingiva and adjacent free mucosa are early indications of vascular compromise following orthognathic surgery.²⁸ The overlying tissue can be an indicator of bony involvement. Three scenarios are possible: loss of vascularity to the soft tissue, whereupon the bone is perfused; loss of vascularity to the bone, whereupon soft tissue is perfused; and loss of vascularity to both the bone and soft tissue. If cyanosis is noted in the immediate postoperative period (hours to days after surgery), IMF, if present, should be released and the mouth inspected for kinked or constricted tissue. Splints must be carefully evaluated to identify areas of pressure on soft tissue by the appliance. If removal of IMF and relief or removal of splints is not helpful or the tissue is already necrotic, then supportive care is necessary to attempt to minimize the amount of bone loss. Loss of the soft tissue and exposure of the underlying bone is often what occurs. In severe cases this should be treated as an intraoral free graft. Meticulous irrigation should be performed several times a day with or without packing of the wound. Like all graft tissues it must be absolutely secure. Stability will allow some degree of revascularization. Hyperbaric oxygen therapy may be helpful to minimize bone loss while promoting neovascularization.

Reconstruction will vary and depend on the size of the resultant defect.

Nerve Injury

Sensory Injuries in the Maxilla

Sensory injuries in the maxilla have not been as thoroughly studied as those seen with mandibular surgery. With a carefully placed circumvestibular incision combined with gentle retraction, nerve injury is inconsequential and limited to the terminal branches of the infraorbital nerve. Recovery of sensation to the lip, cheeks, and nose usually occurs within 2 to 8 weeks.

Paresthesias secondary to damage of the sensory nerve supply to the teeth and mucosa are more common. Decreased sensation to the mucosa is transient and normal sensation commonly returns within 6 to 12 months. Although this is usually the case, patients will occasionally have permanent numbness intraorally on the palate and buccal gingiva. This is annoying, particularly if on the palate, as it can be burned by hot food. To preserve sensation to the palate, some authors feel that the greater palatine neurovascular bundle should be preserved.²⁸

Failure of the teeth to respond to stimulation may also be temporary. However, permanent loss of response to electrical, hot, or cold stimulation is not unusual, and does not necessarily represent a tooth that needs endodontic therapy. The clinician must differentiate a nonvital tooth from one that does not respond to stimulation but has an intact blood supply. A tooth that shows periapical radiolucency on radiographs or a fistula upon examination is a candidate for root canal therapy.

Sensory Injuries in the Mandible

Sagittal Split Osteotomy Transections of the inferior alveolar nerve can occur during a sagittal split osteotomy.²⁹ The most likely time for this to occur is during the splitting process. When the segments are

being separated, care should be taken to visualize the nerve. If the nerve is in the distal segment or encased in cortical bone, appropriate steps should be taken to release it. This may be as simple as releasing the nerve with an elevator from a medullar bone, or it may require additional bone cuts to release it from cortical bone. One study suggested that low body height of the patient and inferior position of the nerve may increase the risk for injury.²⁹ Repair of the nerve with one or more sutures placed in the epineurium has been recommended.³⁰ However, one large series had a 3.5% incidence of transection of the inferior alveolar nerve, which was anterior to or in the third molar region in all instances.¹⁵ Nerve endings were approximated in 9 patients by positioning the segments but not suturing them. The length of follow-up for these patients was 2 to 5 years, and all of the patients had some return of sensation to the normal inferior alveolar nerve distribution. Whether this represented regeneration or new growth from the cervical plexus is unknown.

If the transection occurs at the vertical bony cut, immediate repair may be difficult. To expose more of the nerve in the distal segment a second cut anterior to the first is necessary. When excessive tension is present, the nerve may have to be exposed distally to the mental foramen to allow a tension-free repair. The need for such an extensive procedure needs to be weighed against other goals to be achieved with the surgery.

Injury to the inferior alveolar nerve in the absence of a transection is frequently associated with sagittal splitting of the mandibular ramus. Risk factors for an increased amount of neurosensory disturbance include the age of the patient, whether they have a genioplasty, and the amount of advancement.^{31,32} Multiple techniques have been suggested to prevent these injuries, including osteotomy design, chisel placement, dissection technique, decompression of the lateral fragment,

and steroid use. Vigorous medial retraction may cause the inferior alveolar nerve to be compressed against the lingula and decrease intraoperative nerve conduction.^{29,33} Retraction on the medial aspect of the mandible should be done carefully to avoid compression nerve injuries. The best place to make the lateral (vertical) cut is in the first and second molar region where the cortex is the thickest, the mandible is the thickest, and the nerve is furthest from the lateral cortex.^{15,34} Other suggestions have been made to prevent nerve injuries based on clinical experience, but no controlled studies have been done to prove whether one way is preferable to another.

Injury to the lingual nerve during a sagittal split osteotomy can occur but it is unusual.^{35,36} The course of the lingual nerve near the medial surface of the mandible varies; therefore, any dissection on the lingual aspect of the mandible in the third molar region may temporarily or permanently injure this nerve.³⁷ As with inferior alveolar nerve injuries, lingual nerve injuries should be carefully followed and documented. If the nerve is visualized and has been transected, it should be repaired at the time of surgery.

Other Ramal Procedures Although vertical or oblique ramal osteotomies are frequently suggested as alternatives to a sagittal split osteotomy for horizontal mandibular excess, these procedures may also cause permanent injury to the inferior alveolar nerve. The incidence of permanent paresthesia following an intraoral vertical subcondylar osteotomy has ranged from 9 to 11%.^{38,39} Endoscopic approaches to the ramus may have a different incidence of nerve injury, but experience with these techniques is limited.⁴⁰ The precise mechanism of injury to the inferior alveolar nerve is unclear and steps to prevent this complication require further study. The saw blade should follow the posterior border of the ramus until it reaches a point

well above the antelingual bulge on the lateral aspect of the mandible. Postoperative anesthesia should be carefully followed.

Motor Nerve Injury

Injury to the facial nerve is much more common with extraoral approaches than with intraoral surgery. However, there have been multiple reports of facial nerve injuries with sagittal split and vertical subcondylar osteotomies.⁴¹⁻⁴⁴ In one series that studied 1,747 cases of sagittal splits, the incidence was 0.26%.⁴³ The degree of injury varies from partial to total paralysis and is often seen following a setback of the mandible, but has been seen with a mandibular advancement.⁴² The possible causes of injury are impingement of the nerve when the distal segment was moved back, fracture of the styloid process and subsequent displacement, and introduction of retractors behind the ascending ramus with impingement of the nerve. Most of the reported cases occurred with mandibular setbacks without use of the Hunsuck modification.⁴⁵ The most likely cause of nerve injury is pressure on the nerve trunk, either by the distal segment or by retractors placed behind the mandible (Figure 60-10). To prevent this problem a medial/lingual split should be just distal to the inferior alveolar nerve when a sagittal split is used to set back the mandible. If a medial split extends to the posterior border, bone should be removed proximal to the lingula. Unfortunately the magnitude of setbacks causing this problem is unknown and probably varies with individuals. Care should be taken when retractors are placed behind the mandible on all ramus osteotomies.

When a facial paralysis occurs after surgery, there are a number of electrical tests that can be used to determine the depth of injury and subsequent therapy. Electroneurography, a study of peripheral nerve conduction, or electromyography, which is the detection and evaluation of electrical potentials from muscles,

FIGURE 60-10 Two possible causes of facial nerve injury with a sagittal split osteotomy. A, Retraction on the medial behind the ramus. B, Extension of the distal segment beyond the proximal segment. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic surgery*. can be used.^{46,47} It is important to distinguish between an injury that causes segmental demyelination and one that causes wallerian degeneration. With axonal interruption the ability to transmit an impulse is lost over a period of 5 to 7 days. When axonal degeneration occurs, the prognosis for complete recovery is poor. When this is noted, surgical exploration should be considered to rule out a laceration of the nerve. As long as the axon remains intact at the site of blockage, the nerve will continue to respond to stimulation distal to the blockage even though paralysis is present. Evoked eletromyography (EEMG), a test in which

the degree of muscle twitch elicited is recorded, has been used as a prognostic test.⁴⁸ If the response to EEMG remains greater than 25% at 5 days, the injury is mild and the prognosis is good.⁴⁸

Clinical management of the patient during the paralysis can vary depending on the nerve branches and the type of nerve injury involved. When the patient has difficulty achieving eyelid closure, an eye patch and methylcellulose eye drops may be useful. Physical therapy such as heat, facial massage, and facial exercise performed twice a day have been suggested. Facial cream should be massaged into the skin around the eyes and mouth and over the midface, ideally using an electric vibrator. Exercises may consist of having the patient stand in front of a mirror to watch his or her face while raising the eyebrows, blowing the cheeks, and grinning. Even though no facial movement may be noted, intact nerve fibers will be activated and the exercise will help to maintain muscle tone. Electrical and mechanical stimulation may maintain muscle tone. Steroids had been given orally, intramuscularly, and intravenously for facial nerve paralysis.

Nasal and Sinus Considerations

Alterations in Nasal Form: Septum

Repositioning of the maxilla requires manipulation of nasal components and the maxillary sinus. As a result of these manipulations, alterations can occur with the internal nasal anatomy including position of the turbinates, nasal septum, and nasal valve. Adverse effects of maxillary osteotomies on the alar bases, nasal tip, supratip depression, and upper lip may result in an unesthetic postoperative facial appearance.⁴⁹⁻⁵¹

The maxillary septum may be deviated prior to surgery, at the time of surgery, or during extubation. Hence the septum should be inspected prior to surgery and

at the time of surgery. During a Le Fort I maxillary surgery it is possible to align the septum at its inferior anterior caudal end. At surgery the septum is disarticulated from the entire maxilla. In particular, with impaction, the maxilla will encroach on the presurgical dimension of the nasal septum. Because of this movement, attention must be given to the positioning of the septum at the time of surgery. Failure to do so may result in septal deviation and obstruction, or in abnormal positioning of the columella and nasal tip.⁵⁰ There are several techniques for superior repositioning, including resection of an appropriate portion of the inferior aspect of the nasal septum or creating a groove in the superior aspect of the maxilla. In segmental osteotomies, creating a bony island with parasagittal palatal cuts may eliminate posterior superior pressure. However, it will not eliminate pressure from the anterior portion of the maxilla on the septum.

When septal deviation is recognized postoperatively, three choices for management should be considered (Figure 60-11). These include immediate manipulation, reoperation, or septoplasty at a later time. If appropriate management of the nasal septum was accomplished at the time of surgery but the nasal septum appears to be asymmetric, manipulation with an instrument placed within the nose on each side of the base of the nasal septum may allow for repositioning in the midline position (see Figure 60-11B and C). If rigid fixation has been used and the patient has no airway difficulties, short-term packing may be considered. If septal deviation is due to intraoperative management or if postoperative manipulation poses difficulty, immediate reoperation with further septal surgery may be indicated. If none of the previous approaches seems acceptable, and the patient does not have significant airway difficulty, the deviation can be reevaluated at a later date with consideration for a septoplasty through standard techniques.

FIGURE 60-11 A, Deviated septum initially after surgery. B, Manipulation. C, After manipulation.. Reproduced with permission from Van Sickels JE, Tucker MR. Prevention and management of complications in orthognathic surgery. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1475.

Alterations in Nasal Form: Nasal Valve

An area of concern in maxillary surgery is alteration in internal nasal anatomy, nasal airway resistance, and breathing patterns as a result of maxillary surgery. Expansion of the maxilla with surgery has shown little change in the nasal airway. Some patients remain obligatory mouth breathers even after expansion.⁵² Of greater concern is the possibility that superiorly repositioning the maxilla may decrease the nasal airway. Several studies have documented that the reverse is true.^{53–55} Superior maxillary repositioning appears to increase nasal cross-sectional area, decrease nasal airway resistance, and increase nasal breathing. The explanation for this decrease in nasal airway resistance is most likely related to alteration in configuration of the nasal valve area.^{53–55} The nasal valve is formed by the nasal septum, the floor of the nose, the soft tissue on the lateral aspect of the nose, and the caudal end of the upper lateral nasal cartilage. The increase in alar base width that results from elevating the soft tissues to expose the maxilla causes a slight widen-

ing of the nasal valve and thus reduces nasal airway resistance. Because this valve is at the smallest cross-sectional area of the nose, alterations in this area are likely to have a significant effect on nasal breathing whereas changes in much larger intranasal areas have little effect. This same phenomenon has been demonstrated in patients with cleft palates.⁵⁶

Alterations in Nasal Form: Alar Base

In addition to the internal nasal changes, there are facial esthetic changes that may result from maxillary surgery. Failure to properly manage the nasal septum, paranasal musculature, and labial mucosa may result in undesirable facial esthetic results. Adverse changes in nasal and perioral configuration following maxillary surgery may include excessive alar base widening, increased prominence of the alar groove, upturning of the nasal tip (with an obtuse nasolabial angle), flattening and thinning of the upper lip, and downturning of the labial commissures.⁵⁰ These complications may also be compounded by internal deviation of the nasal septum or asymmetric posi-

tioning of the columella and nasal tip due to septal deviation. These types of problems are difficult to manage and are best treated by prevention. The need to control alar base width and the necessity of reconstruction of paranasal and perioral musculature have been previously described.⁴⁹

Postoperative Sinus Symptoms

Postoperative complications related to the maxillary sinuses are primarily limited to infection, inadequate drainage, and open fistulas. Although many patients experience drainage and some sinus symptoms in the immediate postoperative period, true perioperative infections of the sinus area and long-term sinusitis are rare.^{57,58} Between 2 and 6 months after surgery there will be normalization of the bony and soft tissue structures in over 55% of the patients.⁵⁸ However, at 6 months, 30% of the patients will show some latent mucosal borderline swelling.⁵⁸

Despite the rarity of infections there are several potential causes of infections in the maxillary sinus area. The formation and retention of large blood clots in the sinus cavity is an obvious source of infec-

tion. Preoperative antibiotic prophylaxis with subsequent antibiotic levels present in the clot will help reduce infections from this source. Other potential causes of infection in the sinus are preexisting disease, dental infection secondary to trauma to the teeth, soft tissue ischemia and avascularity, and debris within the sinus. Foreign objects such as wires, bone plates, or screws are rarely, if ever, the isolated cause of a sinus infection and do not appear to cause a significant increase in the incidence of infection after maxillary surgery.⁵⁷

Preoperative assessment of patients presenting for maxillary surgery should include a history and clinical examination, with careful attention to symptoms of any existing maxillary sinus infection. Evaluation of preoperative radiographs may provide some information regarding sinus pathology. Postoperative management of sinus infections should include appropriate antibiotic therapy verified by culture and sensitivity, decongestants, intranasal vasoconstrictors, and irrigation of patent fistulas if present. Generally sinus drainage can be managed within 10 to 14 days with these techniques. When a sinus infection is refractory to medical treatment, sinusoscopy should be considered. These patients should be managed in a manner similar to treatment for patients who have not had surgery.

Unanticipated Mandibular Osteotomy Fractures

Fragment Management

Fragment management, or more appropriately intraoperative management of unusual fragments, is a problem seen more frequently with mandibular procedures, especially sagittal split osteotomy. Additional segments may occur on either the proximal or distal fragments. The incidence of unfavorable fractures with a bilateral sagittal split is 1.9 to 2.2% with a slightly higher incidence when the third molars are present.^{59,60}

These fractures may be in either the proximal or distal segment.

Intraoperative management of an inadequate split is that separation of the proximal and distal segments must first be completed. Intraoral management is the rule. A small or large fragment may have been fractured. Management will vary depending on the size and location of the fragment. It must first be determined where the fracture deviated from the desired split. Often it is necessary to remove the free segment to get access to the remaining mandible. Using a saw or a bur the intact mandible or segments are grooved so that a sagittal split can occur along the original planned lines. Chisels are used to complete the desired split. The key to management is to orient oneself to what is left. Once the split is successfully completed, the distal segment is advanced to its desired position. The position and size of the remaining fragments may make positioning of the condyle difficult. Segments are sequentially stabilized to the remaining fragments. An extraoral approach may be an option, but is usually not necessary. The following examples will illustrate management of various fractures.

Proximal Segment, Mandible Intact

The difficulty in managing segments depends on the location and size of the fractured pieces. A fragment may shear off the lateral aspect of the mandible, leaving the mandible intact. Whenever a buccal fragment shears off, the usual cause is an inadequate bone cut on the inferior border on the lateral vertical cut. The split must then be completed. This can be done by making a deep groove on the inferior border and connecting it with the previous groove coming down the external oblique ridge. By gently prying and, when necessary, cutting bone, the segments will be separated as originally planned. Placing the distal segment in occlusion, the free fragment should be stabilized with screws and

plates. In Figure 60-12 a buccal fragment has been fractured. The main portion of the mandible was intact before completion of the split. The segment is stabilized with a plate and screw osteosynthesis, as shown in Figure 60-13. Condylar position is not difficult to establish when a proximal segment is large enough to be positioned and overlapped with the distal segment in its new position. Bicortical screws can be used between the areas of contact of the two segments. With a small free fragment (as depicted) it is frequently easier to place a plate on it out of the mouth and then reattach it to the proximal segment.

Proximal Segment Split Complete

When the fragment occurs more superiorly, or there is a large advancement, such that there is no contact between the proximal and distal segments when placed into occlusion (Figure 60-14), a different approach must be taken. The condyle and coronoid are in one piece, simulating a horizontal osteotomy of the mandible,

FIGURE 60-12 Buccal segment, fractured off. Adapted from Van Sickels JE, Tucker MR. *Prevention and management of complications in orthognathic surgery*. with or without the angle as a separate fragment. Control of the condylar position is much more difficult. The large fragment that was sheared off should have a plate placed on it outside the mouth. It should be re-inserted and connected to the proximal segment (Figure 60-15). This usually requires two percutaneous incisions. Having done this the proximal segment is easier to manage and it can be united with the distal segment in its new position. This can be done with a series of plates or bicortical screws. Control of condylar position may be established by posterior, superior, and vertical pressure on the reunited proximal segment, followed by clamp placement prior to placement of bicortical screws, or by the use of a clamp on the coronoid process to stabilize the proximal fragment before screw placement.

The last case scenario is a fracture of the condyle with the coronoid and angle in a separate fragment. Here one must plate the condyle to the advanced reunited distal segment and use screws in other parts where there is overlap (Figure 60-16). Correct condylar positioning is extremely difficult to achieve in this environment. Through percutaneous incisions a plate is placed on the condyle. Using the plate as a handle, holes are drilled in the distal fragment and screws placed.

Lingual Segment Fracture

Fortunately, fractures of the lingual fragment occur less frequently than fractures of the buccal fragment. The underlying cause is frequently an impacted third molar or it may be secondary to wedging too high on the medial aspect of the mandible (Figure 60-17). To prevent this type of fracture it is wise to have third molars removed at least 9 months prior to surgery. When an unwanted fracture occurs, the split must be completed along the original planned osteotomy lines. As the free segment is not in the way when the split is completed, it is frequently possible

to leave substantial vascular pedicle attached to it. The distal segment is placed into occlusion. The free fragment is manipulated to an anterior position and is fixed to the proximal segment by one or more bicortical screws. One or more plates or titanium mesh may be placed across the osteotomy site (Figure 60-18).

Excessive Lateral Displacement

Excessive lateral displacement can occur during a vertical subcondylar osteotomy. Depending on the geometry of the move, the proximal fragment or condylar segment may be displaced laterally or medially. The usual position is lateral to the main body of the mandible. Even with moderate flaring there is considerable remodeling possible and this is usually not a problem. Occasionally the proximal segment will be flared excessively. This can be remedied intraoperatively by removing a second wedge at the sigmoid notch region (Figure

60-19). Care must be taken in this region because the masseteric branch or the maxillary artery itself can be injured.

If excessive flaring is noted postoperatively, the segment may be manually repositioned, but if this does not succeed, reoperation is necessary.

Medial Displacement

In some cases of asymmetry the rotation may be such that the condylar fragment may be placed medially. Whether this will increase the incidence of nerve injury is unknown. Medial displacement rarely causes problems. A conceivable patient complaint is irritation of the pharynx. If this happens the medial fragment needs to be contoured or removed.

Proximal Segment Rotation

Lack of control of the proximal segment with a sagittal split osteotomy can have several effects that are both esthetic and

functional. Postoperation muscular pull is such that the proximal segment is pulled anterior and superior while the distal fragment is pulled posterior and inferior (Figure 60-20). Anterior superior rotation of the proximal segment may result in an unpleasant cosmetic result by flattening of the gonial angle and notching the inferior border of the mandible anterior to the angle. This causes a bulge in the cheek secondary to the position of the proximal fragment. The type of osteosynthesis used has been shown to affect the position of the fragment during surgery and in the initial postoperative period.⁶¹

Ideal management of a rotated proximal segment is prevention. Several positioning appliances have been presented to control the proximal segment during surgery.⁶²⁻⁶⁴ Rigid fixation used without positioning appliances has shown minimal rotation of the proximal segment with surgery.⁶¹ However, there is a tendency to

FIGURE 60-17 A lingual split (distal segment) has occurred in the third molar region. Adapted from Van Sickels JE, Tucker MR. Prevention and management of complications in orthognathic surgery. rotate the proximal segment medially and superiorly with large advancements.⁶⁵ This can result in an unesthetic effect for the patient, especially if there was any discrepancy in the height of the ramus prior to surgery (Figure 60-21). To date, the amount of rotation that will cause clinically significant decreases in muscle efficiency and unesthetic facial changes is unknown.

Excessive rotation of the proximal segment should be evaluated as to whether there are functional (decreased bite force, hypomobility) or esthetic (loss of the gonial angle) problems, or both. An

FIGURE 60-21 Radiograph of short ramus.

esthetic problem seen in a patient with acceptable occlusal results may be treated by the use of an alloplastic implant. If the patient has an occlusal problem with esthetic considerations, the sagittal split can be redone (Figure 60-22). When these are combined with decrease in bite force and hypomobility, then reoperation must be combined with a vigorous postoperative physiotherapy program.

Most patients demonstrate decreased maxillomandibular opening compared with their preoperative state. The most dramatic decreases are seen after bilateral sagittal split osteotomies.⁶² Temporomandibular mobility must be restored by postoperative physiotherapy. Ellis examined the range of mandibular motion after a sagittal advancement osteotomy in monkeys, when either IMF or rigid osseous fixation was used.⁶⁶ Animals that did not undergo IMF maintained a greater range of motion in the early postsurgical period and obtained preoperative mobility by 12 weeks postoperatively. Animals that underwent 6 weeks of IMF showed significant decreases in range of motion when compared to the rigid fixation group at each time period post-surgery. Several clinical studies have shown that whether IMF or rigid fixation is used, with postoperative physiotherapy, a normal or near-normal range of motion will return by 2 years after surgery.^{61,67}

There are several potential causes of hypomobility in patients undergoing orthognathic surgery. Scar tissue induced

FIGURE 60-22 Occlusal discrepancy.

by the surgery plays a major role. However, immobilization can compound the effects of surgical dissection and have adverse effects on the muscles, joints, and connective tissues. Immobilization by itself induces atrophy with a marked decrease in muscle fiber diameter. This problem may be compounded if the muscle is immobilized in a shortened position. In addition, following IMF, a series of degenerative changes occur in articular cartilage and synovial membranes.

Techniques that eliminate or minimize immobilization will probably decrease postsurgical hypomobility. Despite this it is strongly suggested that all patients have routine presurgical evaluation of muscle and joint function and a systematic rehabilitation regimen as part of their postsurgical program. Mandibular ramal procedures are potentially the most harmful to the surrounding tissue of the jaws. Mandibular advancements, in particular, are susceptible to postoperative hypomobility. If rigid fixation is used, mild self-directed physiotherapy beginning 1 to 2 weeks after surgery may suffice, consisting of instructions on active and passive exercises. When a patient's progress is limited or when surgery has been associated with longer periods of IMF, then more vigorous physical therapy is needed. If this is unsuccessful, intra-articular pathology may be responsible for the problem and additional steps may need to be taken to restore a normal range of motion.⁶⁸

Temporomandibular Joint Dysfunction

Short-Term Disorders

Joint dysfunction in patients undergoing orthognathic surgery deserves careful preoperative examination. A number of patients presenting for orthognathic surgery will have muscular temporomandibular dysfunction.⁶⁹⁻⁷¹ Although a small percentage of patients will develop

symptoms with surgery, the large majority will improve. Achieving a better functional relationship can help temporomandibular symptoms, but orthognathic surgery should not be offered as a cure for these problems. After surgery patients may have acute or gradual increases in temporomandibular symptoms. Acute exacerbations may be treated with anti-inflammatory medications and physical therapy. Gradual increases or chronic manifestations of temporomandibular problems are managed with standard protocols for these patients. Concern exists that with rigid fixation there will be a higher incidence of temporomandibular dysfunction compared with the use of wire osteosynthesis. Studies that have compared these two populations have not borne out these assumptions.^{67,70}

Long-Term Disorders

Condylar resorption has been noted with and without orthognathic surgery. The cause of delayed relapse may be secondary to a number of factors including preexisting internal derangements. The role that surgery may play in these unusual cases is unknown. The incidence of condylar resorption or progressive condylar resorption ranges from 5 to 10% of the patients who undergo orthognathic surgery.⁷²⁻⁷⁷ Patients who need large advancement of the mandible and who have preoperative temporomandibular symptoms are more likely to have this problem than those who have smaller advancements and no symptoms.^{72,74} Condylar resorption has been noted 12 to 17 months after surgery.⁷⁶ Management includes splint therapy, with a possible role for medications.^{76,77} Secondary surgery is unpredictable, with additional resorption possible in as many as 50% of cases.⁷⁶

Unanticipated Maxillary Fractures

Whereas several reports have discussed management of additional fragments with

mandibular osteotomies, little attention has been directed to maxillary surgery. With modified cuts of the maxilla, the bone leading to the zygomatic buttress (wing) may be thin and fractured (Figure 60-23). Management can be accomplished by using a plate to span the gap and then re-inserting the fragment (Figure 60-24).

Over- or underimpaction of the maxilla can occur at the time of surgery. This can be avoided with an external reference. One choice is to place a pin at nasion at the beginning of surgery. Intraoperative measurements will ensure that the maxilla is at the appropriate position at the end of surgery.⁷⁸ When the maxilla is under impacted, very few options exist. Plates, if present, may be removed and an attempt made to impact the maxilla with suspension wires in an outpatient environment. However, it is unlikely that this procedure will achieve the desired results. When the maxilla is overimpacted, it can rarely be successfully treated by multiple vertical elastics used in the early postoperative

period. If unsuccessful, then a reoperation should be considered.

Postoperative Occlusal Discrepancies

Occlusal abnormalities may be related to a number of factors either in the preoperative, intraoperative, or postoperative phase of patient management. A review of cases of maxillary surgery suggests that the majority of discrepancies between what was desired and what was obtained can be traced to inaccurate preoperative records.⁷⁹

Open Bites

Surgical Causes

Anterior open bites after surgery may be due to the technical difficulties seen with both the maxilla and mandible at the time of surgery. With the maxilla these include posterior interferences that are not recognized when the patient is in IMF. If the maxilla is fixed with condyles that are dislocated out of the glenoid fossa, when the

In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol. 3. Philadelphia (PA): JB Lippincott Company; 1992. p. 1483.

patient is taken out of fixation, the occlusal discrepancy is usually recognized. Occasionally, however, it is not recognized until the next day. Depending on the severity of an open bite, the patient may have to be taken back to the operating room.

Open bites that occur after orthodontic appliances have been removed may be due to relapse of surgically or orthodontically treated transverse discrepancies. Surgical and orthodontic correction of severe transverse discrepancies have been noted to be unstable.⁸⁰ When relapse of the transverse discrepancy occurs, it is usually manifested by an anterior open bite. Management of late discrepancy will depend on its severity.

Dental or Orthopedic Causes

Open bites have been noted to recur years after treatment with both orthodontics and surgery.^{80,81} Stability of orthodontic therapy varies depending on the orthodontic techniques used to treat an open bite.⁸² Rotation of incisors that are flared with closure of an open bite may be no more problematic than for other tooth movements. When extrusion of teeth has occurred with orthodontic mechanics, the results are less predictable. Why this occurs is somewhat controversial. Extrusion may have increased sensitivity to external factors, such as the tongue and circumoral musculature. Lack of stability or recurrence of the open bite is therefore felt to be secondary to the continued presence of etiologic factors and failure of biologic adaptation. Measures taken to correct these problems may include orthodontic cribs or surgical techniques such as partial glossectomies.

Relapse of the Mandible

Relapse of the mandible following a bilateral sagittal split has been well documented in the literature, especially with larger advancements.⁸³⁻⁸⁶ However, occlusal discrepancies can occur secondary to several reasons. Many of these occlusal discrepan-

cies can be traced to the technical aspects of rigid fixation. Occlusal changes seen with rigid fixation may be secondary to condylar torque, condylar sag, or incorrect placement of the fragments at the time of surgery. This may result in anterior or posterior open bites or lateral shifts. Severe discrepancies may need to have a second operation. Minor discrepancies can be treated by early aggressive orthodontics. Posterior open bites of less than 3 mm can be treated with vertical elastics or orthodontic mechanics. Larger posterior open bites may have to be reoperated, with removal of the screws and replacement with either screws or wires. Anterior open bites represent failure to properly place the condyle or instability at the osteotomy site. IMF with anterior elastic traction may prevent reoperation when the cause is instability at the osteotomy site.

The preferred time to initiate therapy is as soon after surgery as the discrepancy is noted. Removal of the screws or plates in an outpatient environment at 3 weeks, coupled with elastic therapy, can sometimes correct some postoperative malocclusions. Failure to place the condyle in the fossa, either unilaterally or bilaterally, needs evaluation as to whether orthodontic therapy can correct the problem or if the surgery needs to be repeated. A lateral shift of the occlusion where the midline is off to one side is usually due to condylar torque at the time of surgery. When placing a clamp between the proximal and distal segments, the proximal segment should be observed for shifts or torque of the segment. If seen the fragments may need to be contoured or the clamp repositioned. After surgery a shift in the midlines secondary to torque of the segments may be treated by orthodontics or by reoperation. Small shifts of 1 mm or less can be managed by orthodontic mechanics. Larger ones may need a second surgery.

Relapse of a skeletal Class III occlusal condition upon release of IMF has been noted.⁸⁷⁻⁸⁹ Several authors believe this can

be caused by pushing the proximal fragment back during surgery. With the release of IMF the mandible rotates forward. To prevent this problem it has been suggested that the inferior border of the proximal and distal segments be aligned and that the medial sling be released.⁸⁸ Others disagree and feel that clockwise rotation of the proximal segment is not responsible for the relapse.⁸⁹ Additionally, the use of a monocortical plate on the proximal segment may provide a more stable result than that seen with bicortical screws (Figure 60-25). When this occlusal discrepancy is seen after surgery, short class III elastics can correct the problem if it is small. If the discrepancy is greater than 3 to 4 mm, a second operation is necessary.

Anterior Open Bite

As discussed above, an anterior open bite may be seen after a bilateral sagittal split osteotomy (Figure 60-26). This is usually due to a failure of the screws and/or plates placed at the time of fixation, or technical difficulties incurred at the time of splitting the segments with resulting edema in the joints which resolves with time. However, an anterior open bite is much more commonly seen in patients following an intraoral vertical ramus osteotomy upon

FIGURE 60-25 Monocortical plate on the buccal surface of the proximal and distal segments.

FIGURE 60-26 Open bite following a bilateral sagittal split. A, At 24 hours. B, After 1 week.

release of IMF.^{90,91} Suggestions to prevent this problem from occurring include removing the coronoid process, placing skeletal wires, or using modified cuts of the ramus and 8 weeks of IMF.⁹¹ Postoperative elastics have been used for 2 to 6 weeks when open bites have been noted.

Miscellaneous Occurrences

Endotracheal tubes have occasionally been cut during maxillary surgery. In some instances patients needed to be reintubated; in others packing around the endotracheal tube is sufficient.

Alar rim injuries are due to pressure on the rim from the nasotracheal tube. Care should be taken when wrapping the

head so that there is no pressure on the tip of the nose or the forehead or ears.

Emphysema in the cervical and facial regions has been noted after a variety of procedures that are unrelated to orthognathic surgery. However, there are several reports of air in the soft tissues of the head, neck, and chest following Le Fort I osteotomies.⁹² Subcutaneous emphysema of the cheeks is probably due to forceful blowing of the nose, which allows air into the surrounding tissues through the maxillary sinus. Forceful coughing can allow air to pass into the retropharyngeal space and into the mediastinum. Alternatively, rupture of a perivascular bleb or traumatic introduction of air through the cervical fascia is possible. Subcutaneous emphysema can be managed by observation, heat, and antibiotics. Therapy for pneumomediastinum consists of close observation, cardiac monitoring, intravenous fluids, and antibiotics. Chest tubes or drainage of the mediastinum may be necessary. Supplemental oxygen as well as pulmonary physiotherapy should be used.

Epiphora

Epiphora may be seen following a maxillary osteotomy and is frequently due to swelling of the nasal mucosa. Alternatively, the nasolacrimal duct may be injured when a concomitant turbinectomy is performed with an osteotomy. This is especially true if the bone cut along the medial wall of the sinus is high. Such tearing is infrequent and transient. Careful dissection and osteotomies around the medial aspect of the piriform aperture may decrease the incidence of this finding. Persistent tearing that does not decrease after 3 weeks may need to be addressed by a dacryocystorhinostomy.

Auriculotemporal Syndrome

The auriculotemporal syndrome, gustatory sweating, or Frey's syndrome is an unusual complication mainly of parotid surgery. After an injury to the auriculotemporal

nerve, the symptoms are believed to be caused by a misdirected regeneration of parasympathetic fibers to denervated sweat glands. A number of authors have reported it occurring after extraoral vertical ramus osteotomies and bilateral sagittal split osteotomies.⁹³⁻⁹⁶ Patients' symptoms occurred 3 months to 3 years after surgery.

Mild cases in which the patient may only have symptoms with spicy foods should be observed, because the symptoms may decrease with time. A variety of treatments have been suggested for more severe symptoms, including topical scopolamine and insertion of fascia lata or acellular human dermis matrix under the skin.⁹⁷ Topical scopolamine has a series of undesirable side effects. Recently there have been reports of the use of botulinum toxin as a successful treatment for this problem.^{98,99}

Facial Scars

Although attempts are made to camouflage extraoral site incisions, unattractive facial scarring occasionally occurs. Egyedi and colleagues noted 6 undesirable scars in a group of 100 patients with extraoral incisions.¹⁰⁰ The criteria they used to determine what was attractive or unattractive are unknown. Percutaneous incisions of 2 to 4 mm seldom leave significant scars. More problematic is when the skin sticks to the underlying muscles. Scar revisions are usually able to improve on an existing scar. Intraoral management with the right instruments may obviate the need for most skin incisions.

Salivary Injuries

Injuries to the parotid gland can occur with extraoral procedures. Painless swelling, parotid sialoceles, and fistulas have been seen in the first week after surgery.¹⁰¹ The treatment of sialoceles or salivary fistulas may include antisialogogues, pressure dressings, and aspiration from a nondependent point. Sialography is not recommended in the acute phases of these injuries, because it may

create a fistula or increase its size. Resolution of a sialocele should be seen within 1 month with nonsurgical therapies. Failure of these more conservative therapies may be followed by more extensive surgical procedures.

Orthognathic Surgery in the Patient with Cleft Palate

Timothy A. Turvey, DDS

Ramon L. Ruiz, DMD, MD

Katherine W. L. Vig, BDS, MS, D Orth

Bernard J. Costello, DMD, MD

The estimated incidence of orofacial clefts involving the lip and palate in the United States is approximately 1 to 2 per 1,000 births or approximately 1 in 700 live births.¹ The average cost of rehabilitation of a child born with an oral cleft is estimated at approximately \$100,000 (US). The occurrence rate of infants born with a cleft lip and/or palate is influenced by race and gender, and the cost varies by the number of procedures and interventions performed.

Care for an infant born with an orofacial cleft begins with primary surgical repair of the lip followed by the palate and continues in defined and appropriate stages to late adolescence, at which point public funding is usually discontinued. The burden of care assumed by the patient and family in the indirect costs of time off from work/school and transportation by the caregiver is not to be underestimated, and it is often inadequately equated with the financial or direct costs of treatment.

The interdisciplinary approach to the management of patients with a cleft lip and/or palate and other craniofacial anomalies requires careful coordination and communication; a cleft palate team establishes a patient-centered approach

that follows critical pathways.²⁻⁵ The timing and sequencing of care is critical because of the interaction of facial growth with the development of the dentition. Clefts of the maxilla, especially the unilateral cleft lip and palate, are associated with a skeletal maxillary deficiency in the transverse, anteroposterior, and vertical dimensions. The dysmorphology in all three dimensions has been attributed to scar tissue following the primary repair of the lip during the first 6 months of life and the palatal repair, which is performed typically at 12 to 18 months. Clefts of the maxilla, both unilateral and bilateral, have been considered to have an intrinsic growth deficiency of skeletal, soft tissue, and dental components. However, in those children who have unrepaired clefts early in childhood, relatively normal occlusal relationships are established compared with those relationships in children who are surgically repaired in the first 2 years of life. This latter group is characterized by anterior and posterior dental crossbites, midface sagittal deficiency, and associated vertical overclosure.⁶ Because the cleft involves the dentoalveolus and occurs owing to the lack of fusion of the primary

palate during embryogenesis, the dental lamina may also be involved, with consequences of extra teeth such as supernumerary teeth, malformed and misplaced teeth, or an absence of teeth in the cleft site. Normal biologic variation is the result of phenotypic variation, which allows one individual to be distinguished from another by facial appearance. Therefore, dental malocclusions may occur on all skeletal patterns, but in the population with a cleft lip and palate, the pathogenesis of clefting is superimposed on the individuals' inherited facial pattern. Additionally, facial clefts are associated with over 300 syndromic conditions,^{7,8} so a patient may have syndromic or nonsyndromic facial cleft; this distinction and diagnosis is confirmed by the geneticist on the team.

Asymmetry is a typical facial characteristic and is one of the stigmas associated with unilateral orofacial clefts. Cleft patients typically express concerns about their facial appearance, but they also have problems with communication because their speech is affected. This is partially because the velopharyngeal mechanism is inadequate to close off the oropharynx from the nasopharynx,

resulting in hypernasality and a lack of intelligibility of the phonetic components.

The severity of the skeletal aspect of the malocclusion and facial asymmetry determines the surgical/orthodontic approach. Mild discrepancies may be camouflaged by the orthodontic dentoalveolar compensation. However, during adolescence the compensation for the skeletal discrepancy may be outgrown; orthognathic surgery is the treatment of choice for patients in their late teens. Because growth prediction is not an exact science, an anterior crossbite corrected in the mixed dentition frequently reestablishes following the pubertal growth spurt and adolescent growth.

The purpose of this chapter is to discuss the surgical and orthodontic correction of the cleft in dysmorphic faces. The focus is on patients with cleft lip and palate who would benefit from bone grafts in the early mixed dentition, and maxillary advancement with contour bone grafting in adolescence when growth of the nasomaxillary complex has stabilized. The successful correction of these secondary skeletal deformities frequently requires treatment protocols that include orthognathic surgery in conjunction with the final phase of orthodontic treatment. Patients with a cleft lip and palate benefit from staged and coordinated procedures to achieve optimal results. These include bone-graft construction of the cleft maxilla and palate in the mixed dentition phase of development, and orthognathic surgery to correct the midface deficiency in adolescence. These procedures are designed to be only stages in the process of reconstruction and rehabilitation.

Timing and Sequencing of Bone Grafting the Cleft Maxilla and Palate

An understanding of craniofacial growth and development is critical in timing both surgical and orthodontic interventions. In bone grafting, dental development is more

important than is the chronologic age of the patient. The decision for determining orthodontic expansion to detect the dental crossbite, as a presurgical phase of orthodontics, depends on the root development of the unerupted canine. If the lateral incisor is developing on the posterior side of the cleft, a bone graft needs to be performed early to allow eruption to the cleft site. Seminal papers defined the age for secondary alveolar bone grafting, which is now a well-accepted procedure after primary lip and palate repair.^{9,10} They divided the timing into early, 2 to 5 years of age; intermediate, 6 to 15 years of age; and late, 16 years to adult. A retrospective interdisciplinary study reported the outcome of bone grafts to the cleft maxilla relative to radiographic and periodontal parameters; as well, it stated that the closure of fistulas and the eruption of the canine through the bone-graft site suggested high success in age-appropriate patients.¹¹ A longitudinal retrospective study provided evidence for the timing and sequencing of the surgical and orthodontic treatment, using cancellous bone harvested from the iliac crest and the stage of development of the unerupted canine, typically between 9 and 11 years of age.¹² Contemporary opinion considers this intermediate time frame to have the greatest benefits and the least risk in compromising midface skeletal and dental growth and development.

Benefits of bone grafting include the following:

- Bone is provided into which the unerupted teeth adjacent to the cleft may erupt or be moved orthodontically. The timing and sequencing of the bone graft is determined by the position of the teeth adjacent to the cleft, their root development, and their stage of eruption, rather than the chronologic age of the patient.
- Supernumerary or malformed teeth may be removed at the time of the surgical placement of the bone graft

into the cleft site. Patent oronasal fistulas either in the palate or the nasolabial vestibule are closed. Fistula closure is achieved by using a three-layered closure technique with the grafted bone sandwiched between the two soft tissue planes.

- The grafted bone provides support and elevation of the alar base in the defect and improves nasal and lip symmetry.
- Because there is continuity of the maxilla, the restorative dentist has the opportunity to provide a more esthetic and hygienic prosthetic replacement, even if teeth are missing. The placement of implants into bone grafts is successful and is a contemporary alternative to a bridge or removable appliance.
- In repaired bilateral clefts of the lip and palate, the placement of bone grafts bilaterally in the cleft sites stabilizes the premaxilla while providing bone into which the adjacent unerupted teeth may erupt.

Through efforts to determine the optimal timing of treatment, several controversies have arisen related to the age of the patient, the type of bone graft, the site from which the graft is harvested, and the optimal timing of orthodontic expansion of the maxilla in relation to the surgical placement of the bone graft.¹²

The surgical technique for bone grafting the cleft maxilla and palate involves a three-layered closure with autogenous cancellous bone graft sandwiched between the nasal floor and the oral mucosa. An incision is made around the cleft to preserve the fixed gingiva to circumscribe the fistula (Figure 61-1). The tissue is then elevated from the bone on both sides of the cleft in the subperiosteal plane to the level of the anterior nasal spine and the lateral piriform rim. The tissue is elevated, inverted, and sutured to form a reconstructed nasal floor (Figure 61-2). Fresh cancellous

bone is then condensed in the cleft defect and over the hypoplastic bone edges of the cleft (Figure 61-3). Oral tissue is either rotated or advanced to close over the bone grafts (Figures 61-4–61-6).

Timing of Midface Advancement Surgery in Adolescents

Biologic and psychosocial concerns govern the decision for the timing of surgical maxillary advancement. It is always prudent to delay surgery of the nasomaxillary complex until growth has stabilized and the peak velocity of somatic growth has passed. This improves the predictability and long-term stability of treatment and reduces the risk that surgical-orthodontic correction will be outgrown. The optimal time for surgical correction of the skeletal discrepancy is when the patient is physically and psychologically prepared. Patients need to appreciate the relevance of facial growth and development and the consequences if surgical correction is

undertaken prior to maturation. Another biologic consideration regarding the timing of surgery is the eruption of the permanent dentition. Delaying surgery until the canine and second molars have erupted minimizes the risk of endodontic requirements and displacement of the second molars. Third molars can usually be removed at the time of maxillary surgery, and their presence should not be a major concern. Patients, parents, and treating doctors participate in the decision regarding when to proceed with surgery; the approach should be patient centered and evidence based with regard to the risks, costs, and benefits. Patient autonomy in the decision should be given the highest priority in orthognathic surgery. This requires that patients be in late adolescence to understand the consequences of the decision and be able to rationalize the expectations for the outcome.

Adolescents are under enormous pressures to conform to their peers. At no other time in life is an individual exposed to concerns about their self-image and physical attractiveness with such additional pressure of peer criticism of appearance differences. Many adolescent patients with clefts are subjected to ridicule about their facial appearance, and

this is accompanied by low self-esteem and impaired socialization. Social withdrawal is another issue resulting from the pressures felt by adolescents, especially those with facial disfigurement. Although counseling can help, the patient must still

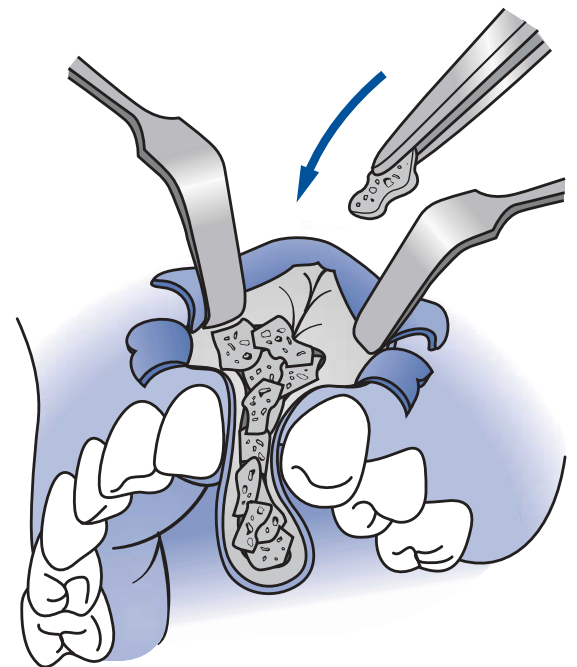

FIGURE 61-3 Cancellous bone particles packed into the defect must extend from the nasal rim to the alveolar crest. Adapted from Turvey TA, Vig KWL, Fonseca RJ. *Surgical management*. cope with the disfigurement; however, this may be improved with surgery.

Improving facial appearance by addressing the skeletal disproportion often

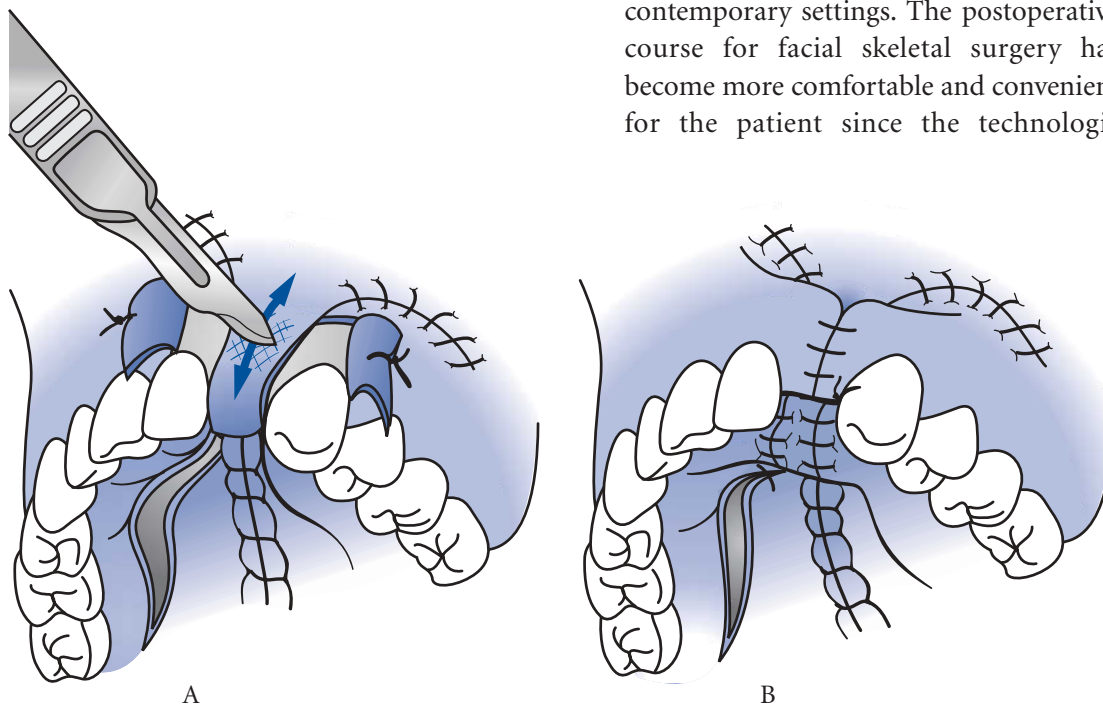

FIGURE 61-5 A, The rotated flap is de-epithelialized in the areas where the fixed flaps will lie. B, The fixed gingiva is then secured to the flap and around the margins of the teeth. results in dramatic and complementary changes. Patients typically perceive these changes positively—the changes send a clear message that someone cares about them and is sensitive to their concerns. An improvement in self-concept and image in patients with a cleft lip and/or palate usually follows surgical correction of the mid-face deficiency and skeletal disproportion. Patients' perception of their quality of life is an important consideration and should not be overlooked in the timing of surgery. However, care should be taken in the psychosocial assessment to identify unrealistic expectations and to recognize those patients who use the stigmas as an excuse for dependency. Identification of these individuals prior to surgery is not easy; interdisciplinary management should include the involvement of a psychologist on the cleft palate team.

The decision to proceed with surgery prior to maturation may result in additional surgery being needed once growth is complete. This need is tempered by the reduced morbidity of repeat surgeries in contemporary settings. The postoperative course for facial skeletal surgery has become more comfortable and convenient for the patient since the technologic

FIGURE 61-6 A sliding buccal gingival flap is elevated from around the teeth and advanced forward, leaving the posterior defect to granulate. advancements of bone plates and screws have essentially replaced the need for intermaxillary fixation. The contemporary use of steroids and antibiotics has controlled swelling and infection, and alternatives to homologous blood transfusion (autologous blood banking and the use of recombinant erythropoietin) are effectively employed. Impatient surgeons or orthodontists should not rationalize early skeletal surgery prior to maturation for their own convenience. Final decisions regarding the timing of surgery should recognize the wishes of patients and parents, and the orthodontists and surgeons should provide the information needed to make an informed decision.

Presurgical Counseling

Patients born with a congenital facial malformation are psychologically different from those patients with acquired dentofacial deformities, who tend to be more prone to neuroticism.¹³ Patients with a cleft have had their problem since birth and have adapted to multiple changes from their previous surgical procedures. Many patients with orofacial clefts have experienced the disappointment of previous

surgical soft tissue revisions that were expected to erase the scar on the lip and correct the nasal asymmetry. However, unrealistic expectations of skeletal surgery should be identified before the surgical intervention, and the patient should be referred for counseling.

Skeletal surgery does not erase the lip scar, but it does provide an opportunity to improve the skeletal support for the soft tissue drape. It can help improve the symmetry of the lip and nasal base and also support the nasal tip. Skeletal support may reduce the stigmas of midface deficiency associated with the cleft defect so that soft tissue revisions may not be needed or desired. The scar commonly falls on a flat unsupported position of the lip and becomes obvious. Often, appropriate skeletal support moves the scar to an area of greater curvature, which reflects light differently and results in a less conspicuous scar. Therefore, patients should be counseled that the skeletal surgery sets the stage for future definitive lip and nasal revisions.

Orthognathic Surgery for the Cleft Patient

In contemporary cleft team settings, most patients with clefts of the maxilla undergo bone grafting at a developmentally appropriate time in the mixed dentition stage. When midface advancement surgery is planned later in adolescence, it is a relatively straightforward procedure. For those patients who have not benefited from previous bone grafts, the situation is more complex. In both circumstances the general principles of flap design for maxillary advancement, ensuring adequate perfusion to the mobilized maxilla, are of paramount importance. A cleft maxilla differs because of the absence of tissues, and multiple surgical procedures are needed to repair and close defects. Perfusion of the mobilized maxilla is dependent on vessels coming from the overlying soft tissues, predominantly the palatal tissues. In cleft patients this tissue is commonly scarred and fibrot-

ic; therefore, care must be exercised when designing the incision to perform the osteotomy. With few exceptions, almost all patients can be treated with a Le Fort I osteotomy via the circumvestibular incision and a down-fracture approach. For those with severe palatal scarring, who have previously undergone an island palatal repair, and those with bilateral clefts of the maxilla, an anterior buccal pedicle should be left on the mobilized maxilla to maintain adequate perfusion. Technically, this is a more challenging operation.

The circumvestibular incision is made from the zygomaticomaxillary buttress to the opposite side, high in the mucobuccal fold (Figure 61-7). Subperiosteal dissection exposes the entire lateral wall of the maxilla from the nose to the pterygoid plate and from the alveolus, above the roots of the teeth, to the inferior orbital rim. The broad exposure permits excellent visualization of all osteotomies. At the time of mobilization, this incision permits the maxilla to be down-fractured and entirely pedicled to the palatal tissues and the remaining buccal tissues below the incision. Good visualization and ease of mobilization are the major advantages of this approach. Hemorrhage control is performed with direct visualization, usually by the ligation of vessels.

When an anterior buccal pedicle remains, the operation is technically more difficult (Figure 61-8). Visualization is reduced, and mobilization by down-fracturing is not possible. Mobilization of the midface is achieved by in-fracturing, combined with anterior traction. For most patients with a cleft palate, the area of greatest resistance to mobilization of the maxilla is the vertical portion of the palatine bone, located in the posteromedial aspect of the maxillary sinus. The bone is thick and access is limited, especially when down-fracturing is not possible. Compounding this is the presence of the greater palatine vessels, which descend from the sphenopalatine fossa to the pos-

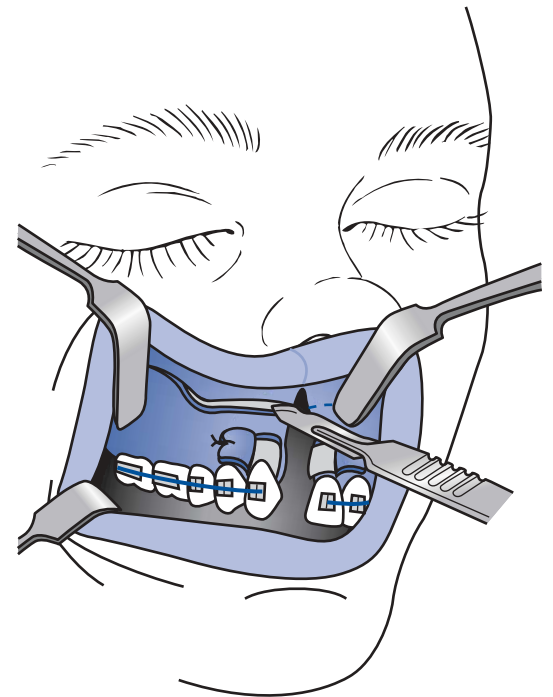

FIGURE 61-7 A circumvestibular incision is used when a Le Fort I down-fracture is performed. The incision is made high on the zygomaticomaxillary buttress to ensure adequate perfusion to the anterior maxilla. Note that the attached gingiva around the teeth on both sides of the cleft is reflected and preserved. The remaining tissue lining the cleft walls is later incised and reflected palatally or buccally, depending on where it is needed for closure (see Figure 61-11B). Adapted from Turvey TA et al.¹⁵

terior maxilla (Figure 61-9). The vessels, which run through the canal in this bone, are prone to rupture during mobilization. Hemorrhage control is limited—packing and the use of a vasoconstrictor (epinephrine 1:100,000) are usually effective.

The surgical technique employed for both of these approaches has been described in detail previously, and interested readers are referred to more detailed sources.¹⁴

Residual oronasal fistulas are common in patients whose maxillas have not been bone grafted previously. An incision design should permit simultaneous closure of oronasal fistulas. Of key importance is the construction of a nasal floor, which is created by using the tissues lining the fistulas (Figures 61-10–61-12).

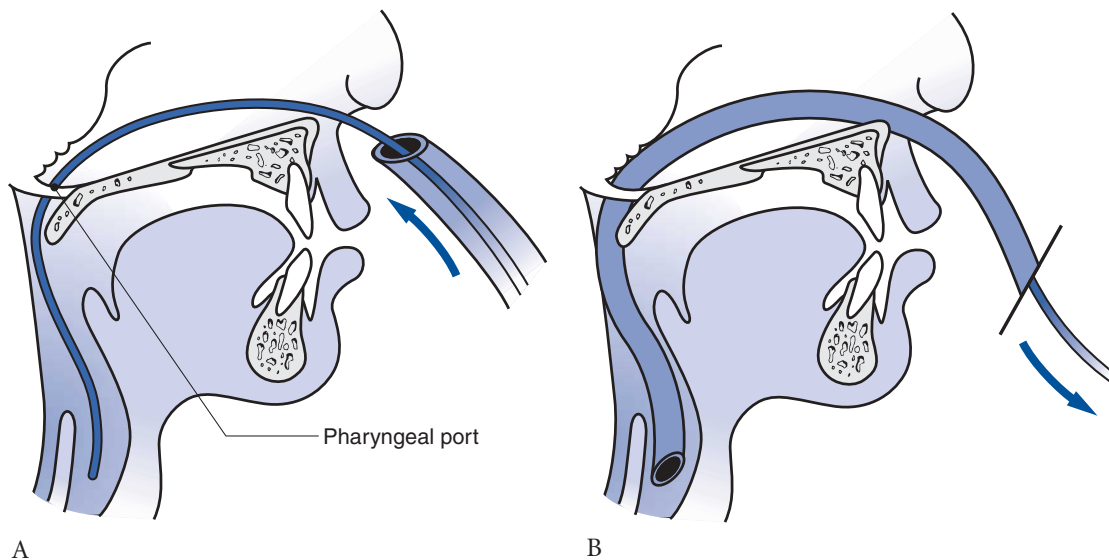

FIGURE 61-8 A and B, A catheter passed nasally through the velopharyngeal ports serves to guide the nasoendotracheal tube past the pharyngeal flap. Adapted from Turvey TA et al.¹⁵

Creativity and care are the important elements in surgery to correct midface deficiency in patients with clefts. Since the skeleton is always asymmetric in cleft patients, it is crucial that the osteotomy is designed for maximum improvement of esthetics (Figure 61-13). If an adequate

improvement cannot be obtained by an osteotomy alone, only bone grafting to enhance skeletal support and shape should be considered. Sometimes even subtle differences between osteotomy designs on the cleft side reflect positive soft tissue changes.

Adequate mobilization is a key factor for success when performing midface osteotomies in the presence of a cleft. The scarring and thickness of bone (particularly in the vertical part of the palatine bone) are two major obstacles. The posteromedial aspect of the maxillary sinus is unusually thick in cleft patients, and it must be cut or fractured to permit adequate mobilization. This is usually accomplished with a small osteotomy tapped along the lateral nasal walls (see Figure 61-9). Failure to weaken these structures prior to mobilization may result in an unfavorable fracture extending to the skull base or orbit. Blindness has been reported following Le Fort I osteotomies in cleft patients, and an inadvertent fracture in this area is the suspected cause.¹⁵ If excessive forces are required to mobilize the maxilla, repeated use of the osteotomy to further weaken the structure is advisable prior to beginning mobilization.

It is often tempting to segment the maxilla of patients with a cleft to improve

occlusal relationships. However, segmenting the maxilla in this population should be undertaken with caution, considering the compromised vascularity and scarring of the tissues. Accepting posterior cross-bites and other occlusal compromises may be judicious, rather than risking necrosis of a segmental osteotomy. A contemporary goal of cleft care is to eliminate and/or reduce the need for prosthetic management. Closing dental spaces with segmental osteotomies is an effective way to achieve this goal. Additionally, this maneuver results in more soft tissue availability to create an intact nasal lining. Although opening the space with segmental osteotomies is possible, it requires bone grafts and a rotation of soft tissues to close the defects. Except in extreme salvage circumstances, dental space opening should be avoided (Figures 61-14 and 61-15).

Bone Grafting with Maxillary Advancement

There are three important reasons to use bone grafts in patients with a cleft when performing midface advancement. First,

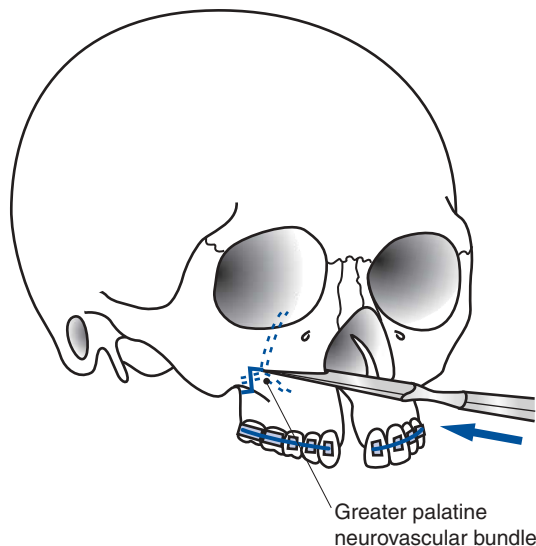

FIGURE 61-9 A small osteotome is tapped through the lateral nasal wall posteriorly toward the perpendicular part of the palatal bone. At this point the resistance increases because this part of the lateral nasal wall thickens. The greater palatine neurovascular bundle descends through this region and is at risk. Adapted from Turvey TA et al.¹⁵

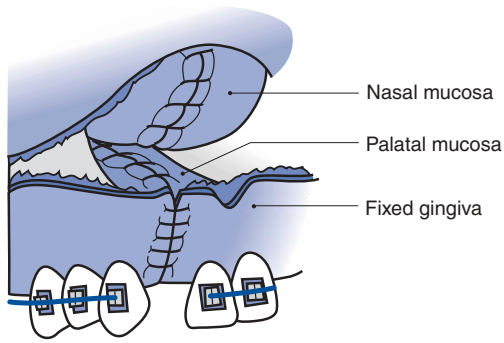

FIGURE 61-10 The mucosa lining the cleft alveolar region is elevated from the nasal side and pushed orally, where it is sutured on both the palatal and buccal sides. The bone edges of the cleft must be adequately exposed for successful reconstruction. The nasal mucosa is also closed primarily. Adapted from Turvey TA et al.¹⁵

A

B

FIGURE 61-11 A, Buccal view demonstrating the tissues lining the cleft elevated, pushed orally, and sutured on the oral side. B, Deeper view into the cleft demonstrating the closure of the oral and nasal tissues and the pocket for the bone graft. Adapted from Turvey TA et al.¹⁵

the bone graft can be wedged into the defects in the lateral maxillary walls; this helps to maintain the position of the maxilla during healing. Second, the bone graft also encourages bone healing and reduces the risks of fibrous union. The third reason to use bone grafts in midface advancement is to contour the middle face. In patients with a cleft, the midface is not just retruded, it is also malformed. Thus, altering the skeletal morphology is important for esthetic enhancement. Augmentation of the cheek projection, infraorbital regions, paranasal regions, nasal bridge, or chin is commonly employed at the time of midface advancement. These maneuvers are helpful and easily performed at the time of surgery, and their importance should not be underestimated.

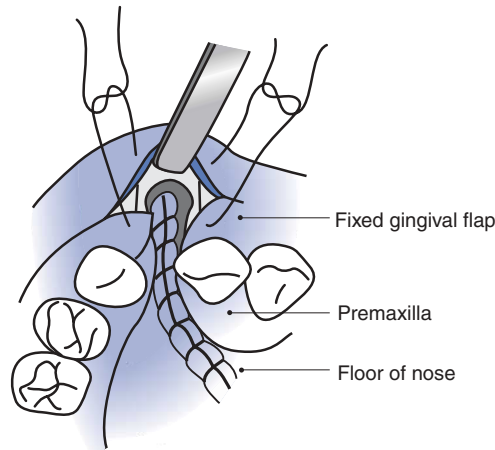

FIGURE 61-12 The nasal floor is constructed with tissues lining the cleft that are mobilized superiorly and sutured. Adapted from Turvey TA et al.¹⁵

The choice of bone-graft material for use in cleft surgery is always fresh autogenous bone. Cancellous bone or cortico-cancellous blocks are generally reserved for filling defects in the alveolus or lateral

maxillary walls. The authors' preference for bone grafts to contour the middle face is split-thickness calvaria. For the chin a pedicled bone graft from the inferior border of the mandible is always employed.

Bone Grafting of the Cleft Maxilla and Palate

Cancellous grafts can generally be condensed into cleft defects and are self-retained. Block grafts or onlay grafts should always be secured with a screw to promote healing, reduce resorption, and the risk of infection.

There are multiple bone donor sources, including the ilium, cranium, tibia, mandible, and ribs. Although harvesting bone requires more surgical time and has associated morbidity, the predictability of the result easily justifies its use. There is no autogenous bone substitute that has the same success in patients with a cleft as does fresh autogenous bone. The morbidity of

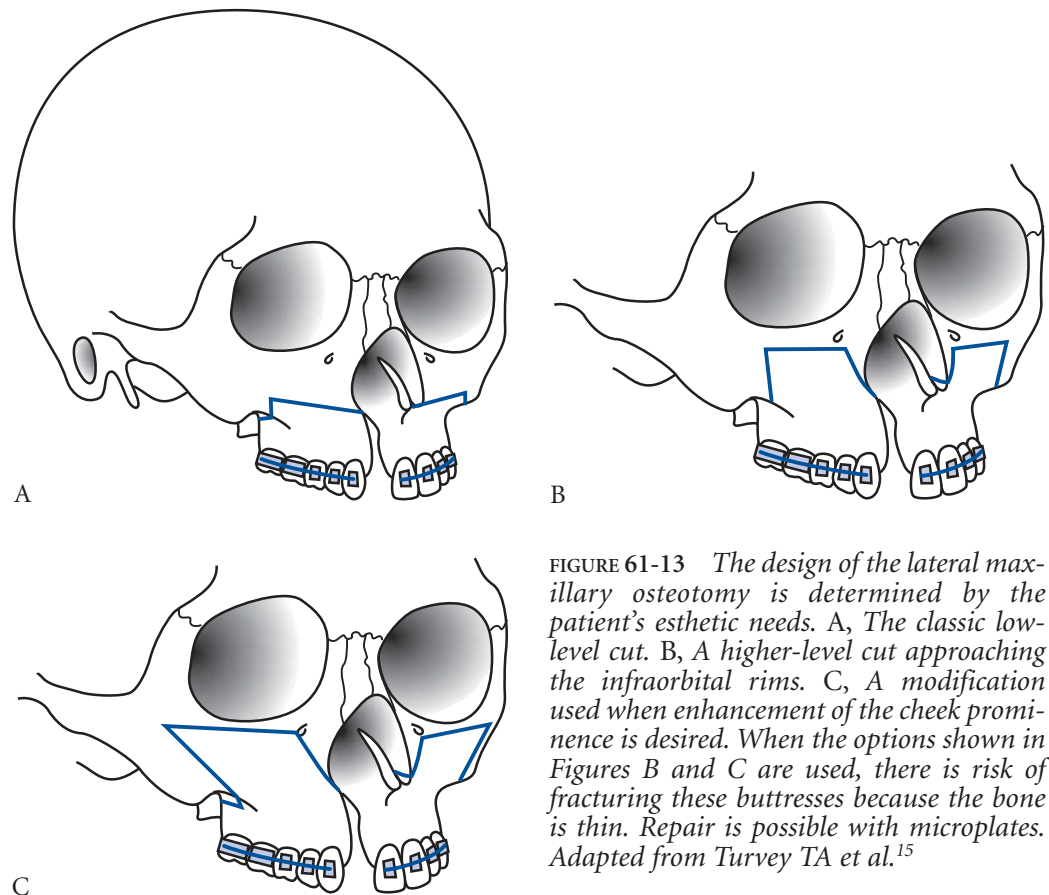

FIGURE 61-13 The design of the lateral maxillary osteotomy is determined by the patient's esthetic needs. A, The classic low-level cut. B, A higher-level cut approaching the infraorbital rims. C, A modification used when enhancement of the cheek prominence is desired. When the options shown in Figures B and C are used, there is risk of fracturing these buttresses because the bone is thin. Repair is possible with microplates. Adapted from Turvey TA et al.¹⁵

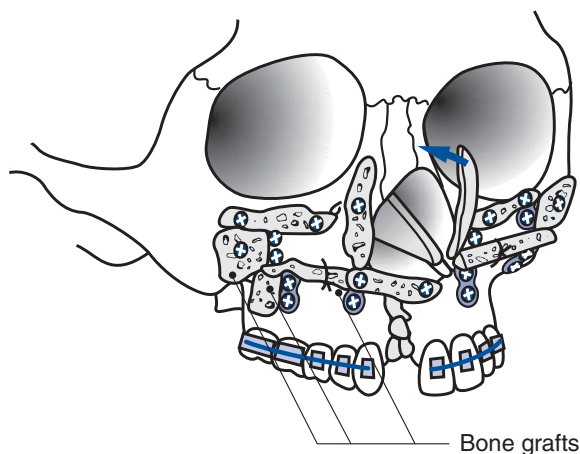

FIGURE 61-14 Onlay bone grafts are positioned and secured with screws. Wires are occasionally necessary to prevent displacement of the inlaid bone grafts into the sinus. Adapted from Turvey TA et al.¹⁵

bone harvest can be reduced with a good surgical technique and should not be an excuse for using bone alternatives.

Stabilizing the Operated Maxilla

The development of more rigid fixation devices permits improvement of results of

cleft skeletal surgery. Originally, stainless steel plates and screws and, later, titanium systems were used instead of the traditional stainless steel wires to secure the position of the maxilla. The many benefits of using more rigid fixation include a reduced time for intermaxillary fixation and better assurance of the position of the midface during healing. A single disadvantage of the use of metallic bone plates and screws is a reduced ability to manipulate tooth-bearing segments with elastic traction during the postoperative period to correct the occlusal result.

Velopharyngeal Considerations

One of the complexities of the cleft malformation involves the function of the velopharyngeal sphincter. Under normal circumstances, sealing the nasal cavity from the oral cavity occurs by a simultaneous elevation of the soft palate and contraction of the lateral pharyngeal walls to produce closure of the nasopharynx from the oral cavity. In many patients with a

repaired cleft palate, the velopharyngeal mechanism is fragile and the patient has learned to overcome a short or scarred immobile palate by compensating and recruiting adjacent structures. Passavant's bar (a hypertrophy of tissue in the posterior pharyngeal wall) is a result of a compensatory effort that many patients with a cleft develop to overcome the deficit and inadequacy of velar movement.

Forward displacement of the maxilla in patients without a cleft is well tolerated, and these patients have adequate compensatory reserve to overcome the change in position of soft palate. A minority of patients with a cleft are not able to tolerate even small degrees of maxillary displacement, and the velopharyngeal function may deteriorate, affecting the patient's speech and communication ability.¹⁶ This potential risk should be evaluated before maxillary-advancement surgery, and patients should be appropriately counseled. In patients with a cleft, the occurrence of velopharyngeal inadequacy following midface advancement is infrequent and additional surgical procedures are usually unnecessary. Almost all patients with a cleft experience hypernasality immediately following surgery. Fortunately, this gradually resolves with time, and most patients return to their baseline speech by 6 months after surgery. It is prudent to delay subsequent surgery to reduce nasality for at least 6 months following maxillary advancement. This allows natural compensation to occur and permits bone healing to proceed without introducing more scarring, which may contribute to relapse.¹⁷

An interesting observation in some patients with pharyngeal flaps who do not have velopharyngeal adequacy prior to midface advancement is an improvement of nasal speech after surgery. Although sibilant distortions secondary to malocclusion are expected to improve, reduction of hypernasality after maxillary advancement is paradoxical. The explanation of this occurrence is the altered dynamics of the sphincter that result after

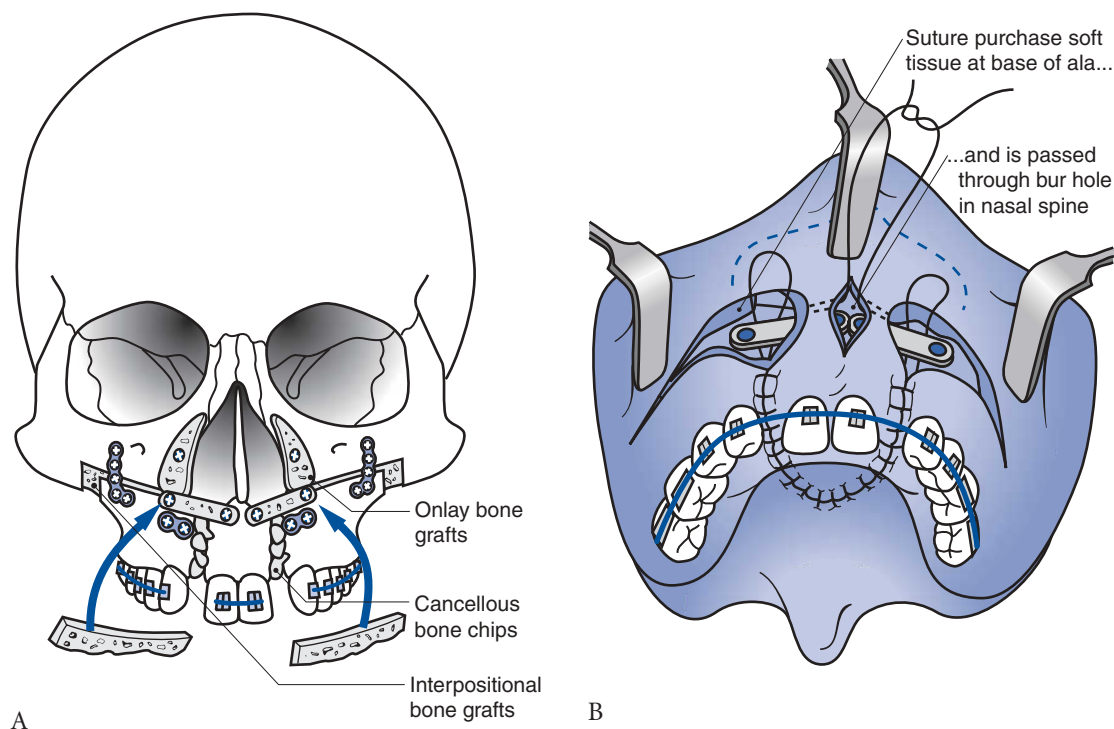

FIGURE 61-15 A and B, The premaxilla is secured with bone grafts, which are used to construct the inferior piriform rim. These grafts are tunneled under the buccal flaps and screwed to the nasal spine anteriorly and to the lateral maxilla posteriorly. Adapted from Turvey TA et al.¹⁵

surgery. Apparently, stretching the flap and its positional change improve the dynamics of the velopharyngeal mechanism so that improved speech occurs in some patients. This observation is not predictable, and patients must be cautioned appropriately.

When a pharyngeal flap is in place and maxillary advancement is undertaken, the flap should be removed only if it does not permit adequate mobilization of the maxilla. When the flap is in place, nasal intubation can be difficult; the anesthesiologist must be prepared to use endoscopic assistance with endotracheal tube insertion (see Figure 61-8).

Distraction Osteogenesis

Suzanne U. Stucki-McCormick, MS, DDS

Distraction osteogenesis (DO), a useful technique to generate bone and soft tissue, can be applied to craniofacial reconstruction, including orthognathic surgery, cleft lip and palate reconstruction, a new mandibular condyle regeneration, a dentoalveolar unit reconstruction for dental implants and transport DO for discontinuity defects.

Regardless of the surgical site, adherence to the following basic Ilizarov principles is the key to surgical success¹:

1. Osteotomy of the bone site with minimal periosteal stripping
2. Latency period: 3, 5, or 7 days, depending on the surgical site
3. Distraction rate: 1.0 mm per day (0.5–2.0 mm)
4. Distraction rhythm: continuous force application is best, yet device activation bid is more practical and allows for better patient compliance
5. Consolidation: until a cortical outline can be seen radiographically across the distraction gap, usually 6 weeks

The distraction technique involves creating an osteotomy in an area adjacent to an area of bone deficiency. Applying slow tension forces separates the bony edges, which creates a regenerate chamber from which the new bone and soft tissues are formed (Figure 62-1). This regenerate chamber may be large and wide, with abundant blood supply from the overlying

muscle and skin, as in mandibular distraction. Conversely, the distraction gap may be small, with thin mucosal coverage, as in dentoalveolar distraction for dental implants. The local periosteal blood supply and the size of the distraction segment influence the treatment plan decisions; in fact, for small bone segment distraction, the rate of distraction may need to decrease to 0.5 to 0.7 mm per day. However, for sagittal distraction of the mandible whereby the bone segments overlap, the distraction rate should increase to 2.0 mm per day. I recommend modifying the Ilizarov principles in each individual, based on the size of the distraction bone segment and the regional blood supply (Table 62-1).

Initially, the regenerate chamber is filled with a fibrous matrix that ossifies from the periphery centrally.² The distraction gap shape and the resultant new DO bone are influenced by the vector of distraction and the rate of distraction. Altering the vector of distraction during active DO will correspondingly alter the three-dimensional shape of the regenerate chamber and the resultant new DO bone (Figure 62-2). If the distraction rate is too rapid, then the regenerate chamber will be hourglass shaped, and the new DO bone will be thinned centrally.

The osteotomy location can affect the shape of the regenerate chamber and the final new bone. If the osteotomy is created in an area of thin bone stock, then the

FIGURE 62-1 During the distraction process the bony edges of the osteotomy (A) are separated slowly over time to create an initial radiolucent regenerate chamber (B), which has the size and shape of the native bone.

regenerate chamber will thin and assume the shape of the native bone. In treatment planning and during surgery, it may be necessary to adjust the osteotomy site, placing the bone cut in an area of maximum bone thickness to create a large and robust regenerate chamber (Figure 62-3).

Until the distraction gap ossifies completely, the regenerate chamber is influenced by the local muscle pull. As distraction proceeds, the regenerate chamber becomes enlarged and is filled initially with a weak fibrous matrix. Simultaneously, the local muscles that are attached to the DO site are stretched. The stretched

Table 62-1 Distraction Protocol

Distraction	Latency (d)	Rate (total) (mm/d)	Rhythm
Mandible	5	1.0	bid
Maxilla	5	1.0	bid
Alveolus/implant	5–7	0.5–0.7–1.0	bid
Transport	5–7	1.0	bid
Condyle: transport	5–7	1.0	tid, qid
Mandible: children	3–5	1.0–2.0	bid
Mandible: sagittal	5–7	2.0	bid
Transport: neck dissection	7–10	0.5–1.0	bid
Transport: XRT	7–10	0.5	bid

bid = twice a day; qid = four times a day; tid = three times a day; XRT = external beam radiation therapy.

muscles tend to return to their original sarcomeric length, pulling on the regenerate chamber and on the intervening immature bone matrix, causing an alteration of the vector of DO and displacement of the distraction segment in the direction of the muscle (Figure 62-4). This effect is most noticeable by the action of the temporalis and the mylohyoid musculature. Vector control maneuvers, including the use of surgical guides, orthodontic appliances, and interim partial dentures with a portal for DO device access, help to maintain and adjust the vector of distraction.³

Clinicians may use the fibrous matrix nature of the regenerate chamber to their

advantage to mold the regenerate into the proper orientation and location, including distraction of a segment outside the normal anatomic periosteal plane. Specifically, clinicians may mold the regenerate at any time in the distraction process—during active DO and at the end of DO.

During active distraction, the regenerate is molded by altering the vector of the distractor. Some DO devices have mechanical hinges that allow the clinician to adjust

the vector of distraction. This is done easily in an office setting, often using local anesthesia, if necessary. If performing a significant (≥ 3 mm) molding move or vector change, then I recommend that a short (1 to 3 days) latency is observed prior to commencing with the distraction protocol. This allows for healing of the disrupted microvasculature and osteoid matrix within the regenerate chamber that the vector change produced. A longer latency (2 to 4 days) is recommended if the bone segment is small, as in dentoalveolar distraction for dental implants.

Perform regenerate molding at the end of active distraction to help guide the end of active distraction to help guide the bone segment into its final position.⁴ After only 3 weeks of consolidation, remove the distractor prematurely, and reposition the segment to its final position. Use traction orthodontic elastics to guide the segment to its final position and to hold the segment in this position until final ossification occurs. At the time of device removal, however, the segment may be repositioned

FIGURE 62-2 Initially the distraction vector is linear (A). Once 5 mm of regenerate chamber has been created, the distractor can be adjusted, altering the vector of distraction, which correspondingly alters the three-dimensional shape of the new bone (B).

FIGURE 62-3 For transport distraction to create a new mandible (A, B), the osteotomy should be placed in an area of maximal bone stock (C, D) to create a robust regenerate chamber.

FIGURE 62-4 During the final stages of distraction osteogenesis, the weak regenerate chamber is under the influence of local muscle pull. A, Here the mylohyoid created an open bite, which was counteracted by orthodontic elastics. B, Using callous manipulation with orthodontic elastics, the open bite was closed.

manually and held in place with rigid fixation plates and screws.

Perform “dancing” of the distraction segment if a discrepancy occurs in planned distraction amounts, such as bilateral mandibular advancement for asymmetries.⁵ Initially, both segments are advanced at the planned distraction rate.

When the larger, less asymmetric side reaches its final position, the segment becomes the dancing side, advancing the DO segment in the morning then turning it back the same amount in the evening. In the meantime, the lesser more asymmetric segment continues to be advanced at the planned rate until it catches up with the contralateral side. Carry out any final adjustments to the mandibular positioning when the asymmetry has been corrected by advancing or dancing the two sides as needed (Figure 62-5).

As with orthognathic surgery, treatment planning for distraction osteogenesis includes predicting the amount and trajectory of the planned bone movement. Although the DO device may be activated 1.0 mm per day, this does not translate to 1.0 mm of bone advancement per day. The amount of actual bone movement is always less than the distance that is indicated on the distraction device, therefore the clinician monitors the patient’s progress closely, including radiographs.

The surgical approach and technique are similar to orthognathic surgery. When locating and positioning the bone cut, also consider the placement and orientation of the distraction device. Mark the planned osteotomy. Then, create a corticotomy, verifying the ability to place the distractor in the proper orientation. Make the screw fixation holes for the distraction device, and remove the device. The corticotomy is then converted atraumatically to an osteotomy, and the distraction device is fixated into place. The device is activated to ensure impedance-free advancement of the distraction segments.⁶ Remove any bony interferences, and return the device to its closed neutral position. Prior to initial device orientation and placement, activate the distractor 1.0 to 2.0 mm. Thus, after the osteotomy and the device are secured into place, the DO device can be “closed” 1.0 to 2.0 mm, reducing and minimizing the initial distraction gap created by the bone cut.

Mandibular Distraction

For patients with craniofacial microsomia, mandibular distraction of the affected side is a useful technique for generating both bone and soft tissue. The surgical approach is similar to a sagittal osteotomy. Create a bone cut in the ramus of the mandible on the affected side above the lingua along the ramus to the posterior border of the mandible above the gonial angle. Position the distractor, and convert the corticotomy to an osteotomy, after which the distraction device is secured. Intraoral distractors are preferred to external devices to decrease scarring. Compared with a completely submerged device, DO devices in which the distraction mechanism is intraoral yet extramucosal allow the clinician to monitor the distractor directly without the need for radiographs. In addition, removal of the device is facilitated if the distraction mechanism is extramucosal. The vector of distraction is calculated based on the trajectory of the bone segment and on the local anatomy, including bone stock, tooth buds and/or roots, and position of the inferior alveolar nerve. Achieve chin point correction by vertical distraction of the ramus (Figure 62-6).⁷

FIGURE 62-5 To correct asymmetry the devices are initially distracted by the same amount (A), then using “disk dancing,” the regenerate chamber can be advanced or returned to bring the segment into proper position (B).

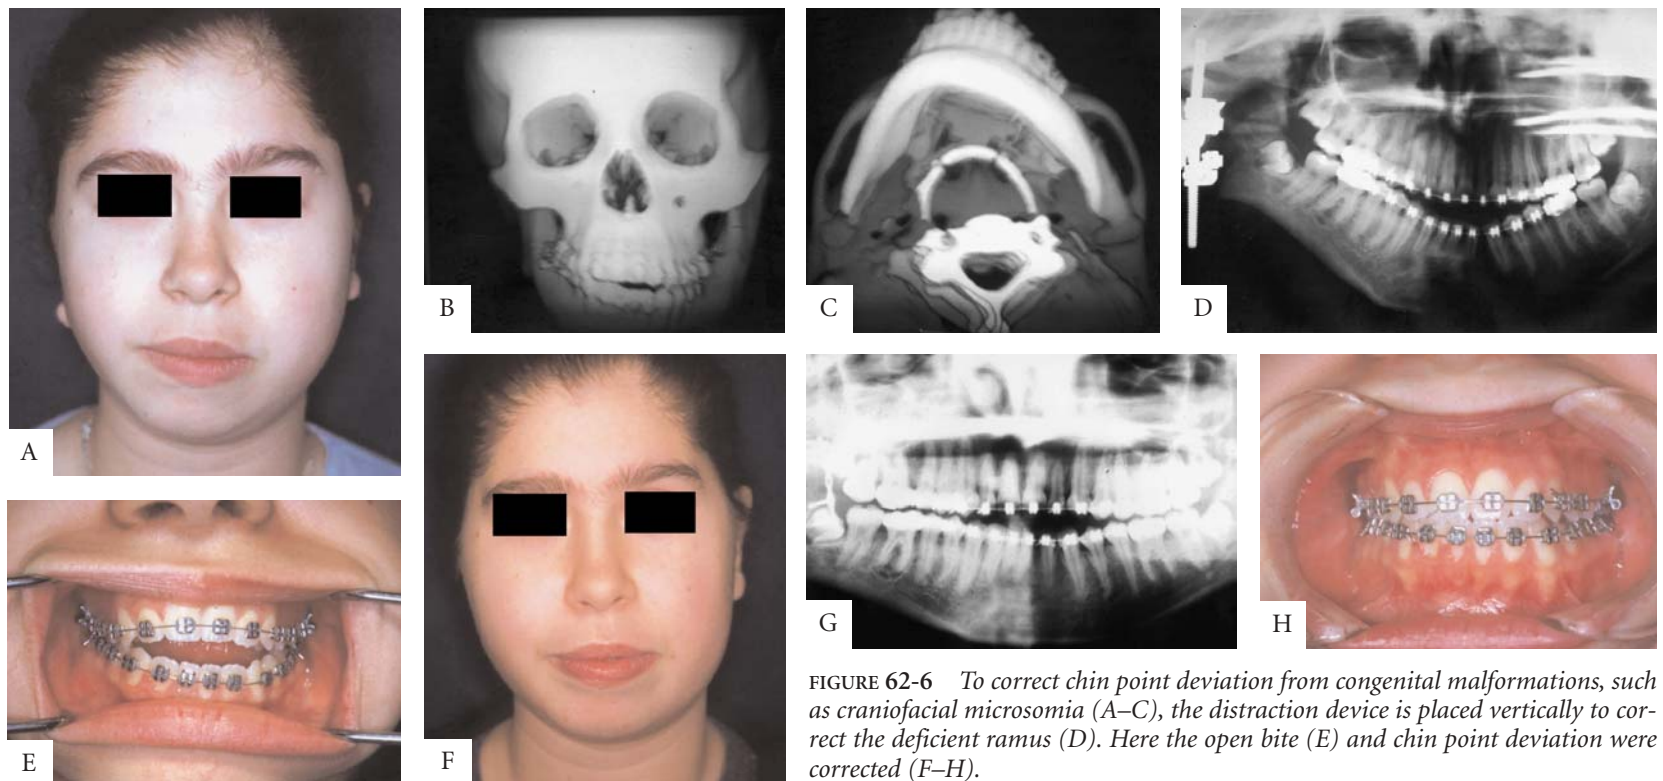

FIGURE 62-6 To correct chin point deviation from congenital malformations, such as craniofacial microsomia (A–C), the distraction device is placed vertically to correct the deficient ramus (D). Here the open bite (E) and chin point deviation were corrected (F–H).

The distraction process continues 1.0 mm per day until the mandibular asymmetry is corrected. I recommend age-dependant overcorrection to compensate for the decreased growth potential of the genetically affected side.⁸ Remove the distractor when a cortical outline can be seen radiographically (Figure 62-7). Perform mandibular distraction for all Pruzansky-Mulliken classifications of craniofacial microsomia (Figure 62-8).⁹

Mandibular distraction plays a unique role for infants with airway compromise, as a consequence of micrognathia.^{10,11} Early distraction of the body of the mandible bilaterally has shown promise for improving airway volume and in decreasing airway resistance, leading to early decannulation or avoidance of a tracheotomy.^{12,13}

For large mandibular advancements or for patients with a history of temporomandibular joint disorders, DO is a useful treatment alternative. Use a modification of the classic sagittal split technique for such cases.⁵ As the proximal and distal segments overlap, the distraction rate is increased to

2.0 mm per day (0.5 mm qid [4 times a day]). Further, create a groove in the superior aspect of the horizontal bone cut above the lingual to allow for impedance-free rotation of the proximal segment during DO (Figure 62-9). Ideally, the distractors are placed parallel to the midsagittal plane of the mandible, although this is not always achieved.^{14,15} Class II orthodontic elastics are placed to “unload” the temporomandibular joint. At the time of surgery, place a maxillary occlusal surgical guide that extends to one-half of the occlusal surface of the maxillary second molar, with the final occlusion indexed. As distraction proceeds, guide the mandible into the proper occlusion using light elastics. Sagittal distraction of the mandible appears to provide condylar axis stability and has minimal deleterious effects on the temporomandibular joint.⁵

Mandibular Widening

DO, a useful tool to create space for severe mandibular crowding, is often combined with maxillary transverse widening and surgically assisted palatal

expansion (Figure 62-10).¹⁶ For the mandible, make a vestibular incision similar to a genioplasty, approach the mandible, and score the planned osteotomy site. Create the osteotomy in the corpus of the mandible with a bur or a saw. Perform the interdental osteotomy with fine chisels in a tunneling technique, reducing the periosteal stripping, being careful to avoid encroaching on or injuring the periodontal ligament of the teeth in the osteotomy line. The tissue type in the osteotomy site is the template for DO. Consequently, if the osteotomy is positioned completely in the bone, bone will be created. If the osteotomy encroaches on periodontal ligament tissues, the distraction gap fills with bone and moderate amounts of periodontal ligament-like tissues, leading to a pseudo-union.¹⁷ For the central incisors that are extremely crowded, carry out the interdental osteotomy laterally between less crowded teeth; namely, the lateral incisor and the cuspid. Create a horizontal step 5 mm below the roots of the incisor teeth, and make the main osteotomy of corpus of mental region vertically in the midline.

FIGURE 62-7 The distractor is advanced until the deformity is corrected (A–C). Initially, osteotomy (D) produces a radiolucent regenerate chamber (A) that ossifies with time (E), at which point the distractor is removed (F).

The distractor of choice is placed. Most distractors are tooth and bone borne. Distractors that are solely bone borne tend to produce a V-shaped regenerate chamber, with more widening at the level of the alveolus and less widening at the level of the inferior border.

After a 5- to 7-day latency, distraction proceeds at 1.0 mm per day. Be sure to apply slow incremental distraction forces; DO forces generated during mandibular widening may translate to the mandibular condyle.¹⁸ Minimal in nature, these forces cause mild adaptive bony changes that are well tolerated. Nevertheless, monitor patients closely for any complaints of preauricular pain or limitation of motion, which would indicate altering the 1.0 mm per day DO protocol from

0.5 mm twice daily to 0.25 mm four times daily device activation.

After DO, the surgeon may place a plastic pontic tooth in the gap between the central incisors to stabilize the teeth and to prevent their central migration.¹⁹ To prevent migration of the teeth into the DO gap, include these teeth in the orthodontic arc wire, with the possible placement of a light spring. Remove the distractor once a cortical outline can be seen on the radiograph. Place a lingual arch to help stabilize the new transverse dimension.

Simultaneous Maxillary and Mandibular Distraction

Patients who have craniofacial microsomia often have maxillary hypoplasia and a concomitant occlusal cant toward the

affected side. Using mandibular DO during the primary or mixed dentition phase often autocorrects the maxillary occlusal cant (Figure 62-11). If the maxillary molar teeth are present in full occlusion or if the patient is in permanent dentition, then a concomitant maxillary distraction, along with the mandibular distraction, may be indicated.^{20,21} The surgeon performs a corticotomy at the Le Fort I level, including pterygoid disjunction, taking care to avoid the unerupted tooth buds or roots during the bone cut. The maxilla is loosened but not down-fractured. Orthodontic elastics (8 oz) are then applied bilaterally, with increased elastic traction on the affected side to guide the maxilla to its proper orientation during the DO process (Figure 62-12). Elastic traction that results in max-

FIGURE 62-8 This patient with grade III craniofacial microsomia (A–C) successfully underwent ramal distraction (D–F) to correct his deformity (G, H).

illomandibular fixation (MMF) is not required to guide the maxilla along with the mandible during DO.²²

Maxillary Distraction

Likewise, use DO for maxillary advancement. This technique is especially useful for patients with large advancements or in patients postpalatoplasty for cleft lip and palate whose scarring causes inadequate tissue or difficulty in moving the maxilla.^{23,24} The surgical approach is sim-

ilar to conventional orthognathic surgery, with the osteotomy at the Le Fort I level. The maxilla is freed but not completely down-fractured. If the maxilla is inadvertently completely down-fractured, then loosely place a suspension suture (2-0 polydioxanone suture) in the bone across the bone gap at the level of the first molar tooth and the zygomatic buttress to help stabilize and prevent inferior tipping of the posterior maxilla. The distractors are pre-bent to

facilitate device placement. The zygomatic buttress region is a good point for device fixation. Ideal trajectory would locate the two distractors that are parallel to each other and the midsagittal plane. Achieving this congruity is much more difficult in the maxilla owing to local anatomy, device design, and location of the osteotomy, limiting device placement and orientation. Ensure that the resultant moment arm of the two distractors will not cancel each other as the distractors

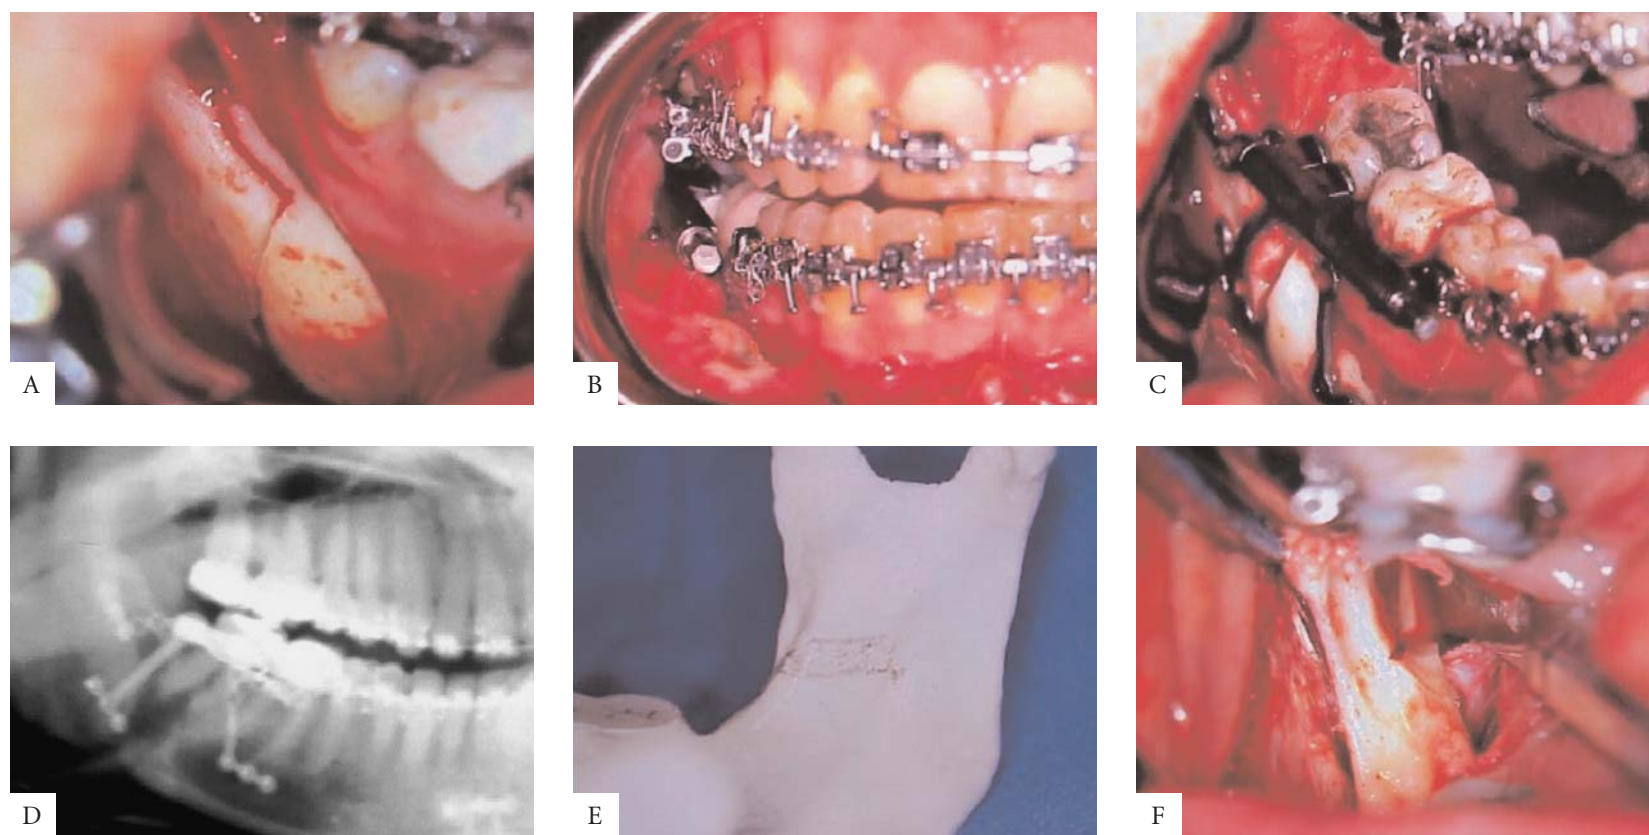

FIGURE 62-9 A–D, Classic sagittal split osteotomy technique can be modified to allow for mandibular advancement. E, F, The horizontal bone cut is modified to allow for impedance-free advancement during distraction osteogenesis. (Courtesy of Dr. J.J. Moses.)

FIGURE 62-10 A, B, Patients with narrow arch forms and dental crowding are aided using mandibular widening as well as surgically assisted maxillary expansion. C, D, Bone-borne devices can be placed into the vestibule. E, F, The resultant increase in transverse dimension can be stabilized with a lingual orthodontic appliance.

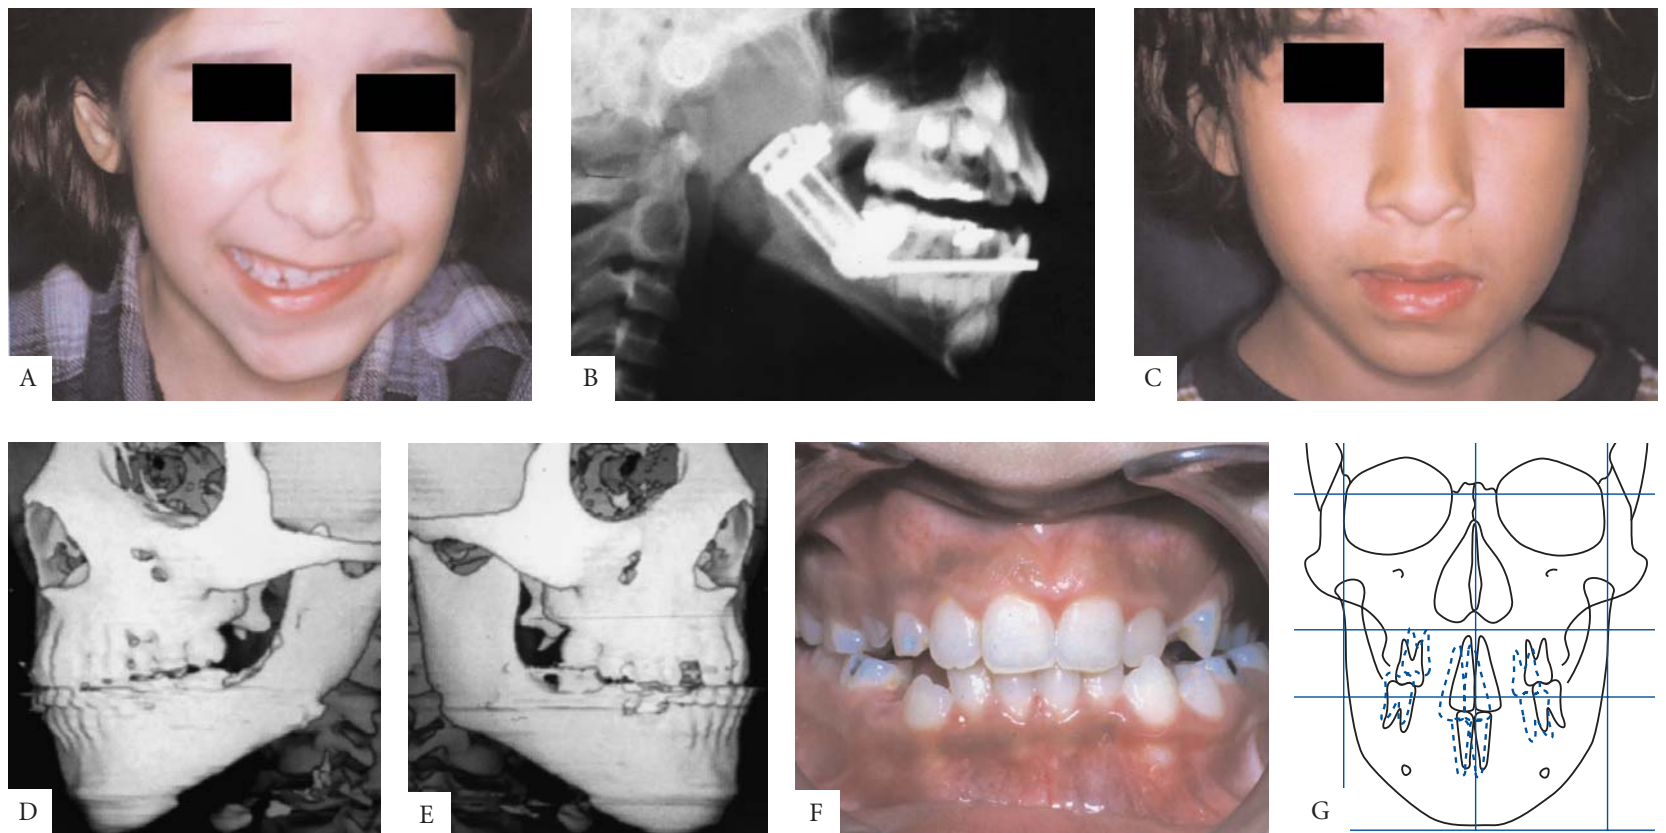

FIGURE 62-11 This patient in mixed dentition with significant occlusal cant (A) underwent mandibular distraction using a submerged device (B) to correct the deformity (C). The neomandible (D) mimics the native mandible (E) in size and form. The mandible was overcorrected with the dental midline distracted one-half tooth toward the contralateral side (F). The maxillary occlusal cant was autocorrected as the mandible was placed in the proper position and with the eruption of the permanent teeth (G).

reach their maximal length. Use anterior traction elastics to guide the maxilla to its proper position. Put an intravenous tubing that is cut to size over the two ends of the distraction device activation rods to prevent lip ulcers (Figure 62-13).

Expanding the soft tissue envelope is often the rate-limiting step in large maxillary advancements. In these patients (> 8 to 10 mm advancement) or for those who have palatal scarring, the use of an external halo frame is indicated. Although a bit cumbersome and unsightly, the external frame can produce significant and dramatic maxillary advancements (Figure 62-14). The surgery is similar to conventional orthognathic surgery. Perform a high Le Fort or stepped osteotomy, if indicated. Secure the device below the height of contour of the skull; otherwise, the halo may dislodge vertically.

Active DO requires careful observation, as the center of rotation of the maxilla is at the level of the roots of the maxillary first molar.²⁵ Left unchecked, the maxilla will be distracted anteriorly and superiorly, creating an open-bite malocclusion. Using the external halo frame, adjust the arms vertically to allow the maxilla to advance in a downward and forward vector. Similarly, to allow for correction of a maxillary asymmetry, the arms of the halo device can be differentially activated (ie, 0.5 mm on one side and 1.0 mm per day on the other (see Figure 62-14). Once the ossification of the distraction site is complete (ie, until the maxilla is stable to palpation, usually in 5 to 6 weeks or when radiographic evidence of a cortical outline is seen), the halo device is removed in the office without the need for rigid fixation of the maxilla. Occasionally, prior to complete ossification of the site, the patient

may request to have the halo removed. The device is removed with concomitant placement of rigid fixation plates.

Maxillary Segmental Distraction

In patients who have a wide alveolar cleft, perform a segmental osteotomy in the lesser segment, advancing it via distraction to close the alveolar defect.²⁶ The bone cut is usually located between the bicuspid and the molar teeth of the lesser segment (Figure 62-15). In the same way, place the bone cut in the greater segment between the incisor and the cuspid teeth to distract the gap closed from either one or two directions. Use of orthodontic appliances and the arch wire allows the distraction segment to follow the curvature of the maxillary arch. During post-distraction, place an orthodontic spring on the arch wire, paralleling the regenerate chamber to

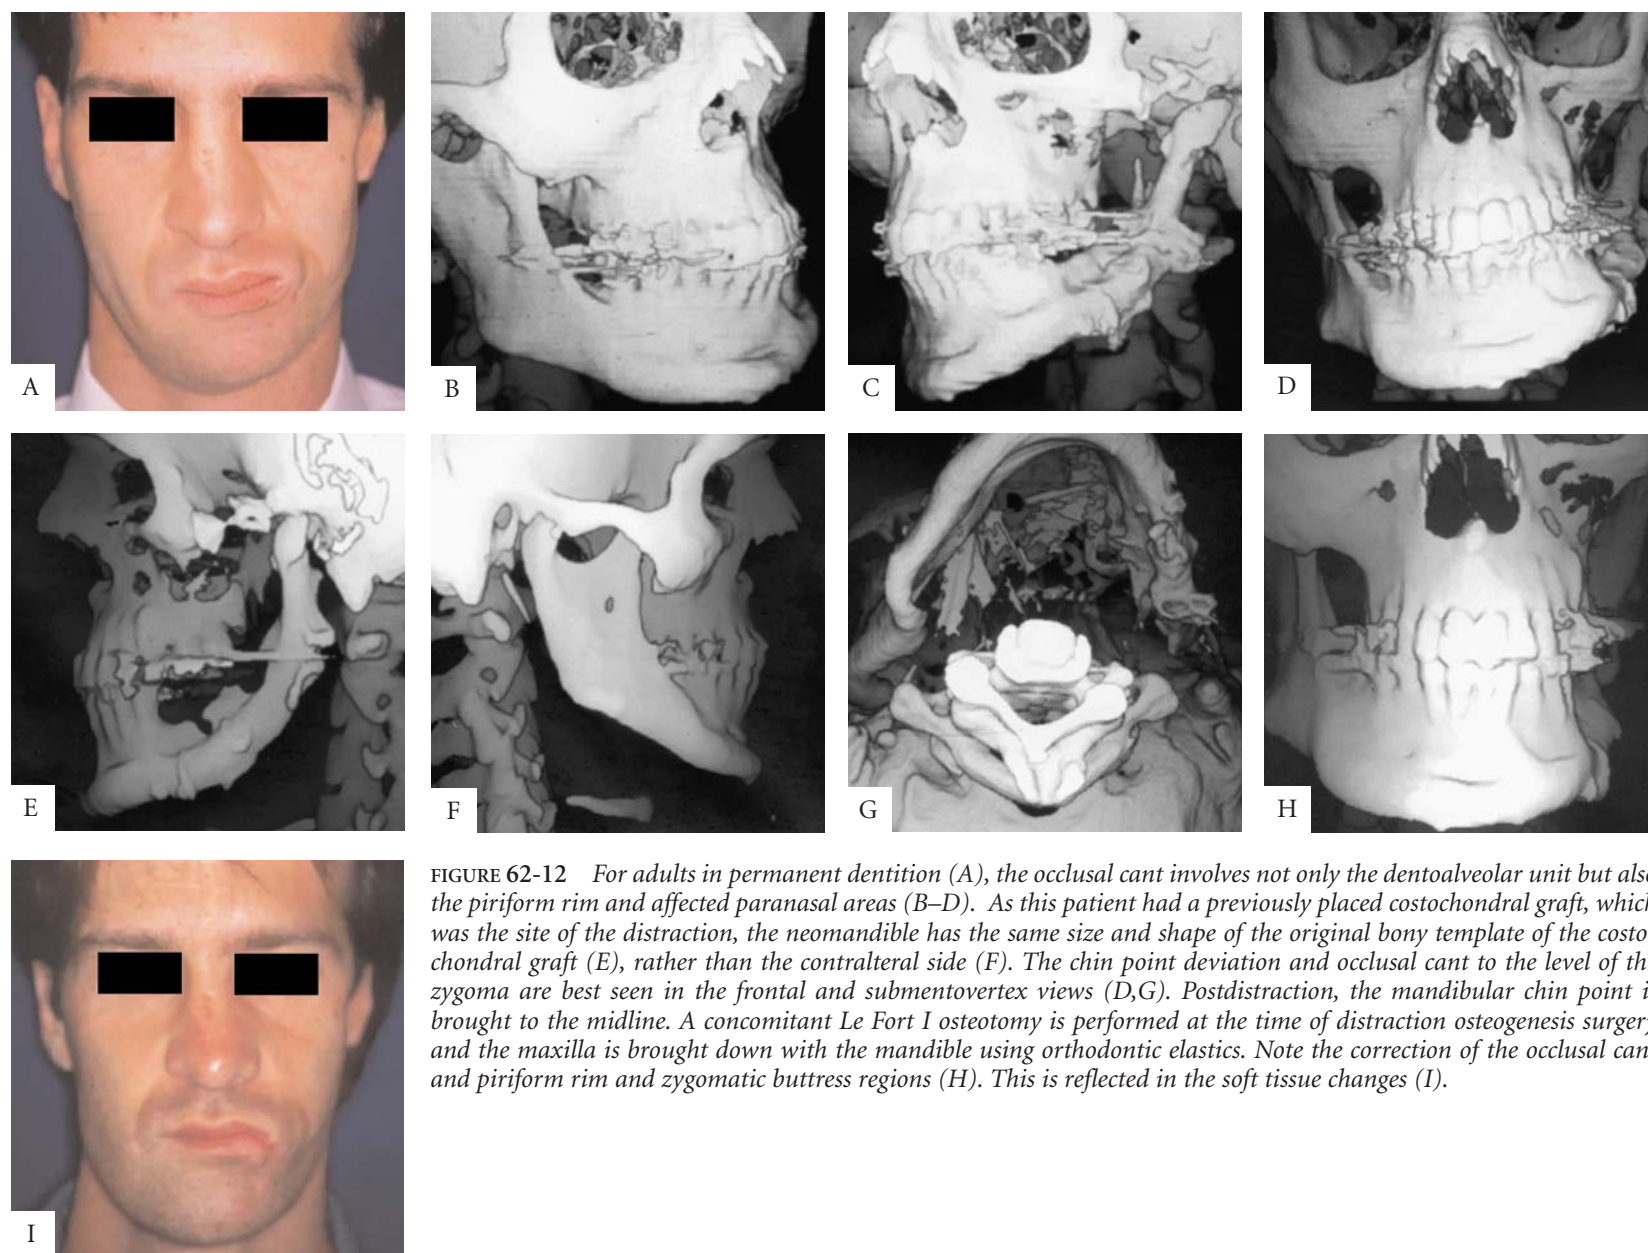

FIGURE 62-12 For adults in permanent dentition (A), the occlusal cant involves not only the dentoalveolar unit but also the piriform rim and affected paranasal areas (B–D). As this patient had a previously placed costochondral graft, which was the site of the distraction, the neomandible has the same size and shape of the original bony template of the costochondral graft (E), rather than the contralateral side (F). The chin point deviation and occlusal cant to the level of the zygoma are best seen in the frontal and submentovertex views (D,G). Postdistraction, the mandibular chin point is brought to the midline. A concomitant Le Fort I osteotomy is performed at the time of distraction osteogenesis surgery and the maxilla is brought down with the mandible using orthodontic elastics. Note the correction of the occlusal cant and piriform rim and zygomatic buttress regions (H). This is reflected in the soft tissue changes (I).

help hold the segment in proper orientation. In 1 to 2 weeks after distraction ossification, move the bicuspid and cuspid teeth orthodontically back to their correct position into the ossified DO bone, leaving the anterior dentoalveolar unit for implant reconstruction or for final periosteoplasty and smaller bone graft, if indicated. This segmental distraction is a form of transport DO.

For patients who have congenital agenesis of the premaxilla or who experience traumatic loss of the dentoalveolar unit,

anterior maxillary segmental distraction is indicated (Figure 62-16). Use tunneling techniques to perform the anterior osteotomy, making the horizontal bone cut parallel to the occlusal plane to facilitate segment advancement along a horizontal vector (Figure 62-17). Bilateral distractors are placed, and distraction proceeds after a 5-day latency at a rate of 1.0 mm per day. Anterior traction elastics aid in the forward thrust of the segment. The distractors are removed once a bony outline can be seen radiographically and

FIGURE 62-13 An intravenous tubing can be placed over the free end of maxillary distractors to avoid lip ulcers. The tubing is removed to activate the device then reapplied.

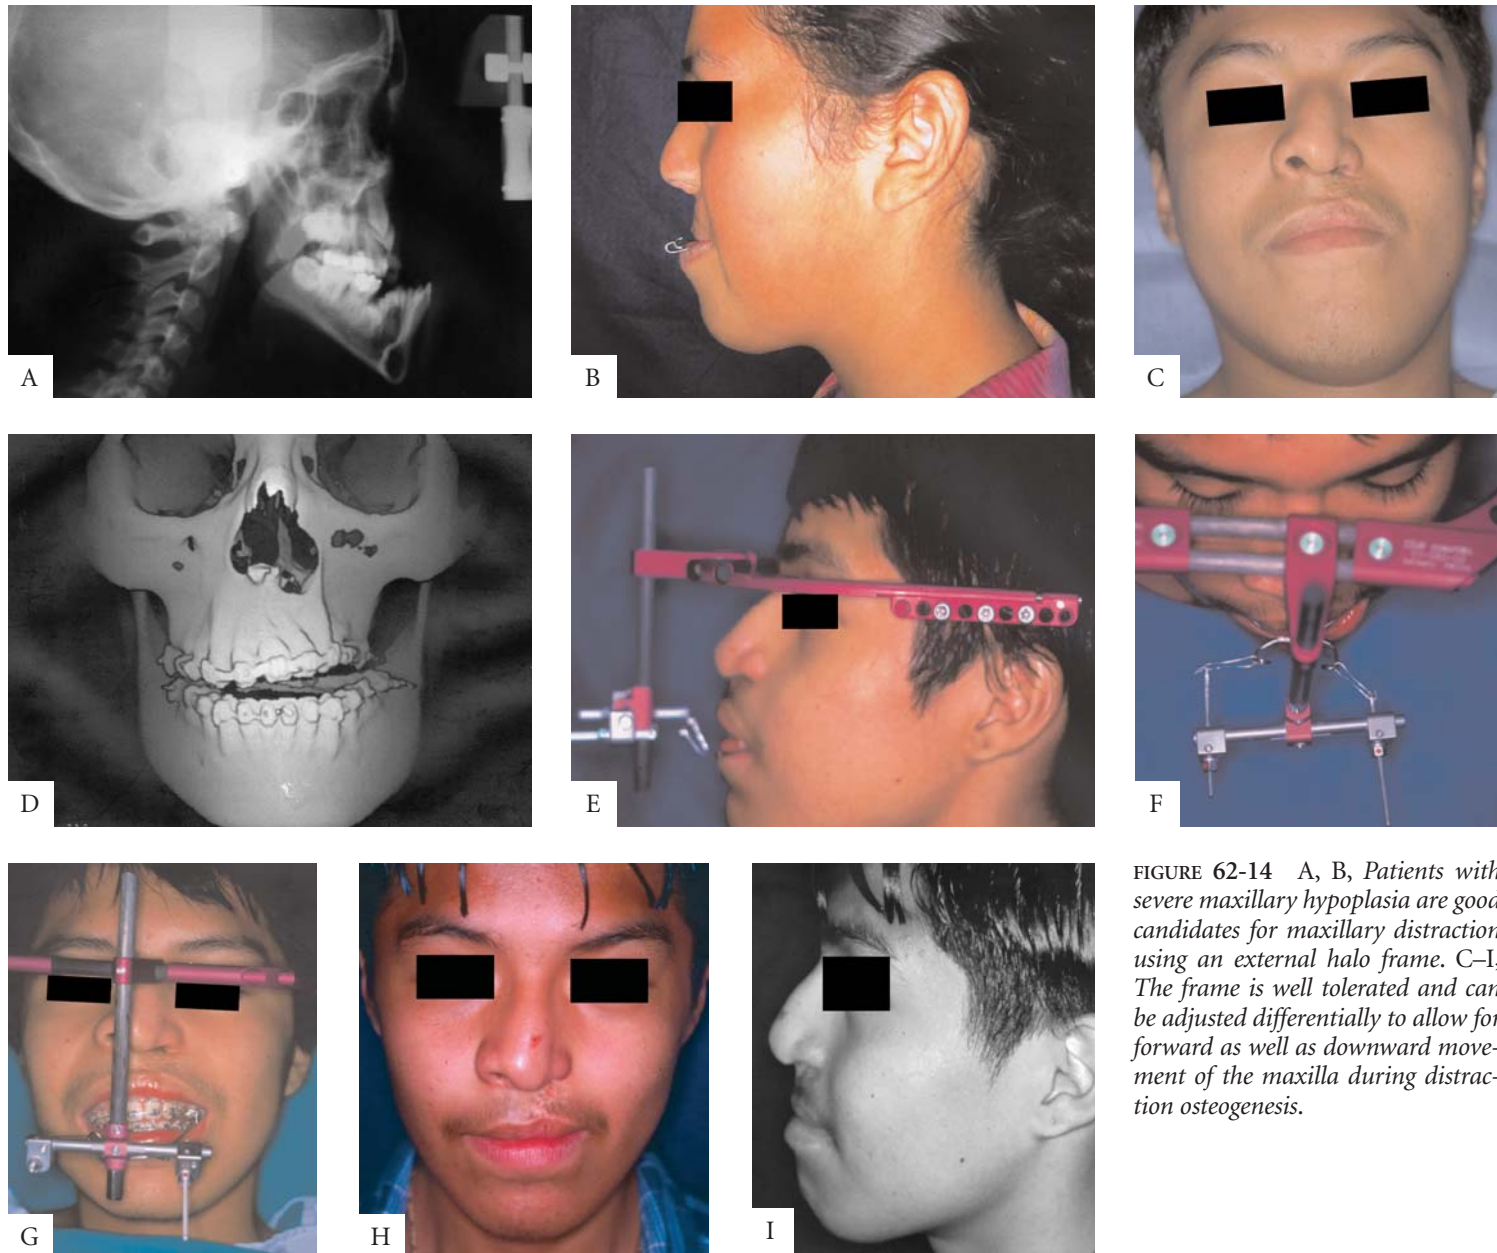

FIGURE 62-14 A, B, Patients with severe maxillary hypoplasia are good candidates for maxillary distraction using an external halo frame. C-I, The frame is well tolerated and can be adjusted differentially to allow for forward as well as downward movement of the maxilla during distraction osteogenesis.

once the segment is stable. The distractors can be removed prior to complete ossification (3 to 4 weeks) to mold the regenerate or at the patient's request. Position rigid fixation plates at the time of device removal. Resorbable rigid fixation plates are useful for this purpose; the site will ultimately undergo dental implant reconstruction.

Transport Distraction Osteogenesis

The power of DO is that both bone and soft tissues are regenerated. Transport distraction

involves creating a transport disk in the bone stump, adjacent to a discontinuity defect or a resection site. The transport disk is then advanced 1.0 mm per day as the distraction gap increases in size to span the discontinuity defect (Figure 62-18).²⁷ The resultant regenerate chamber will have the same size and shape of the transport disk. Careful treatment planning is necessary to plan the site of the osteotomy, thus determining the shape of transport disk and regenerate (Figure 62-19). Occasionally, a tooth may need to be sacrificed to allow for osteotomy placement in an optimal position.

Both external and submerged devices have been used for transport DO. Three points of fixation are required for transport DO: (1) in the proximal stump, (2) in the distal site, and (3) in the transport disk. Use a rigid fixation plate as a substitute for the three points of fixation along with a conventional distractor. The rigid fixation plate also acts as a guide for the transport disk during distraction (see Figure 62-18). Once the transport disk reaches the docking site, the segment is held in neutral fixation until a cortical outline is seen in the regenerate. At the time of

FIGURE 62-15 Segmental distraction can be performed for focal bone and soft tissue deficiencies such as alveolar cleft defects. A–C, The bone cut is made between the molar and bicuspid teeth and the orthodontic wire acts as a guide during distraction osteogenesis. D–F, A new dentoalveolar unit is formed and the cuspid and bicuspid teeth can be moved back into proper position orthodontically post-distraction osteogenesis.

FIGURE 62-16 Patients with anterior maxillary congenital deformities including anodontia (A, B) are treated with anterior segmental maxillary distraction osteogenesis (DO) and concomitant posterior mandibular DO widening (C, D).

FIGURE 62-17 A, Patients with traumatic avulsion of the premaxillary segment can be treated with segmental anterior distraction osteogenesis. B, The bone cut is made parallel to the occlusal plane and the distractors placed via a tunneling technique (Courtesy of KLS Martin L.P., Jacksonville, FL). C, D, A flat plane occlusal splint is inserted to allow for impedance-free maxillary advancement.

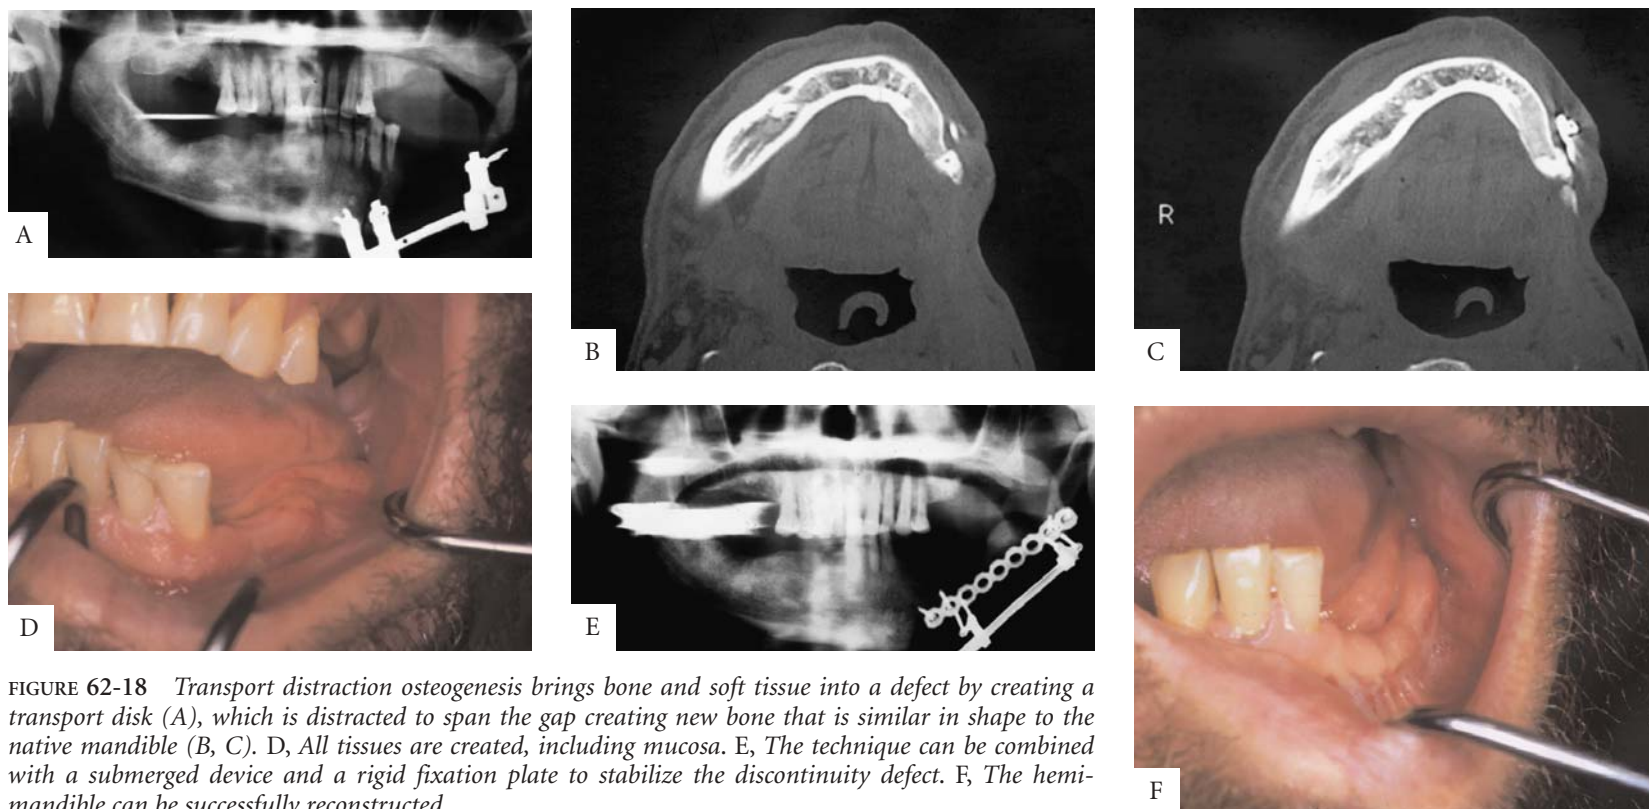

FIGURE 62-18 Transport distraction osteogenesis brings bone and soft tissue into a defect by creating a transport disk (A), which is distracted to span the gap creating new bone that is similar in shape to the native mandible (B, C). D, All tissues are created, including mucosa. E, The technique can be combined with a submerged device and a rigid fixation plate to stabilize the discontinuity defect. F, The hemimandible can be successfully reconstructed.

distractor removal, the surgeon may need to position a small bone graft between the transport disk and the docking site because the transport disk becomes rounded and encased with a fibrocartilagenous cap. Obtaining osseous union necessitates removal of this intervening fibrocartilagenous cap.

During active DO, monitor the patient closely to rule out soft tissue dehiscence. Occasionally the leading edge of the transport disk can migrate through the soft tissue. The suggested local wound-care measures include antibiotics and antimicrobial mouth rinses. A blood supply that is compromised (eg, a patient status post-radiation therapy) indicates disk dancing until the dehiscence site closes.

Symphyseal reconstruction can be difficult because the regenerate chamber tends to assume a straight line, rather than follow and maintain the curvilinear shape.²⁸ Use molding devices, including an intraoral surgical guide, to facilitate and maintain the shape of the regenerate chamber (see Figure 62-19).²⁹ Viewed

from above, the dentoalveolar unit assumes an arcuate form. Viewed from below, the mandible assumes five lines: two body regions, two parsymphyseal regions, and one symphyseal region. Thus, plan for five linear distraction vectors to reconstruct the mandible (Figure 62-20).

One alternative treatment plan calls for the creation of a large transport disk (1.5 to 3.0 cm) advanced in a linear fashion until the junction of the next linear segment.²⁸ The disk is held in neutral fixation for a few days or weeks until early ossification occurs. Subsequently, the disk is divided into two segments, with one-half of the original transport disk held in place to the reconstruction plate. The other one-half becomes a new transport disk reoriented in the proper vector, which, after a 3- to 5-day latency, is advanced by distraction in the new trajectory (see Figure 62-20).

Transport distraction has been used successfully either in primary reconstruction at the time of bone resection or in secondary reconstruction. For primary

reconstruction, the devices are placed at the time of resection. If a concomitant neck dissection is done, then the latency period should be increased to 7 days. For secondary reconstruction, limited surgical dissection is advocated. As the soft tissue bed may be heavily scarred, the distraction rhythm may need to be altered to four times a day rather than twice a day to allow incremental stretching of the overlying soft tissues. Tension within the overlying soft tissue may cause daily “relapse” by

FIGURE 62-19 Surgical guides can be fabricated to help maintain the curvilinear shape of the regenerate during transport distraction osteogenesis.

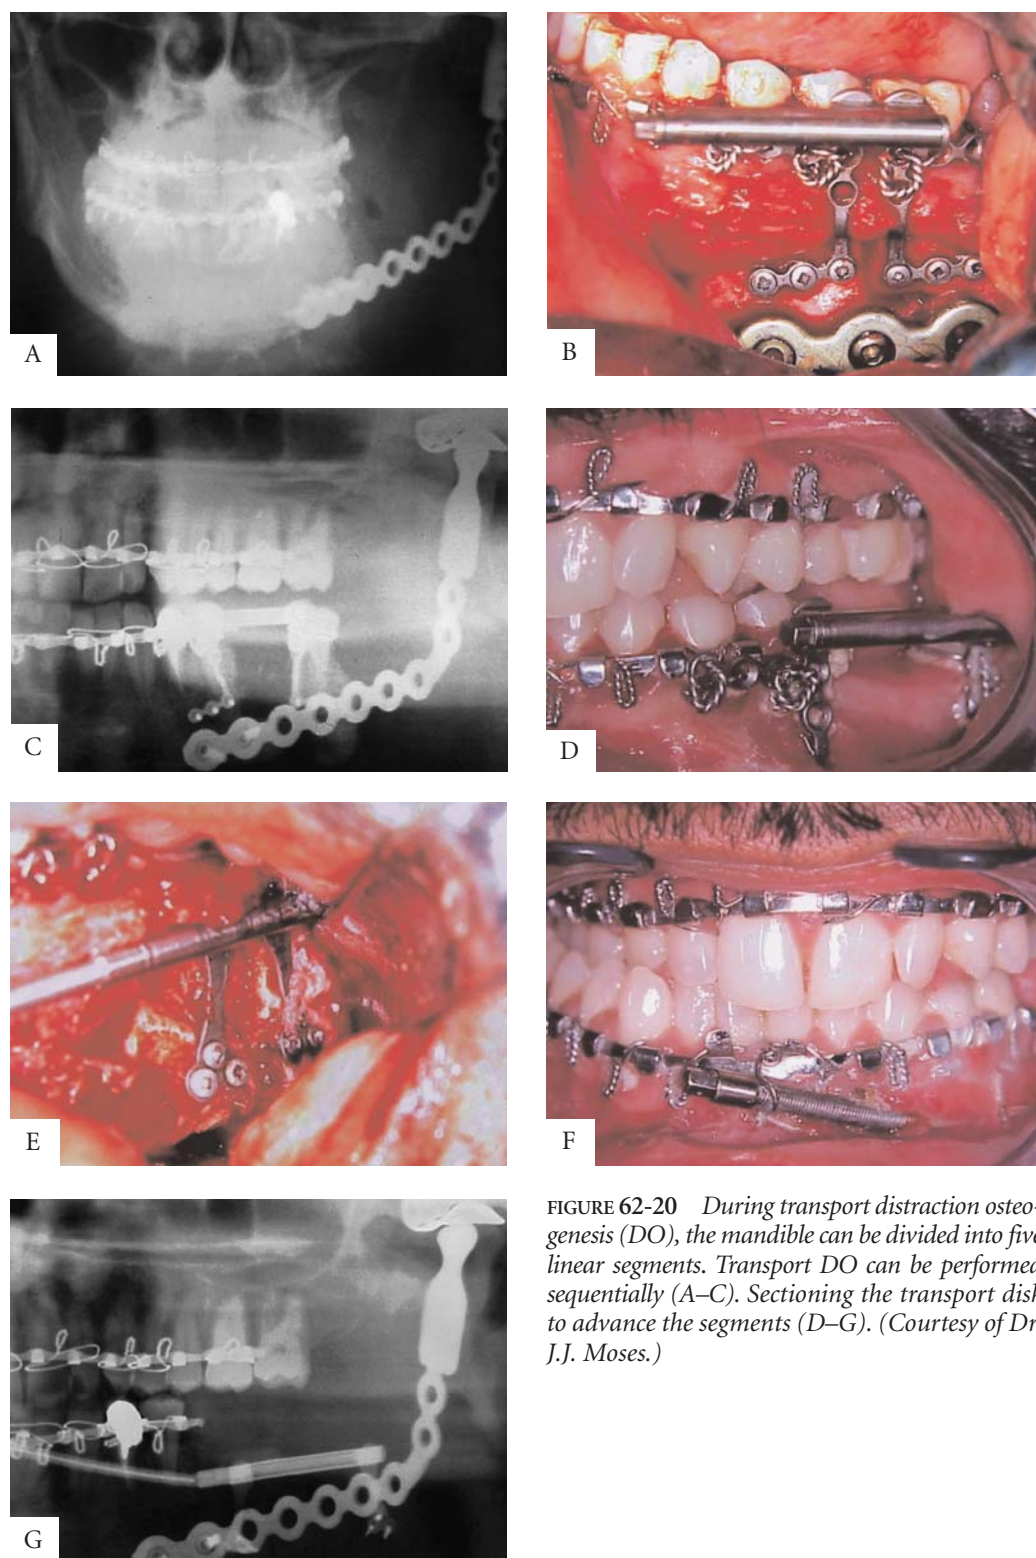

FIGURE 62-20 During transport distraction osteogenesis (DO), the mandible can be divided into five linear segments. Transport DO can be performed sequentially (A–C). Sectioning the transport disk to advance the segments (D–G). (Courtesy of Dr. J.J. Moses.)

exerting a counterforce on the transport disk. Transport DO has been used to successfully create a neomandible in patients who have had post-resection radiation therapy.^{30,31} Although predistraction

hyperbaric oxygen therapy is appropriate, it is not mandatory. During active distraction, neovascularization has occurred.³² Use transport DO to reconstruct a neomandible without hyperbaric oxygen ther-

apy. The distraction rate is reduced to 0.5 mm per day, and the overlying soft tissues are carefully monitored.

DO can be used in conjunction with conventional reconstructive techniques (eg, microvascular flaps). One concern, however, is that the donor bone, such as a fibula, may not have the ideal form post-mandibular reconstruction for implant placement and prosthetic reconstruction. Use distraction as a secondary technique to obtain ideal height and width for implant reconstruction.³³ The technique is similar to that for DO of an atrophic mandible for dental implants.

Transport Distraction to Generate a Neocondyle

During transport DO, the transport disk becomes rounded and covered by a fibrocartilagenous cap. This cap is removed to ensure osseous continuity in mandibular reconstruction. Use this fibrocartilagenous cap to reconstruct a neocondyle.^{34–36} Create a reverse L osteotomy in the ramus of the mandible from the sigmoid notch behind the lingua to 1.0 to 1.5 cm above the inferior border of the mandible (Figure 62-21). The distractor is oriented vertically, almost parallel to the posterior border of the ramus, to guide the transport disk into the fossa, creating a neocondyle. In the same way, the segment can be overdistracted to increase posterior vertical ramal height and to reestablish the gonial angle. For bilateral cases, a coronoidectomy prevents rotation of the proximal segment from temporalis muscle pull during the DO process.

In patients who have bony ankylosis, carry out a gap arthroplasty concomitantly with the distraction surgery (Figure 62-22). As the neocondyle assumes the form of the fossa, it is important to surgically shape the new fossa well in all three planes of space during the gap arthroplasty portion of the procedure. Distraction is initiated after a 5-day latency period and proceeds until the transport disk reaches the glenoid fossa.

FIGURE 62-21 A reverse L osteotomy is performed in the ramus of the mandible for condylar transport distraction osteogenesis.

The patient will remark that they can feel pressure as the articulation of the condyle and fossa is reestablished. This is confirmed radiographically. The DO device is held in neutral fixation until a cortical outline is viewed in the regenerate chamber near the angle of the mandible.

Patients with condylar resorption (idiopathic, degenerative, and rheumatoid arthritis) experience a loss of posterior vertical height and an anterior open bite as a consequence of the resorptive process of the condyle. The slow applica-

tion of force over time via DO to generate new bone is ideally suited to patients requiring mandibular advancement who have a history of temporomandibular joint involvement. Using the same osteotomy, the ramus is over distracted, creating an edge-to-edge Class III profile (Figure 62-23). Remove the distractors after 3 weeks of osseous consolidation, and mold the regenerate using orthodontic elastics to rotate the mandible counter clockwise and to close the open bite. Elastic maxillomandibular fixation is not required to mold the regenerate. Insert a maxillary splint to decrease the load on the temporomandibular joints. Likewise, instruct patients to wear the molding elastics in intervals, allowing other time intervals for free mandibular movement (ie, 4 hours in elastics and 3 hours off). Monitor patients closely, and if the patient complains of preauricular discomfort or limitation of motion, adjust the regenerate molding protocol.

Regardless of the etiology, all patients undergoing condylar transport DO are in active physical therapy during the entire DO

process and are also instructed about at-home physical therapy exercises. Success of the transport DO technique to create a neocondyle depends on mandibular motion.

Alveolar Distraction Osteogenesis for Dental Implants

Bone grafting techniques for alveolar ridge reconstruction prior to dental implant reconstruction are well established. For cases requiring greater than 4 to 5 mm, apply vertical height augmentation, or if the overlying soft tissue may not support osseous augmentation, alveolar DO is a useful treatment alternative.³⁷⁻³⁹

Carry out a vestibular incision to approach the site. Minimal periosteal stripping is advocated as the transport disk is small. Carefully create the bone cut, using a saw or bur for the horizontal cut, and use chisels at the alveolar crest, sparing the lingual or palatal periosteum. The distractor is adapted to the site. Apply the distractor to the outer cortical surface of the regenerate chamber or place with a central activation pin extending transosseously (Figure 62-24). Once placed, activate the distractor

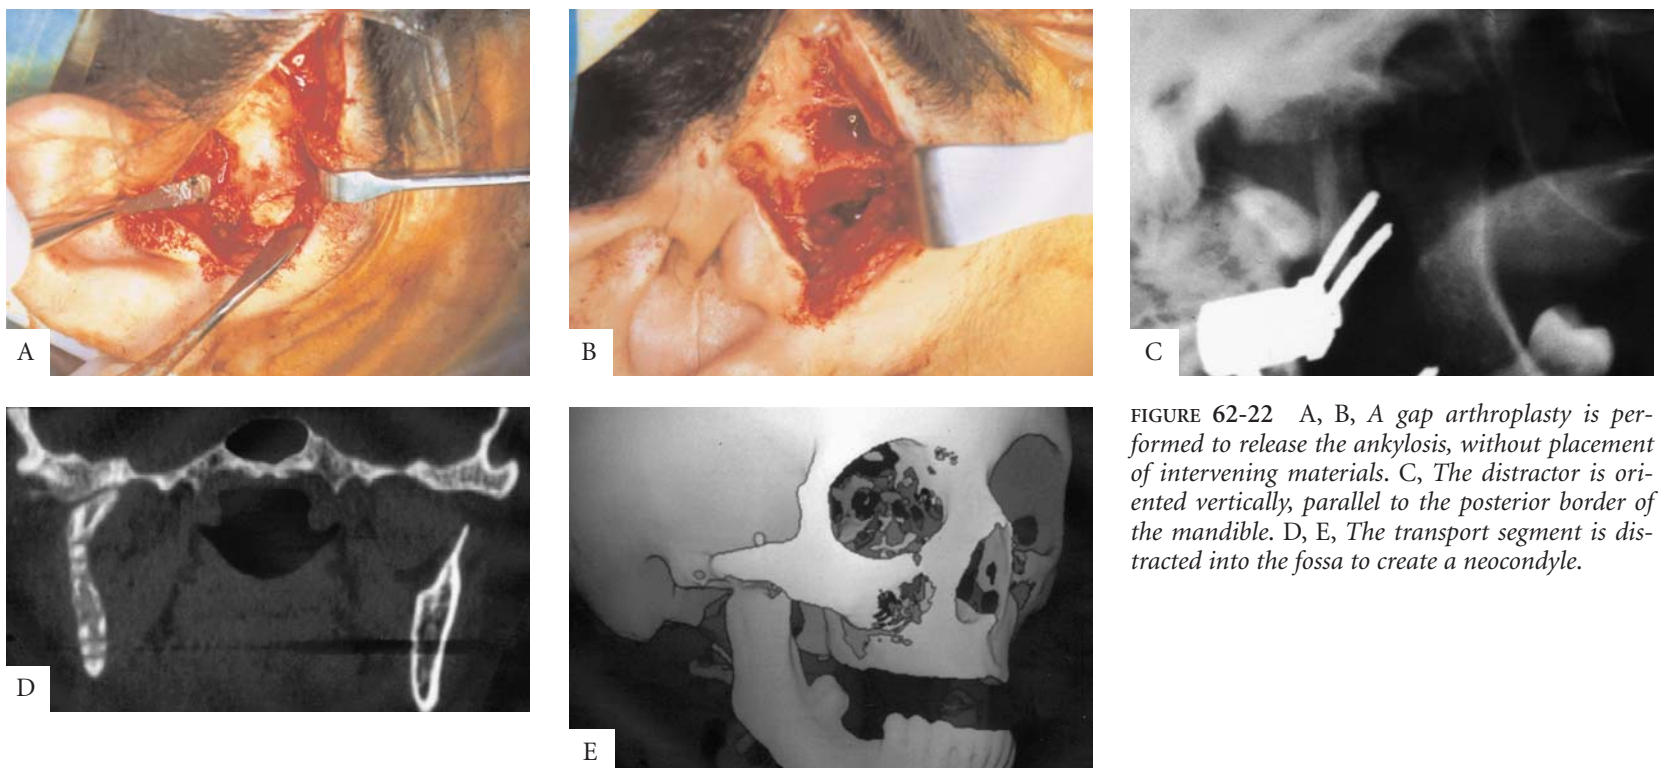

FIGURE 62-22 A, B, A gap arthroplasty is performed to release the ankylosis, without placement of intervening materials. C, The distractor is oriented vertically, parallel to the posterior border of the mandible. D, E, The transport segment is distracted into the fossa to create a neocondyle.

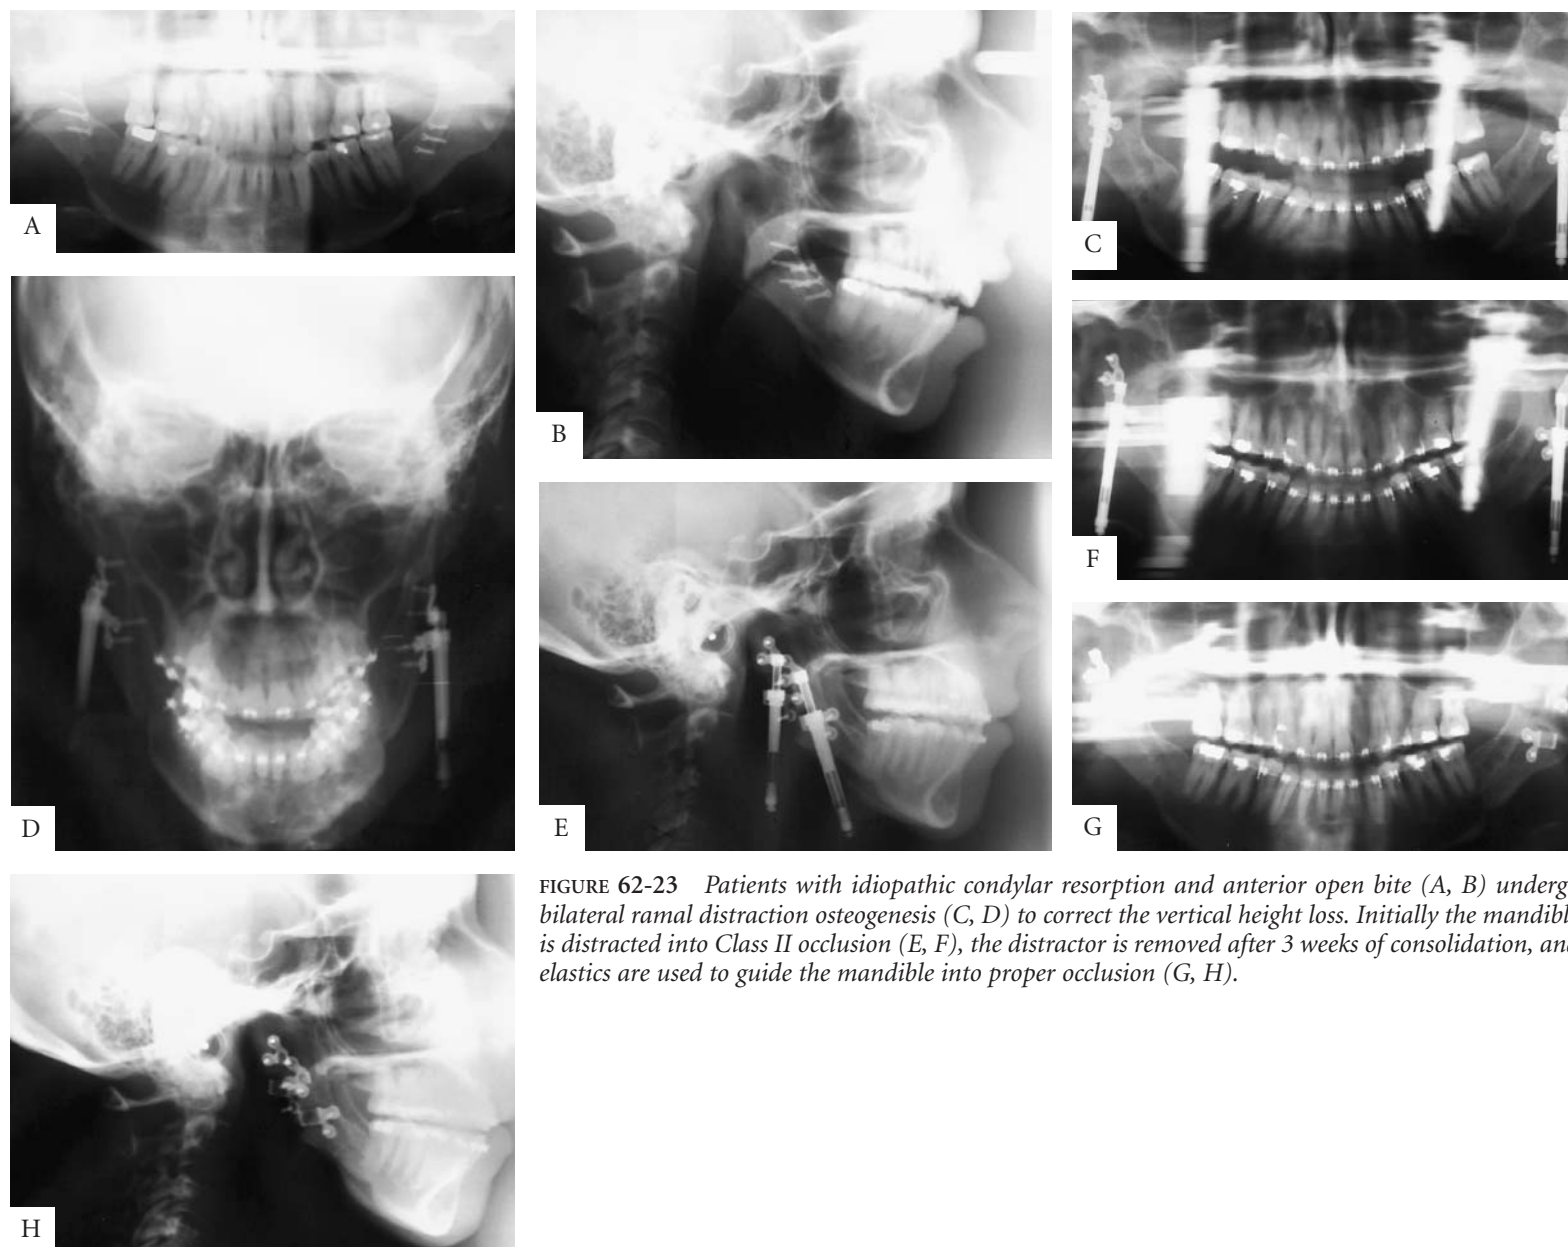

FIGURE 62-23 Patients with idiopathic condylar resorption and anterior open bite (A, B) undergo bilateral ramal distraction osteogenesis (C, D) to correct the vertical height loss. Initially the mandible is distracted into Class II occlusion (E, F), the distractor is removed after 3 weeks of consolidation, and elastics are used to guide the mandible into proper occlusion (G, H).

FIGURE 62-24 Alveolar distractors are interosseous (A) or extraosseous (B). C, After device application the distractor is activated to ensure impedance-free moment of the segment. The transport disk is then returned to the closed position.

to check for impedance-free movement of the distraction segment. Remove any bony interferences. The wound is closed and after a 3- to 5-day latency, the distractor is activated up to 0.7 to 1.0 mm per day. The distraction disk is small; thus, a rate of 0.5 to 0.7 mm per day is advocated if the blood supply to the segment is compromised. Distraction proceeds until the desired amount of bone is obtained. Often the segment is overdistracted to a position above the alveolar crest of the adjacent teeth. During implant placement, the excess crestal bone can be sculpted and contoured using a periodontal bur that produces an esthetic implant site. The segment is held in place to allow for ossification. Some authors recommend 8 weeks of ossification, whereas others recommend 12 weeks prior to implant placement.^{37,39} Initially, the regenerate chamber is radiolucent. This decreases with time, but the regenerate chamber will continue to be less radio-

dense for up to 1 year post-distraction. Applying platelet rich plasma (PRP) into the distraction gap at the time of initial distraction surgery may increase DO bone ossification.⁴⁰

Both interosseous and extraosseous distraction devices work well; however, they have some drawbacks. Devices placed on the outer cortical surface may cause slight buccal resorption of the outer cortex, requiring a “patch graft” at the time of device removal. Placing a guided bone regeneration (GBR) membrane next to the bone below the distraction device will also act to decrease this buccal resorption.⁴¹ Devices that are placed transosseously result in fibrous tissue in-growth around the central distraction pin. This tissue is removed at the time of the device removal but can limit immediate implant placement. Dental implants may be placed at the time of distractor removal or at 1 month later. Second-stage implant place-

ment allows the soft tissues to mature and facilitates treatment planning for ideal implant placement. Place implants to span the regenerate chamber, including a portion of the distal osteotomy site.

Vector control is paramount with small-segment distraction, such as DO for dental implants. The small bone segments are under local muscle pull, especially the mylohyoid. Vector control devices, including orthodontic appliances and interim treatment partials with an access hole for the DO device activation rod, are useful to help guide the distractor into place (Figure 62-25). Callus manipulation as previously described may be performed under local anesthesia to re-direct the proper path of distraction. New alveolar DO devices that incorporate hinges allow the clinician to redirect the vector during active distraction (Figure 62-26).^{42,43}

Local osseous anatomy can influence distraction device placement. The fixation plates of an extraosseous device may require bending to make the distraction pin more vertical and to optimize the ideal vector. Placing the device flush directly on the bone surface can direct the bone segment in an inappropriate direction, as is the case with the atrophic anterior maxilla and mandible (Figure 62-27). Similarly, to ensure proper device trajectory, the central pin hole of an intraosseous device may require angling more buccally than along the central axis of the alveolus. The fixation plates may need altering that takes into account the local anatomy, including the mental nerve and piriform rim regions. In fact, place the extraosseous device in a cantilever fashion with the central portion of the device offset (Figure 62-28).

Knife-edge ridges can be a difficult problem. Distracting the alveolus in a straight vertical direction will produce an increase in height but a narrow bone stock. Perform differential distraction by performing the lingual cut incompletely, allowing the lingual site to act as a “hinge.”^{44,45} The

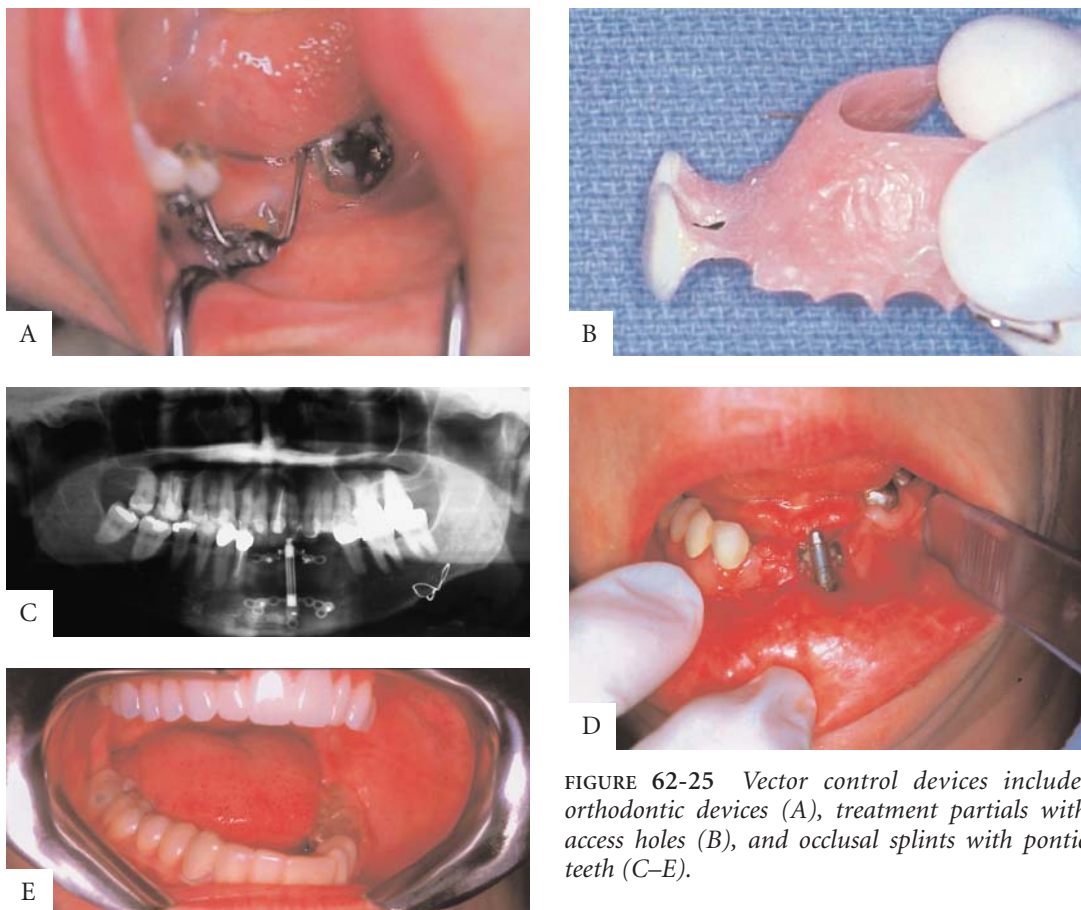

FIGURE 62-25 Vector control devices include: orthodontic devices (A), treatment partials with access holes (B), and occlusal splints with pontic teeth (C–E).

FIGURE 62-26 A and B, Alveolar distraction devices with internal hinges allow for vector adjustment during active distraction osteogenesis. (Courtesy of Dr. M. Robinoy.)

device is placed, and distraction proceeds as usual. The hinge motion allows the buccal wall to be initially distracted differentially more than the lingual; specifically, the buccal site “opens” to create a flat crestal surface suitable for implants (Figure 62-29).

Posterior saddle deformities of the mandible are also problematic. The curve of Spee dictates that straight vertical distraction results in generating more bone in the retromolar region. To alleviate this

FIGURE 62-27 Placing the extraosseous distractor flush on the native bone will produce a poor trajectory to the vector.

problem, make an L-shaped bone cut adjacent to the remaining teeth, and use a monocortical miniplate to fixate the posterior-most portion on the bone cut (Figure

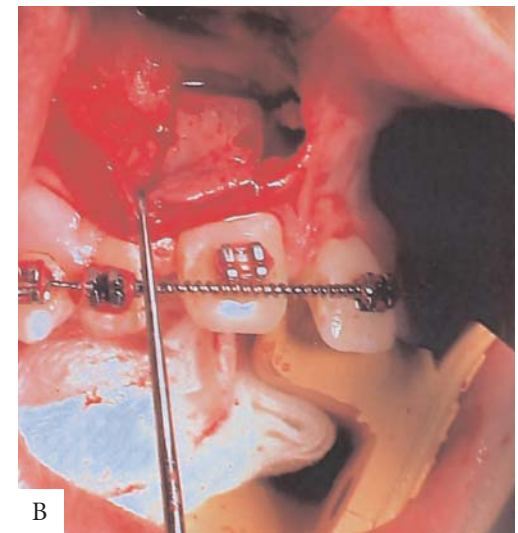

FIGURE 62-28 A, Distraction osteogenesis (DO) was performed prior to extraction of this malpositioned, ankylosed, previously hopelessly avulsed tooth. B, DO prior to extraction facilitated proper crestal bone and gingival height. C, D, The DO device is placed lateral to the transport disk in a cantilever fashion to optimize bone stock for device placement.

62-30).^{45,46} Distraction proceeds with the anterior portion of the distraction segment rotating and hinging around the distal fixation plate to differentially increase the anterior region.

Use distraction to reconstruct atrophic edentulous maxillas and mandibles. The technique is the same. One device is placed in the midline, and the vector is adjusted to distract the bone segment up and buccally. To avoid fracture of the atrophic mandible, modify the bone cut to a trapezoidal shape. Rounding the internal corners of the osteotomy eliminates local inherent stresses, which have been associated with mandibular fractures.⁴⁷ For severely atrophic cases, place a reconstruction plate, in conjunction with the distraction devices, at the time of the osteotomy.⁴⁸

Complications

Most complications associated with the distraction technique are iatrogenic and

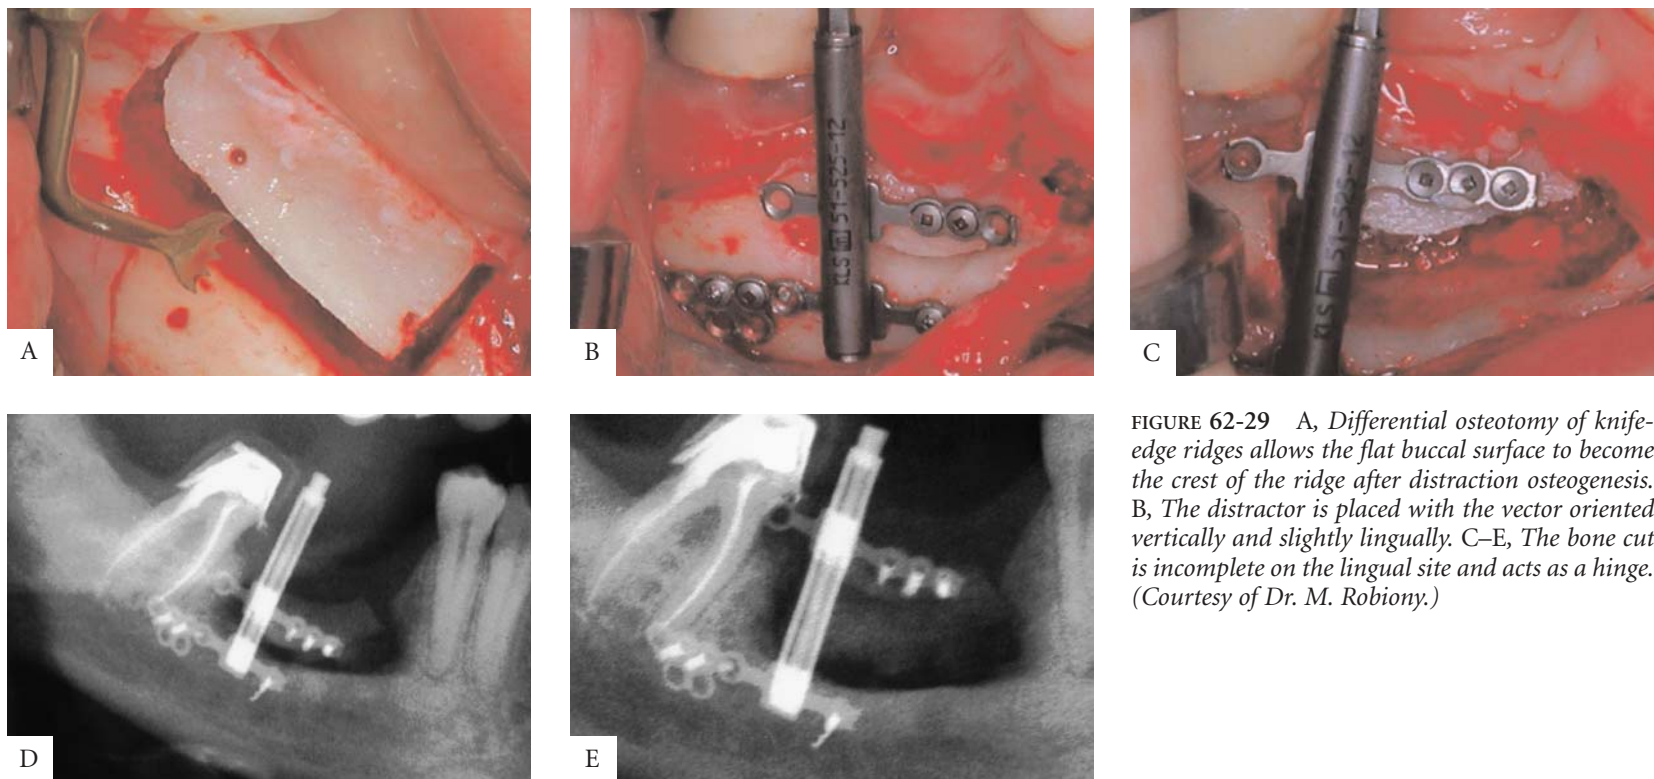

FIGURE 62-29 A, Differential osteotomy of knife-edge ridges allows the flat buccal surface to become the crest of the ridge after distraction osteogenesis. B, The distractor is placed with the vector oriented vertically and slightly lingually. C–E, The bone cut is incomplete on the lingual site and acts as a hinge. (Courtesy of Dr. M. Robiony.)

easily managed.^{49,50} Inaccurate planning may lead to poor vector trajectory of the bone segments. Molding the regenerate can alleviate this problem. Careful follow-

up is mandatory during the entire distraction process, including the time of post-distraction ossification. During this latter time period, the regenerate chamber is fully extended and is most under the influence of local muscle pull. Also, the period of post-distraction ossification is the best time to easily mold the regenerate.

Wound dehiscence problems can occur. Local wound care, including antibiotics and antimicrobial mouth rinses, alleviates this problem. Disk dancing can be performed to allow the local wound site to heal after which DO can begin. Occasionally, however, the distractor fixation screw heads become visible, but this is not a concern. Overdistraction of the segment can compensate for potential crestal bone loss from screw-head exposure.

Surgical and Nonsurgical Management of Obstructive Sleep Apnea

B. D. Tiner, DDS, MD

Peter D. Waite, MPH, DDS, MD

Sleep and dreaming have been sources of mystery and fascination since biblical times. Sleep consists of inevitably recurring episodes of readily reversible relative disengagement from sensory and motor interaction with the environment.¹ The function of sleep remains a mystery, and only in recent years has there been research into specific symptom complexes and causes of sleep disorders. In 1979 the Association of Sleep Disorders Center and the Association for the Psychophysiological Study of Sleep published the first classification of sleep and arousal disorders.²

Modern sleep research became possible in 1924 when Hans Berger, a German psychiatrist, described the recording of human electroencephalography.³ Loomis and colleagues in 1935 published a quantitative description of the four levels of sleep based on electroencephalogram (EEG) characteristics.^{4,5} The historic discovery of a cyclic phase of sleep characterized by rapid conjugate eye movements was made by Aserinsky and Kleitman in 1953.⁶ Subsequent studies confirmed this to be a very active phase of sleep that correlated closely with dreaming.⁷

Normal Sleep Stages

Normal sleep architecture includes both quiet sleep (nonrapid eye movement [non-REM] sleep) and active sleep (rapid eye

movement [REM] sleep). Non-REM sleep consists of four stages which are based largely on the original criteria of Loomis and colleagues.^{4,5} Stage 2 predominates and comprises 45 to 50% of total sleep time. The four stages of non-REM sleep represent progressively deeper sleep marked by the increasing appearance of high-amplitude slow waves in stages 3 and 4, which are collectively known as delta sleep. Non-REM sleep is characterized by a general slowing of all levels of activity. Progression through all four stages of non-REM sleep usually occurs rapidly after sleep onset. REM sleep occurs after non-REM sleep has been established, and the first REM period normally occurs after 70 to 90 minutes of non-REM sleep. The average duration of a period of REM sleep is about 20 minutes. The initial REM period of the night is usually very brief, but subsequent REM periods become longer. During an average night of REM/non-REM cycle progression, 4 to 6 REM periods normally occur at intervals of 60 to 90 minutes. REM sleep occupies about 20 to 25% of total sleep time in a healthy young adult. REM sleep EEG patterns look very similar to those seen during the wakeful state. Generalized skeletal muscle atonia (except for the ocular muscles) and absence of reflexive activity are other features unique to REM sleep. Marked physiologic changes also

occur during REM sleep. Temperature, blood flow, and oxygen use in the brain are increased. Heart rate, blood pressure, and respiration show dramatic fluctuations and increase in average rate.

During sleep the control of respiration is influenced by two systems: the metabolic control system and the behavioral control system.⁸ The influences of hypoxia and hypercarbia on ventilation are the predominant components of the metabolic control system of respiration. This system predominantly controls respiration during non-REM sleep. The behavioral control system governs respiration during voluntary activities, such as swallowing or speaking, and may suppress the ventilatory response to metabolic stimuli. During REM sleep, the effects of hypoxia and hypercarbia on ventilation are much less than during non-REM sleep, and the behavioral control system may predominate. With a blunted response to hypoxia and hypercarbia, irregular respirations, and decreased skeletal muscle tone of the upper airway muscles during REM sleep, an episode of partial or complete airway obstruction with apnea or hypopnea may occur.

Sleep Apnea Syndrome

The sleep apnea syndrome is a disorder characterized by abnormal breathing in

sleep and sleep fragmentation. At least 30 episodes of apnea occur during 7 hours of nocturnal sleep in these patients. Apnea is defined as the cessation of airflow from the nostrils and mouth for at least 10 seconds. These apneic episodes can result in hypoxemia, hypercarbia, systemic and pulmonary hypertension, polycythemia, cor pulmonale, bradycardia, and cardiac dysrhythmias. Sudden death has occurred in patients with sleep apnea. Throughout the night the alternating episodes of apnea and arousal from sleep may occur as frequently as 400 to 600 times, with each typical apnea episode lasting 15 to 60 seconds. These episodes can amount to as much as 50% of a night's sleep. The frequent disruption results in symptoms similar to sleep deprivation. These include excessive daytime sleepiness, fatigue, depression, personality changes, and impotence. These dysfunctional symptoms are common primary complaints and are often the reason people seek treatment.

Epidemiologic data suggest that sleep apnea syndrome may be quite common, particularly in its milder forms. In fact, obstructive sleep apnea is the second most common sleep disorder, insomnia being the most common. A 1993 Sleep Commission Report estimated that 20 million Americans have sleep apnea, with the majority being undiagnosed and untreated.⁹ The exact prevalence is unknown, but sleep apnea syndrome may affect up to 2 to 3% of adult males.⁸ In certain populations the prevalence may be as high as 10%. Most patients are diagnosed after age 40, but sleep apnea can occur at any age. There is a strong male predilection, with men outnumbering women by up to 8 to 1 until menopause. This implies a hormonal influence. The cost for diagnosis and treatment of this sleep disorder accounts for over \$50 million (US) in hospital bills each year. Overall, sleep disorders and sleepiness cost the United States economy a minimum of \$15.9 billion (US) in direct costs each year.¹⁰

Classification

Central sleep apnea, obstructive sleep apnea, and mixed sleep apnea are the variations of apnea that occur in the syndrome. In central sleep apnea, respiratory muscle activity ceases simultaneously with airflow at the mouth and nostrils.¹¹ This disorder is found in patients with central nervous system (CNS) insufficiency that affects the outflow of neural output from the respiratory center to the diaphragm and other muscles of respiration. CNS disorders associated with central sleep apnea include brainstem neoplasms, brainstem infarctions, bulbar encephalitis, bulbar poliomyelitis, spinal surgery, cervical cordotomy, and primary idiopathic hypoventilation.

Patients with central sleep apnea have been treated with some success by using respiratory-stimulating drugs such as theophylline, progesterone, and acetazolamide. In severe central apnea, modalities of treatment have included phrenic nerve pacemaker implantation to ensure regular respiration during sleep and nocturnal mechanical ventilation with a negative pressure ventilator for more severe cases. There are no simple and convenient methods of treatment for mild central apnea.

The most common type of sleep apnea by far is obstructive. This is characterized by sleep-induced obstruction of the upper airway that results in cessation of airflow with preservation of respiratory effort, respiratory center drive, and diaphragmatic contraction.¹¹

Mixed sleep apnea is a combination of central and obstructive apnea. This pattern begins with an episode of central apnea with no airflow detectable at the mouth and nostrils and no respiratory muscle activity. The pattern ends with an episode of obstructive apnea with only cessation of airflow at the mouth and nostrils.¹¹

Differential Diagnosis

Profound hypersomnolence is a characteristic feature of both sleep apnea and nar-

colepsy; hence, they are often confused. However, unlike sleep apnea, narcolepsy affects both sexes equally, with most patients experiencing the onset of symptoms around or shortly before puberty.¹² The first symptom to appear with narcolepsy is usually excessive daytime somnolence (EDS). The sleep attacks can range from mild to severe and are characterized by the sudden onset of overwhelming sleepiness that lasts 30 seconds to 20 minutes. Following brief naps, the narcoleptic usually feels refreshed and relatively free from disturbing symptoms for up to 2 hours. Serious accidents, marital discord, and the inability to hold jobs frequently result from these sleep attacks. Another feature of narcolepsy is the abrupt loss of muscle control (cataplexy). Attacks can be particularly disabling, because they are characteristically precipitated by emotional experiences such as laughter, anger, or excitement. Additional associated symptoms of narcolepsy include sleep paralysis and hypnagogic hallucinations. Sleep paralysis is the skeletal muscle atonia of REM sleep persisting into the awake state. Hypnagogic hallucinations are REM sleep imagery occurring while falling asleep. Patients are sometimes misdiagnosed as schizophrenic if hypnagogic hallucinations are prominent.

Diagnosis of narcolepsy is made by documenting sleep-onset REM periods during a nocturnal polysomnography.¹² In normal sleep REM sleep is usually not seen until about 70 to 90 minutes into sleep. The clinical features of narcolepsy probably represent abnormal manifestations of REM sleep.

Treatment modalities for narcolepsy include behavioral therapies, CNS stimulants, tricyclic antidepressants, or monoamine oxidase inhibitors (only in resistant cases) and L-tryptophan.¹³

Other disorders that may be confused with sleep apnea syndrome include sleep-related abnormal swallowing syndrome, gastroesophageal reflux, depression, alcohol or drug dependence, and sleep-related nocturnal myoclonus.

History of Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea has a remarkably short history considering the incidence and disabling symptoms of the syndrome. Burwell and colleagues published the first description of the syndrome in 1956.¹⁴ Their report compared an obese, somnolent, polycythemic patient with the sleepy red-faced boy, Joe, in the Charles Dickens novel *The Posthumous Papers of the Pickwick Club* (1837). However, Burwell and colleagues did not link their patient's excessive daytime sleepiness to nocturnal sleep fragmentation. In 1966, Gastaut and colleagues were the first investigators to demonstrate repeated apneas in pickwickian patients during sleep.¹⁵ They correctly attributed the excessive daytime somnolence in these patients to nocturnal sleep fragmentation caused by repeated apneas.

The misdiagnosis of narcolepsy in patients with sleep apnea and the general skepticism of excessive daytime somnolence as a valid clinical sign are the two main reasons sleep apnea syndrome was overlooked for so long.

Clinical Manifestations

Sleep apnea patients present with a variety of symptoms and clinical manifestations. Patients with obstructive sleep apnea most often complain of EDS. The patients may experience serious social, economic, and emotional problems from the EDS associated with this disorder. The uncontrollable desire to sleep may predispose the patients to occupational or automobile accidents.

Almost all patients or their bed partners give a history of heavy, loud snoring which has usually been present for several years before the EDS was noted. The snoring is produced from the passage of air through the oropharynx causing vibrations of the soft palate. Typically the snoring is interrupted periodically by

apneic episodes that last 30 to 90 seconds. Bed partners usually describe an episode in which the snoring stops and the patient seems to stop breathing for a period of time. A loud snort followed by a hyperventilation usually signals an end to the apneic episode.

Other common presenting complaints are morning headaches and nausea that result from the hypercarbia which develops with the hypoventilatory episodes. Depression, personality changes, and intellectual deterioration may also develop.

The systemic hypertension that is a common finding in obstructive sleep apnea may be related to the catecholamine release triggered by the systemic hypoxemia. In more advanced severe cases, pulmonary hypertension, polycythemia, and cor pulmonale may develop and become life threatening. However, most patients do not manifest these disturbances because their ventilation during wakeful periods is sufficient to prevent these complications of chronic hypoxia.

A prominent sinus dysrhythmia is commonly associated with the apneic episodes. The extent of bradycardia is directly proportional to the severity of the oxygen desaturation. The greatest degree of cardiac slowing occurs in obstructive apneas in which a Müller maneuver is performed. Increased vagal efferent tone mediates the bradycardia.

The development of severe and life-threatening medical complications from the apneic events clearly depends on the frequency, duration, and degree of hypoxemia and associated hypertensive response.

Physical Findings

A major feature of obstructive sleep apnea is obesity. The increased body weight correlates with increased frequency of apnea and the severity of hypoxemia. However, the morbidly obese, somnolent, hyperventilating patient with cor pulmonale represents only a small number of sleep apnea patients. Lower BMI (body mass index)

patients with obstructive sleep apnea often have more abnormal cephalometrics than obese people.^{16,17}

Obstruction can occur at a number of points in the airway. Physical examination of these patients may reveal hypertrophy of the tonsils or adenoids, retrognathia, micrognathia, macroglossia, deviation of the nasal septum, a thick short neck, or tumors in the nasopharynx or hypopharynx. Both primary and secondary medical conditions are associated with obstructive sleep apnea, owing to their effects on the upper airway anatomy. These may include temporomandibular joint disorders, myxedema, goiter, acromegaly, and lymphoma.

Most patients with classic obstructive sleep apnea have no identifiable craniofacial anomaly. However, there does appear to be a significant subpopulation of sleep apnea patients with craniofacial anomalies.^{18,19} Lowe and colleagues found several alterations in craniofacial form in subjects with obstructive sleep apnea that may reduce the dimensions of the upper airway and subsequently impair stability of the upper airway.²⁰ A sample of 25 adult male patients with moderate to severe obstructive sleep apnea showed a posteriorly positioned maxilla and mandible, a steep occlusal plane, overerupted maxillary and mandibular teeth, proclined incisors, a steep mandibular plane, a large gonial angle, increased upper and lower facial heights, a posteriorly placed pharyngeal wall, and an anterior open bite in association with a long tongue.²⁰ Bacon and colleagues evaluated 32 patients with sleep apnea by cephalometry and demonstrated an anteroposterior shortening of the cranial base, a posterior facial compression with narrowing of the pharyngeal airway, and an increased lower facial height.¹⁸ Rivlin and colleagues reported on nine obstructive sleep apnea patients with posterior displacement of the mandible.²¹ The number of apneas correlated with the total posterior displacement.²¹

Diagnosis

Physical Examination

A diagnostic evaluation includes a thorough history and physical examination, fiberoptic endoscopy, radiologic evaluation, and polysomnography. Little additional information can be gained from routine laboratory tests. Except in severe cases, pulmonary function tests, electrocardiogram (ECG), arterial blood gases, and chest radiographs are often normal during wakefulness in sleep apnea patients.

Other diagnostic tests that may aid in evaluating sleep apnea patients include a complete blood count (CBC), serum electrolytes, and thyroid function tests. Secondary polycythemia may be revealed by a CBC, and nocturnal carbon dioxide retention may be reflected by increased bicarbonate levels. Hypothyroidism, a contributing cause of sleep apnea, may be identified from thyroid function studies.

After a complete history is obtained from the patient and his or her bed partner, a complete clinical examination of the mouth, nasal, pharyngeal, and laryngeal areas is performed. The emphasis of the clinical examination should be the identification of anatomic abnormalities that may contribute to or produce obstruction during sleep. The nose is examined for a deviated nasal septum and enlargement of the turbinates. Micrognathia, retrognathia, and macroglossia may be noted in examination of the oral cavity. Occasionally masses or tumors in the nasopharynx or hypopharynx may be noted. In the pharynx, adenotonsillary hypertrophy, a long soft palate, a large base of the tongue, and excess pharyngeal mucosa are potential causes of obstruction. The larynx is examined for vocal cord webs and paralysis of the vocal cords. Obstructive sleep apnea patients may present with any combination of these anatomic abnormalities.

After topically anesthetizing the nasal cavity and pharynx, a fiberoptic endo-

scope is introduced through the nose. In sequential fashion the nasopharynx, oropharynx, hypopharynx, and larynx are examined. The appearance and position of the soft palate, base of tongue, and lateral pharyngeal walls are evaluated. Changes in the position of the base of the tongue such as forward movement with protrusion of the mandible are noted. The appearance of the pharyngeal airway and degree of pharyngeal wall collapse is noted while the patient performs a modified Müller maneuver. To accomplish this maneuver the patient attempts to inspire with the mouth and nose closed. Increased negative pressure in the pharynx will demonstrate the point of collapse.

Cephalometric Examination

A lateral cephalogram is routinely obtained in the radiologic evaluation of sleep apnea patients (Figure 63-1). Cephalometric analysis is performed to identify any skeletal and soft tissue abnormalities that may exist. The advantages of cephalometry are its easy access, low cost, and minimal radiation exposure. However, it should be recognized that there are obvious limitations of evaluating a three-dimensional area with a two-dimensional lateral cephalometry.

Mandibular or maxillary position can be evaluated by a number of methods including the SNA and SNB angles. Patients with skeletal deficiencies are more likely to have obstruction at the base of the tongue or at the level of the soft palate. Riley and colleagues determined that obstructive sleep apnea patients had an inferiorly positioned hyoid bone, a longer-than-normal soft palate, and a narrowing at the base of the tongue.^{22,23} The position of the hyoid bone is determined by drawing a perpendicular line from the mandibular plane (MP) through the hyoid bone (H). The mean MP-H distance for normal subjects is 15.4 ± 3 mm (see Figure 63-1). The position of the hyoid bone is important because it serves as a central anchor for the muscles of the tongue and thereby partly deter-

mines tongue position. Soft palate length is measured from a line drawn from posterior nasal spine (PNS) to the tip of the soft palate shadow (P). The mean PNS-P distance in normal subjects is 37 ± 3 mm. Posterior airway space is determined by a line drawn from point B through the gonion (Go) intersecting the base of the tongue and the posterior pharyngeal wall. Figure 63-2 demonstrates change in posterior airway spaces following maxillomandibular advancement. Mean posterior airway space in normal subjects was determined to be 11 ± 1 mm. Lower face height is measured from the anterior nasal spine (ANS) to the menton (Me). There is no absolute value for this measurement in obstructive sleep apnea patients. However, some studies have

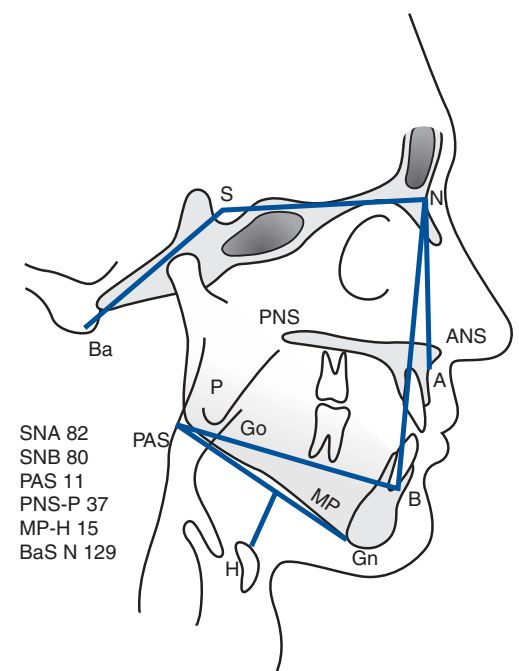

FIGURE 63-1 Cephalometric screening used for initial evaluation of patients with obstructive sleep apnea syndrome. shown an increased lower face height and a shortened cranial base with obstructive sleep apnea patients.¹⁸

Computed Tomography

Computed tomography (CT) is an alternative to cephalometry and has been used to provide a quantitative assessment of the upper airway at various levels. With three-dimensional CT reconstructions, Lowe and colleagues found obstructive sleep apnea patients with larger tongue surface areas and smaller airway surface areas.²⁴ Haponik and colleagues found significantly decreased cross-sectional areas of the nasopharynx, oropharynx, and hypopharynx in obstructive sleep apnea patients when compared with control subjects by using CT scanning.²⁵ Some authorities feel that the airway can only be assessed by a CT scan. However, Riley and colleagues compared patients who

had three-dimensional CT scans and found a statistically significant correlation between the posterior airway space (PAS) measured on the lateral cephalogram and the volume of the pharyngeal airway measured on CT scans.^{23,26} Waite and Villos demonstrated by helical CT analysis that maxillomandibular advancement increases both anteroposterior and lateral dimension of the airway at all levels from nasopharynx to hyoid.²⁷ Many studies are currently being done to determine the effects of patient position and changes in airway. A cephalogram and a CT scan are static evaluations at a fixed time of a dynamic system and they should be viewed as only part of the overall evaluation of the patient.

Polysomnography

Nocturnal polysomnography remains the gold standard for establishing the diagnosis of sleep apnea, quantitating its severity, and determining the success of treatment modalities. The study is performed in a sleep laboratory and the patient's sleep is monitored overnight. At least 4 hours of total sleep time must be recorded for a diagnostic study. The components of the polysomnogram include the EEG, electro-oculogram (EOG), electromyogram (EMG), and electrocardiogram (ECG, lead V₂). Sleep staging and architecture are determined by the EEG, EOG, and EMG tracings. Potentially lethal cardiac dysrhythmias are detected by the ECG. Oxygen saturation is measured by ear oximetry. A 5% or greater decrease in arterial oxygen saturation from baseline is significant during episodes of apnea or hypopnea. Respiratory effort and breathing pattern are measured using respiratory inductive plethysmography or by measuring intrathoracic pressure changes with an esophageal balloon catheter. The distinction between an episode of central apnea and obstructive apnea is made by correlating airflow at the nose and mouth with movement of the abdominal and thoracic respiratory muscles. Central apnea occurs

if both airflow and respiratory muscle movement stop simultaneously. An episode of obstructive apnea occurs when airflow at the mouth and nose ceases but respiratory muscles in the abdomen and thorax continue to move dysfunctionally.

Of particular interest are the number of respiratory events (apneas and hypopneas), the number of oxygen desaturations below 90%, and the lowest oxygen desaturation. The respiratory disturbance index (RDI) can be calculated from these data:

$$\text{RDI} = \frac{\text{Apneas} + \text{Hypopneas}}{\text{Total sleep time}} \times 60$$

An RDI greater than 5 is considered abnormal and an RDI greater than 20 is considered clinically significant, because EDS usually does not occur below this level. Obstructive sleep apnea also becomes clinically significant when oxygen desaturation events fall below 85%.

Site of Obstruction

Following a complete presurgical evaluation, each patient is grouped according to the site of obstruction: type I, oropharynx; type II, oropharynx and hypopharynx; type III, hypopharynx. In a review of 40 obstructive sleep apnea patients, Riley and colleagues found the majority of patients had a type II obstruction (soft palate and base of tongue).²⁸

The mandible, base of tongue, hyoid, and pharyngeal wall are intimately related by their muscular and ligamentous attachments. The mandible is related to the base of the tongue by the genioglossus muscle. The tongue, through multiple muscular and connective tissue attachments, is related to the hyoid bone and to the mandible in such a way that retraction of the mandible results in a narrowing of the airway and posterior movement of the tongue. Compensatory mechanisms exist in non-sleep apneic patients to prevent occlusion of the airway. However, in sleep apneic patients, these mechanisms do not exist or are unable to compensate adequately.

Obstruction of the upper airway is primarily prevented by the action of the pharyngeal dilating muscles contracting in phase with respiration. Reduced muscle tone is normal and prominent during REM sleep. However, obstructive sleep apnea patients may have a significant reduction in muscle activity during non-REM sleep so that the pharynx becomes narrower and airway resistance increases. In patients with abnormal skeletal development the reduction in size of the resting airway may predispose them to upper airway obstruction during sleep.

The patency of the upper airway is determined by a balance between the pharyngeal musculature and the negative oropharyngeal pressures that are generated from resistance to airflow in the nasopharynx. Because the airway of obstructive sleep apnea patients is unstable even at rest, any structural narrowing of the airway will eventually hinder the muscular component of the balance. Collapse of the airway in obstructive sleep apnea is primarily a result of high intraluminal negative pressures associated with hypotonic pharyngeal wall musculature and disproportionate anatomy in either the oropharynx or hypopharynx or both. Disproportionate anatomy includes any combination of large base of tongue, long soft palate, narrow mandibular arch, shallow palatal arch, or retrognathic mandible.

Medical Treatment

Once the diagnosis has been confirmed, the treatment approach for sleep apnea is determined by the severity of the physiologic derangements and the predominant type of apnea. Regardless of the predominant type of apnea present, all patients should be cautioned that certain drugs may precipitate or exacerbate obstructive sleep apnea. Alcohol and other central nervous system depressants have been shown to aggravate sleep apnea and even to precipitate apnea and oxygen desaturations in normal persons.²⁹

Weight loss and nasal continuous positive airway pressure are the initial modes of therapy that should be initiated in obese patients with moderate obstructive sleep apnea. A study of 16 patients who lost an average of 20 kg showed fewer apneas, reduced oxygen desaturations, and less daytime sleepiness than a control group of patients who did not lose weight.³⁰ Many patients can relate weight gain in preceding years to an increase in severity of their obstructive sleep apnea symptoms. Unfortunately weight loss by dietary measures is seldom sustained, and obstructive sleep apnea symptoms recur with weight gain. Riley and colleagues found that 47 of 50 obstructive sleep apnea patients who were between 20 and 100% overweight at the time of diagnosis had regained all the weight they had initially lost 5 to 7 years later.³¹

The role of oxygen therapy in the treatment of sleep apnea is controversial. In a study by Motta and Guillemainault, the administration of oxygen increased the duration of apneic episodes and led to worsening of acidosis and hypercarbia during both REM and non-REM sleep.³² It is unknown how many of their patients had chronic obstructive lung disease. Other studies have shown that supplemental oxygen therapy consistently reduced the severity of oxygen desaturation and decreased the frequency of apnea.^{33,34}

The combined experience of these reports suggests that oxygen therapy limited to a flow rate of 2 L/min can be used safely in most obstructive sleep apnea patients and will produce beneficial effects on respiration. The dangers of profound hypoxemia are greater than the concerns of prolonged apnea, acidosis, and hypercarbia. The effects of oxygen therapy on a patient with severe airway obstruction or chronic respiratory acidosis should be monitored with oximetry or polysomnography.

Several drugs have been used in the treatment of obstructive sleep apnea syn-

drome with variable results. The carbonic anhydrase inhibitor acetazolamide stimulates respiration by producing a metabolic acidosis. This drug reduced the number of apneas and decreased the severity of oxygen desaturations in a group of patients with central sleep apnea.³⁵ However, in several cases, acetazolamide given to patients with mild obstructive sleep apnea produced more frequent obstructive apneas of longer duration.³⁶ Therefore, acetazolamide is probably not indicated in the management of obstructive sleep apnea syndrome.

Some patients with obstructive sleep apnea benefit from the respiratory stimulant effect of progesterone, especially those with the obesity-hypoventilation syndrome.³⁷⁻⁴⁰ Progesterone increases alveolar ventilation and improves oxygenation, but its effect on frequency of apnea is limited. Major side effects that limit its long-term use include decreased libido, alopecia, and impotence.

The tricyclic antidepressant protriptyline is the most effective and best studied drug for the treatment of obstructive sleep apnea.⁴¹ In a study of 12 patients, Smith and colleagues showed a reduction in apnea frequency and oxygen desaturation during non-REM sleep, in addition to a decrease in REM sleep.⁴² Protriptyline produces its beneficial effect by a preferential stimulation of upper airway muscle tone and by decreasing the percentage of time spent in REM sleep, thereby reducing the more severe REM-related apneas. Anticholinergic side effects such as dry mouth, constipation, urinary retention, and impotence are frequent and limit its use.

Oral Appliances

The use of a variety of prosthetic devices is another approach to treatment. The nasopharynx and the posterior tongue are the two anatomic areas of concern. Insertion of a nasopharyngeal airway has been used to prevent upper airway occlusion at the level of the soft palate.⁴³ The American Sleep Disorders Association recommends

that oral appliances may be used in patients with primary snoring, mild obstructive sleep apnea, or in patients with moderate to severe obstructive sleep apnea who refuse or are intolerant of nasal continuous positive airway pressure. The Food and Drug Administration has granted market clearance for 32 oral appliances for snoring but only 14 of these have received market clearance for treatment of snoring and obstructive sleep apnea (Table 63-1).⁴⁴ Common side effects of oral appliance therapy include excessive salivation, xerostomia, soft tissue irritations, transient discomfort of the teeth and temporomandibular joint (TMJ), and temporary minor occlusal changes. Uncommon, more serious complications include permanent occlusal changes and significant TMJ discomfort.

Removable anterior repositioning splints have been used somewhat successfully to temporarily advance the mandible while passively bringing the tongue forward with it.⁴⁴⁻⁴⁶ The optimal amount of forward movement is between 50 and 75% of the patient's maximum protrusive distance. An important design feature of these devices is that the appliance must maintain the mandible in the forward position while the patient is asleep. Bear

and Priest used a mandibular anterior repositioning splint to determine whether surgical advancement of the mandible would have any lasting and positive effect on a patient's obstructive sleep apnea.⁴⁷

A tongue-retaining device (TRD) that pulls the tongue forward without moving the mandible forward has also been used successfully in some patients with mild to moderate obstructive sleep apnea.^{48,49} The TRD functions by placing the tongue into a cup or bubble positioned between the anterior teeth. Surface adhesion holds the tongue in place and the appliance requires that the patient's jaw remains partially open. One disadvantage of the TRD is that the tongue is not always held forward because surface tension of the tongue in the bubble is lost after a time. The TRD and mandibular anterior repositioning splints both force nasal breathing, which can be difficult for patients with inadequate nasal airways.

Arguably, the most researched oral appliance is the Klearway titratable appliance developed by Alan Lowe, DMD, PhD, at the University of British Columbia, Canada. It features a maxillary and mandibular component connected with an adjustable screw mechanism (Figure 63-3). The components

are made of a thermoactive acrylic resin that is slightly soft at body temperatures and very compliant at high temperatures. This property decreases major tooth discomfort and considerably increases retention in those patients who have lost a significant number of teeth. A unique feature of the Klearway appliance is that it permits both lateral (1 to 3 mm) and vertical (1 to 5 mm) jaw movement during sleep which reduces the risk of TMJ and jaw muscle discomfort. This movement also facilitates oral breathing in patients with nasal airway obstruction. The screw mechanism of the appliance allows for an 11 mm anterior movement of the mandible with a total of 44 incremental steps of 0.25 mm. In a study of 38 patients with moderate to severe obstructive sleep apnea by Lowe and colleagues, the Klearway appliance reduced the RDI to less than 15 per hour in 80% of the moderate group and in 61% of the severe group.⁵⁰ The Klearway appliance is marketed worldwide by Great Lakes Orthodontic Ltd., Tonawanda, NY, USA.

Another commonly used and effective oral appliance is the Herbst appliance, which is an anterior mandibular positioning device. It consists of two full-coverage clear acrylic components snapped onto the maxillary and mandibular teeth connected with two rod and tube attachments that allow vertical opening, protrusion, limited lateral movement, and no retrusive movement. It is used only at night and advances the mandible 5 to 7 mm or at least 75% of the patient's maximum protrusive distance. A study by Clark and colleagues on 24 patients with mild to severe obstructive sleep apnea patients using the Herbst appliance showed a significant improvement in the RDI after 4 months of appliance use in 58% of the subjects on the post-appliance polysomnogram.⁵¹

Another disadvantage of oral appliances is the need to wear them nightly. As with any device, compliance has been shown to be a problem with oral appliances. If appliance therapy is successful,

further treatment options may include mandibular advancement surgery to achieve the same forward tongue position on a permanent basis.

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) through the nose has been shown to be quite successful in treating a broad range of obstructive sleep apnea patients and is presently the most successful nonsurgical treatment.⁵²⁻⁵⁴ The nasal CPAP is administered while the patient is asleep by means of a tight-fitting mask that is connected to a compressor. A CPAP of 7 to 15 cm of water acts as a pneumatic splint of the upper airway and prevents passive collapse of soft tissues during respiration. Stimulation of mechanoreceptors of the genioglossus muscle leading to increased airway tone has also been suggested as a mechanism of action. Sullivan and colleagues were the first to report the successful treatment of sleep apnea with nasal CPAP in 1981.⁵⁵ In most cases this therapy is effective in eliminating apneas and hypopneas, improving arterial oxygen saturations, reducing or eliminating excessive daytime sleepiness, and eliminating sleep disruption and fragmentation. CPAP may be combined with surgery and weight loss, or it may be used as a sole form of therapy. Although initially recommended for short-term relief of sleep apnea, the use

of nasal CPAP for long-term care of patients has increased over the past few years. In recent years bilevel positive airway pressure (Bi-PAP) systems that allow independent regulation of inspiratory and expiratory pressures and the newest modification in CPAP systems, Auto-CPAP, have been used to more effectively treat obstructive sleep apnea and increase tolerance and compliance.^{56,57} Auto-CPAP units adjust the CPAP throughout the night rather than delivering one fixed pressure. Optimal CPAP is delivered to the patient adjusting for positional changes, alcohol or sedative effects, sleep-state-dependent changes (REM vs non-REM), and the effects of upper airway infections or congestion. Bi-PAP (\$2,500) and Auto-CPAP (\$1,600) systems are more expensive than traditional CPAP (\$600 to \$800) systems.

Despite the uniform success of this therapy, patient compliance remains a problem. Compliance rates at 12 months have been reported as low as 54%.⁵⁸ The average nightly use of CPAP is 4.8 hours and the rate of use is usually determined in the first week of use. Overall approximately one-third of patients love CPAP, one-third struggle with CPAP but eventually tolerate it, and one-third hate CPAP and never use it. Patient dissatisfaction results from nasal dryness and congestion, sore throat, dryness of the skin and eyes, claustrophobia, and the inability to tolerate the noise, dis-

comfort, or mask. Careful patient selection and follow-up are essential if nasal CPAP is selected as a treatment modality.

Surgical Treatment

Surgery has been the primary form of therapy for obstructive sleep apnea. To be successful the surgical procedure must either bypass the obstructive area or prevent collapse of the soft tissues in the upper airway at the obstruction. Many patients and surgeons tend to view surgical treatment of obstructive sleep apnea as a quick and permanent cure. However, a clear definition of what constitutes a cure is lacking in the literature. This problem often makes a determination of the efficacy of individual surgical procedures difficult. Only objective data obtained from a postoperative polysomnogram can be accepted as proof of efficacy for surgical procedures. Currently the procedures used in the surgical treatment of obstructive sleep apnea include tracheostomy, nasal surgery, uvulopalatopharyngoplasty, and several orthognathic surgical procedures. Selection of the individual procedure is determined by the severity of the sleep apnea, the presence of a maxillofacial skeletal deficiency, the site of the obstructive segment, and the presence of morbid obesity.

Tracheostomy

Tracheostomy was the first efficacious surgical procedure for treating obstructive sleep apnea, performed by Kuhlo and colleagues in 1969.⁵⁹ It is almost 100% curative in relieving the signs and symptoms of obstructive sleep apnea because it bypasses all the potential obstructive sites in the upper airway. After tracheostomy there is a rapid and striking reduction in daytime somnolence and a marked improvement in sleep architecture due to a major reduction in the frequency of arousals. Sinus dysrhythmias, bradycardia, pulmonary hypertension, hypoxemia, and apnea all improve dramatically with the procedure. Tracheostomy

clearly is an effective surgical treatment for patients with obstructive apnea.

The disadvantages of a permanent tracheostomy can have a devastating effect on sleep apnea patients. Almost all patients experience psychological depression from the social and medical problems associated with a lifelong tracheostomy. The tracheostomy leaves the patient esthetically disfigured and exposes the patient to common local complications such as bleeding, infection, pain, and granulation tissue formation. Patients are also at increased risk for the more serious complications of tracheal stenosis or erosion into an adjacent blood vessel. Because of these disadvantages and complications, a permanent tracheostomy should be reserved for severe cases of obstructive sleep apnea with significant cardiovascular symptoms. Simmons and colleagues have suggested that tracheostomy should be the primary therapy for all patients who spend substantial time in severe oxygen desaturations below 50% and for those who have life-threatening cardiac dysrhythmias during sleep apnea.⁶⁰ Tracheostomy may also be used as an interim treatment until adjunctive procedures to reconstruct the upper airway are completed.

Nasal Surgery

Significant obstruction in the nasal cavity has been shown to cause excessive daytime sleepiness, sleep fragmentation, hypopneas, and periodic breathing during sleep.⁶¹ In most patients with moderate to severe obstructive sleep apnea, nasal obstruction is not the major contributing factor. The obstruction may be due to a deviated nasal septum, nasal polyps, or enlargement of the turbinates. In these patients septoplasty, nasal polypectomy, or turbinectomies are usually helpful only as adjunctive surgical procedures in the treatment of obstructive sleep apnea. Unless the obstruction in the nasal cavity is severe, surgical correction usually will not yield any significant improvement on a repeat polysomnography.

Uvulopalatopharyngoplasty

The oropharynx and soft palate can cause significant airway obstruction during sleep. At least 10% of persons over the age of 40 years snore regularly and significantly. Loud and intermittent snoring is found in almost all patients with obstructive sleep apnea. In many cases habitual snoring is present for many years before sleep apnea is diagnosed. Ikematsu followed a large number of habitual snorers over several years and found that 91% of these patients had decreased oropharyngeal dimensions and longer soft palates and uvulas than normal subjects.⁶² He was able to eliminate their snoring by surgically excising the excessive soft tissue in the palatal folds and partially excising the uvula.

With minor modifications, Simmons and colleagues and Fujita and colleagues popularized the uvulopalatopharyngoplasty (UPPP) for the treatment of obstructive sleep apnea.^{60,63} The procedure was designed to eliminate oropharyngeal obstruction by performing a tonsillectomy and adenoidectomy, excising the uvula, removing redundant lateral pharyngeal wall mucosa, and resecting 8 to 15 mm along the posterior margin of the soft palate.

The surgical technique of UPPP varies to some degree by patient and surgeon, but the basic goal is to shorten the palate and widen the posterior airway space (Figure 63-4). A mucosal incision is created with electrocautery on the anterior surface of the soft palate. The dissection is frequently carried laterally to include the palatine tonsil. The tonsillar bed is coagulated and hemostasis achieved. Palatal muscle is excised and mucosa from the nasopharynx is pulled forward for primary closure. Multiple interrupted resorbable sutures are placed. If the tonsil is removed, the mucosa of the anterior fauces pillar is closed to the posterior fauces pillar. This attempt to remove redundant pharyngeal

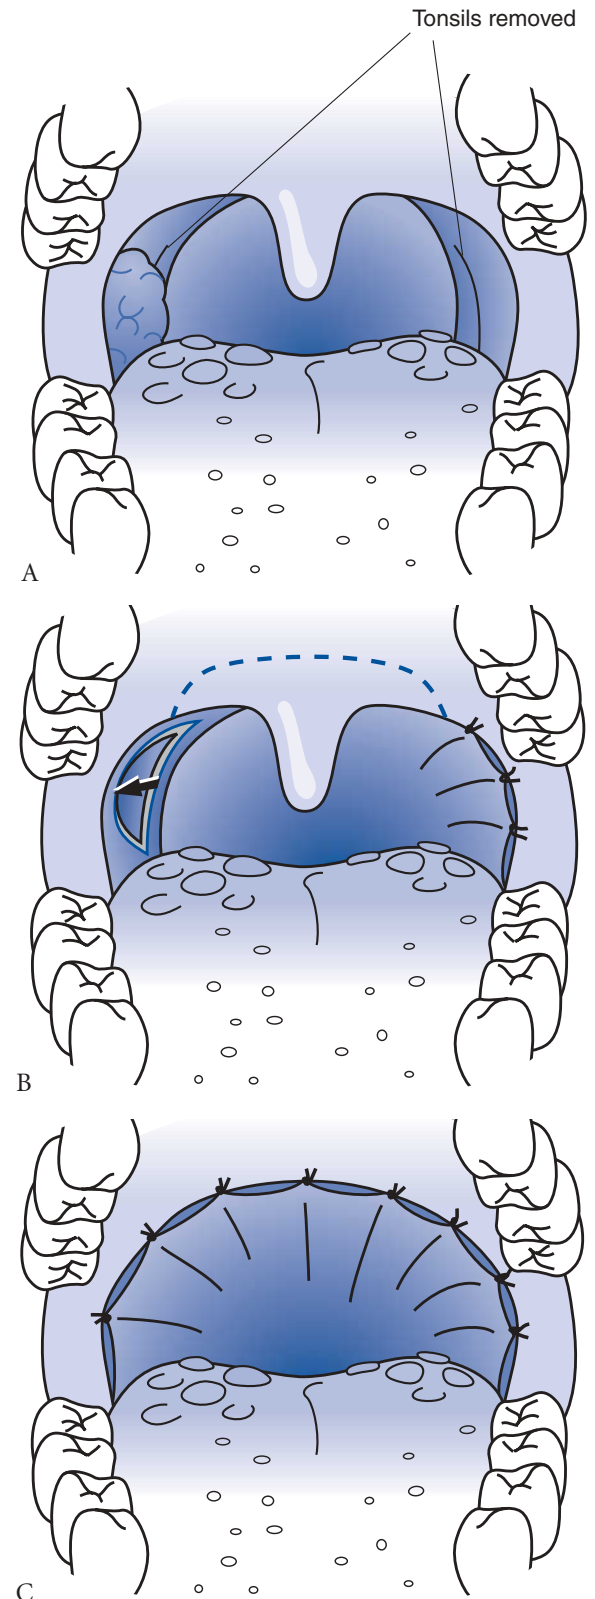

FIGURE 63-4 A–C, Uvulopalatopharyngoplasty. Tonsils and uvula are removed and the anterior pillar is closed to the posterior pillar. Adapted from Tiner BD, Waite, PD. *Surgical and nonsurgical management of obstructive sleep apnea*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1540.

tissue and stretch or tighten the posterior pharyngeal wall results in constriction. In addition, frequently by shortening the soft palate, the width of the soft palate is thickened, as demonstrated cephalometrically. Lymphoid tissue from the tonsillar fossa can be removed separately or in conjunction with the uvula (Figure 63-5). The amount of velum to be excised is determined by the location of palatal competence and closure of the nasopharynx. These can be estimated or identified during nasopharyngoscopy. Palatal incompetence can occur but usually is of minimal concern if the patient swallows carefully. Pain with swallowing usually lasts for several weeks.

UPPP results in symptomatic improvement in the patient and eliminates habitual snoring in almost all cases. However, reports show that significant objective improvement on the postoperative polysomnogram ranges only from 41 to 66%.^{58,60,64,65} This procedure only eliminates the obstruction at the level of the soft palate and does not address obstructions occurring in the hypopharyngeal and base

FIGURE 63-5 Surgical specimen of tonsils and uvula. Reproduced with permission from Tiner BD, Waite, PD. Surgical and nonsurgical management of obstructive sleep apnea. of tongue areas. Many patients have more than one site of obstruction. If UPPP is performed when the presurgical evaluation demonstrates obstruction localized to the soft palate–tonsil area, then the success rate of the surgical procedure approaches 90% treating obstructive sleep apnea.^{23,26}

Complications from UPPP are related to changes in palatal function. Permanent velopharyngeal incompetence occurs in approximately 5% of patients and is more common during the first 2 months postoperatively. Patients experience occasional reflux of liquids into the nose and mild nasal air escape during speech. However, hypernasal speech and changes in the quality of the patient’s speech are usually not seen. Simmons and colleagues reported a 5 to 10% rate of minor wound infections that resolved with antibiotics.⁶⁴ Palatal stenosis is definitely a risk with this operation and occurs in about 1% of patients. It occurs more frequently with excessive resections of the posterior tonsillar pillars and injudicious use of electrocautery. Postoperative pain after UPPP is significant, and narcotic analgesia should be used with caution to prevent sedation-induced exacerbation of obstructive sleep apnea. Postsurgical deaths have resulted from the combination of pharyngeal edema and narcotic use.

Laser-Assisted Uvulopalatoplasty

In the late 1980s Dr. Yves-Victor Kamami (Paris, France) designed a procedure to reshape and recontour the soft palate under local anesthesia with a CO₂ laser to treat snoring and selected patients with obstructive sleep apnea syndrome.⁶⁶ He originally named the procedure “laser resection of the palatopharynx” or LRPP. Initially the procedure was accomplished in four or five sessions spaced at monthly intervals. Over time the procedure evolved into a one-stage technique for most patients. It consisted of two paramedian vertical incisions placed lateral to the uvula extending up toward the junction of the

hard and soft palates for 2 to 3 cm. A second horizontal incision was placed just under the roof of the uvula leaving a small uvula to prevent centripetal scar formation. Over a 5-year period, Kamami treated 63 obstructive sleep apnea patients with this technique. The RDI was reduced by more than 50% in 55 patients that were classified as successful responders. The RDI improved from 41.5 to 16.9 for the average responder, and for the entire group the average RDI improved from 41.3 to 20.3.

In the early 1990s in the United States, Dr. Yosef Krespi modified the procedure and renamed it “laser-assisted uvulopalatoplasty” or LAUP. He initially used the procedure to treat loud habitual snoring. In a study of 280 patients treated in the office under local anesthesia, 84% were cured with an average of 2.7 sessions.⁶⁷ Overall results for obstructive sleep apnea patients treated with LAUP are far less encouraging, with an average successful surgical response of 52.2%.⁶⁸ Based on these findings the current main indications for LAUP include loud habitual snoring, upper airway resistance syndrome, and mild obstructive sleep apnea (apnea index < 20). All snoring patients who elect to undergo LAUP should be evaluated for obstructive sleep apnea preoperatively and again postoperatively if obstructive sleep apnea was previously diagnosed. If not, then the patient and surgeon may be lulled into a false sense of security by eliminating the snoring without eliminating the undiagnosed obstructive sleep apnea, potentially increasing patient morbidity and mortality.⁶⁹

The most common complication following LAUP is a moderate to severe sore throat. Patients experience pain 8 to 10 days after surgery and reach their peak pain intensity on the fourth or fifth postoperative day. Pain control is achieved with oral analgesics and anesthetic gels. The risk for velopharyngeal insufficiency is low since the procedure is frequently done in stages and the surgeon has the opportunity to evaluate speech and soft palate function

after each session. Patients are also at low risk for bleeding and infection. The great majority of patients can eat, drink, and speak almost immediately and can resume full activities the following day.

Orthognathic Surgery Procedures

Various orthognathic surgical procedures have been described for the treatment of obstructive sleep apnea. The majority of patients have airway obstruction at the level of the soft palate and at the base of the tongue (type II obstruction). Orthognathic surgical procedures can change the size of the airway in several regions. Mandibular advancement and genial advancement probably work by changing the position of the mandible and hyoid bone with subsequent effects on the genioglossus and hyoglossus muscles. Obstructive sleep apnea patients with identifiable craniofacial anomalies can clearly benefit from a variety of these procedures.

Mandibular Advancement Total mandibular advancement was the first orthognathic surgical procedure used in the treatment of obstructive sleep apnea. Kuo and colleagues in 1979 and Bear and Priest in 1980 reported complete reversal of sleep apnea symptoms in patients with horizontal mandibular deficiency treated by mandibular advancement.^{47,70} More recently Alvarez and colleagues reported the successful treatment of an edentulous patient with sleep apnea by mandibular and genial advancement.⁷¹

A bilateral sagittal ramus osteotomy is usually the procedure of choice for total mandibular advancement. The amount of advancement is determined preoperatively from the orthognathic surgery database. Adjunctive orthodontic treatment is frequently necessary to obtain the desired occlusion and to eliminate dental compensations that would otherwise limit the amount of advancement. After advancement with the standard surgical technique, the fragments are rigidly fixed with screws or bone

plates. For large advancements of 7 mm or more, long-term stability is enhanced with a 5- to 7-day course of maxillo-mandibular fixation and skeletal suspension wires. In advancements of 6 mm or less, maxillomandibular fixation is usually not necessary.

The exact reason for how mandibular advancement improves obstructive sleep apnea is not clearly known, but the suspected effect is the pulling of the tongue forward off the pharyngeal wall. This effect is created by anteriorly moving the insertion of the genioglossus and geniohyoid muscles. If this were the only factor, then anterior chin procedures would be equally effective as total mandibular procedures. Variations of geniostomies have been designed to maximally pull the tongue muscles forward.

Genial Advancement A rectangular osteotomy apical to the teeth but maintaining the inferior border of the mandible allows the genial tubercles with their muscular attachments to be maximally advanced with minimal cosmetic change (Figure 63-6). A modified vestibular mucosal incision is made in the anterior mandible. Periosteum is reflected down to the inferior border. An oscillating saw is used to make parallel horizontal cuts that include the genial tubercle. The osteotomy is designed in a shape similar to a drawer so that it can be pulled outward with the genial muscles. The bone must be broad enough cuspid to cuspid to be rotated 90° and set on top of the buccal cortex. The outer cortical and cancellous bone of the rectangle can then be removed and the inner cortex rigidly fixed with bone screws. Any hemorrhage from the cancellous bone should be controlled.

This procedure does not change the esthetic chin or advance the anterior belly of the digastric muscle, which may be helpful in suspending the hyoid. In contrast to this procedure a horizontal sliding geniostomy does advance the genial tubercles and the anterior belly of the digastric muscle.

FIGURE 63-6 Genial tubercle advancement. The outer table of symphysis is removed and the inner table is secured with 2 mm screws. Adapted from Tiner BD, Waite, PD. *Surgical and nonsurgical management of obstructive sleep apnea*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillo-facial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1542.

Genial Advancement with Hyoid Myotomy and Suspension In 1984 Riley and colleagues described an alternative technique in which an inferior mandibular osteotomy and an associated hyoid myotomy and suspension were used in the treatment of obstructive sleep apnea (Figure 63-7).⁷² This technique is similar to a horizontal mandibular osteotomy, which is commonly used for advancement genioplasty. The osteotomy is designed to include the genial tubercle on the inner cortex of the anterior mandible where the genioglossus muscle attaches. Repositioning the anteroinferior segment of the mandible forward with the attached genioglossus muscle theoretically pulls the tongue forward and improves the hypopharyngeal airway. In conjunction with the osteotomy, the body and greater cornu of the hyoid are isolated

FIGURE 63-7 Inferior mandibular osteotomy and hyoid myotomy. A, Omohyoid, sternohyoid, and thyrohyoid muscles released (see Figure 63-8 for more detail on muscular relationships). B, Inferior segment is advanced anteriorly and locked on the anterior mandible. Adapted from Tiner BD, Waite, PD. *Surgical and nonsurgical management of obstructive sleep apnea*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1543.

through a submental incision. The infrahyoid muscles are transected, taking care to remain on the hyoid bone at all times to avoid injury to the superior laryngeal nerves (see Figure 63-7A). This allows the hyoid bone to be pulled anteriorly and superiorly. Strips of fascia or nonresorbable suture are passed around the body of the hyoid and attached to the intact portion of the anterior mandible to complete the hyoid suspension.

In 1989 Riley and colleagues published a review of 55 patients with obstructive

sleep apnea who were treated with inferior mandibular osteotomy and hyoid suspension.⁷³ Forty-two patients had obstruction at both the oropharynx and hypopharynx and received concomitant UPPP and inferior mandibular osteotomy with hyoid myotomy and suspension. The remaining 6 patients were determined to have obstruction localized to the base of the tongue and underwent the osteotomy and hyoid suspension only. All patients were reevaluated 6 months following surgery by polysomnography. Thirty-seven patients (67%) were considered to be responders to surgery based on the polysomnogram results. Genioglossus advancement ranged from 8 to 18 mm with a mean of 13 mm. All responders to surgery showed significant improvement in their RDI and oxygen desaturation events. Eighteen patients (33%) were considered nonresponders and failed to show significant improvement by polysomnography. The presence of preexisting chronic obstructive pulmonary disease was found to be a determining factor in increasing the risk of failure.

In 1994 Riley and colleagues reported on a new modified technique for hyoid suspension that fixed the hyoid to the thyroid cartilage instead of the anterior margin of the mandible.⁷⁴ When this modified technique was performed with inferior mandibular osteotomy, in lieu of the original hyoid suspension technique, the surgical response rate (with or without UPPP) was raised to 79.2%. The 5 nonresponders in this study of 24 patients achieved postoperative RDI values close to levels at which they would have been considered surgical responders.

Long-term follow-up of these patients has shown that the indication for this procedure is limited. Patients with normal pulmonary function, normal skeletal mandibular development, the absence of obesity, and moderate obstructive sleep apnea are candidates for treatment with inferior mandibular osteotomy with hyoid myotomy and suspension.

The most serious reported complication from a hyoid suspension has been severe aspiration in one patient, in which the thyrohyoid membrane was totally sectioned.²⁸ Other complications have included wound infections, transient sensory disturbances of the mental nerve, and mandibular fracture. An advantage to hyoid suspension is that it circumvents the need for maxillomandibular fixation and does not affect the occlusion.

Maxillomandibular Advancement Combined advancement of the maxilla and mandible with or without hyoid suspension is the most recent and efficacious surgical procedure for the treatment of obstructive sleep apnea. The surgical technique includes a standard Le Fort I osteotomy in combination with a mandibular sagittal split osteotomy for advancement of the maxilla and mandible. A concomitant inferior mandibular osteotomy with or without hyoid myotomy and suspension, as previously described, is also performed. This surgery may result in a significant facial change, which is most often favorable (Figures 63-8 and 63-9). Several authors have described the use of maxillomandibular advancement (MMA) in treating large series of obstructive sleep apnea patients.⁷⁵⁻⁸⁰ In a series of 23 patients, Waite and colleagues performed a high sliding horizontal geniotomy without the hyoid myotomy and suspension.⁷⁵ All patients were reevaluated by polysomnography at 6 weeks postoperatively. The surgical success with MMA was 65% based on a postsurgical RDI of less than 10. Riley and colleagues reported the largest series of obstructive sleep apnea patients treated with MMA in which 98% (89 of 91) were successfully treated based on a postoperative RDI of less than 20 with at least a 50% reduction in the RDI compared to the preoperative study.⁷⁶ It should be noted that 67 of the 91 patients (74%) did not receive phase 1 therapy based on their two-phase protocol for reconstruction of the upper

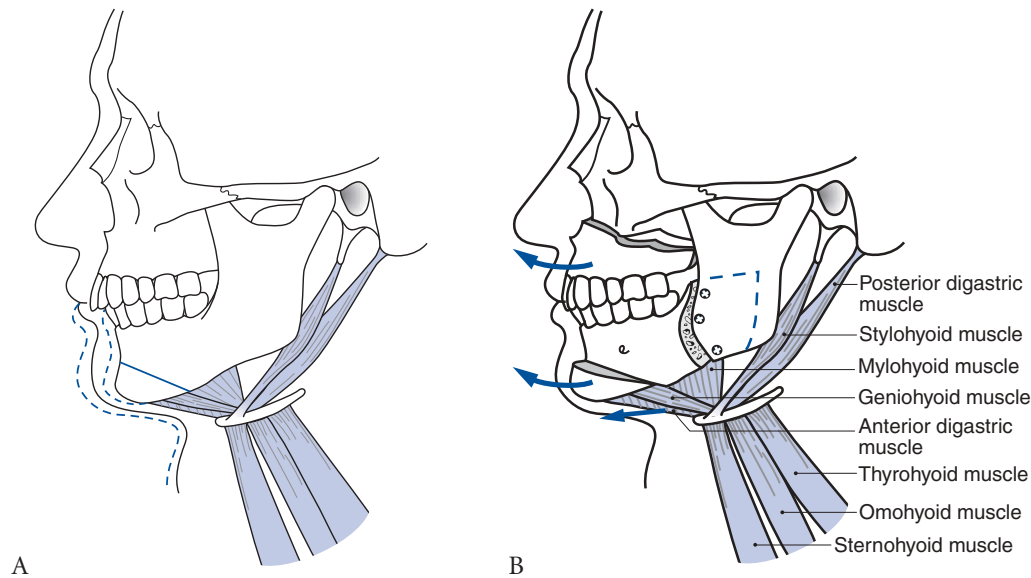

FIGURE 63-8 Schematic drawings of preoperative (A) and postoperative (B) two-jaw advancement, genial advancement, and hyoid suspension. Adapted from Tiner BD, Waite, PD. *Surgical and nonsurgical management of obstructive sleep apnea*. airway. Despite this, the MMA was labeled a phase 2 procedure. In 1997, Hochban and colleagues reported a 98% success rate on 38 obstructive sleep apnea patients consecutively treated with a 10 mm MMA as the primary surgery, without any adjunctive procedures.⁷⁷ Their criteria for success were based on the more rigid postoperative RDI of less than 10. Patient selection for MMA was based on subjective symptoms of excessive daytime sleepiness, an RDI of greater than 20, and specific craniofacial characteristics determined cephalometrically. Only 2 patients who were morbidly obese were treated surgically. Based on their excellent results the authors concluded that a stepwise algorithm of staged surgical procedures was not justified. In a series of 50 obstructive sleep apnea patients consecutively treated with MMA, Prinsell reported a 100% success rate based on a postoperative RDI of less than 15, an apnea index (AI) of less than 5, or a reduction in the RDI and AI of greater than 60%.⁷⁸ In this series occasional concomitant nonpharyngeal procedures and an anterior interior mandibular osteotomy were accomplished with the MMA as a sin-

gle-stage operation. In 1999 Lee and colleagues proposed a three-stage protocol for the surgical treatment of obstructive sleep apnea patients.⁷⁹ All 35 patients in their series had type II obstruction with collapse at the oropharyngeal and hypopharyngeal areas. Stage 1 reconstruction consisted of a UPPP and inferior sagittal osteotomy with genioglossus muscle advancement, or an anterior mandibular osteotomy. If stage 1 was unsuccessful, then patients advanced to stage 2, which consisted of MMA with rigid fixation. A hyoid myotomy and suspension was the sole component of stage 3 reconstruction. Based on postoperative polysomnography, 69% (24 of 35) were considered surgical responders based on an RDI of less than 20. Of the 11 stage 1 failures, 3 elected to proceed to stage 2 reconstruction with MMA. All patients who underwent MMA had a postoperative RDI of less than 10, indicating a 100% response rate. No patient required stage 3 reconstruction. Bettega and colleagues treated 51 consecutive obstructive sleep apnea patients according to the Stanford two-step surgical procedure.⁸⁰ Forty-four patients had phase 1 surgery with a success

FIGURE 63-9 Preoperative (A) and postoperative (B) photographs of a patient with obstructive sleep apnea syndrome who underwent two-jaw surgery with a genial advancement. Reproduced with permission from Tiner BD, Waite, PD. *Surgical and nonsurgical management of obstructive sleep apnea*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1545.

rate of 22.7% (10 of 44). Twenty patients underwent MMA as part of phase 2 in the protocol. Of these, 75% (15 of 20) were considered to be surgical responders based on a postoperative RDI of less than 15 and at least a 50% reduction in the RDI. Of the 5 failures, 3 had postoperative RDIs of less than 20.

The PAS consistently increases with maxillomandibular advancement. However, there is no direct relationship between the gain in PAS and the remission of sleep apnea. MMA is effective for patients who have obstruction at the base of the tongue. This surgical treatment is the most efficacious procedure for expanding the pharyngeal airway and improving or eliminating obstructive sleep apnea. It remains the best current alternative to tracheostomy.⁸¹ Indications for this procedure include severe mandibular deficiency ($SNB < 74^\circ$), morbid obesity, severe obstructive sleep apnea ($RDI > 50$, oxygen desaturations $< 70\%$), hypopharyngeal narrowing, and failure of other forms of treatment.⁸² The success rate of MMA appears to increase when adjunctive procedures such as UPPP, partial glossectomy, septoplasty, or turbinectomies are included in the treatment plan. This lends support to the theory that most obstructive sleep apnea patients have multiple levels of obstruction.

Adjunctive orthodontic therapy is usually indicated in patients selected for MMA. Presurgical orthodontics improves the postoperative occlusion and eliminates pre-existing dental compensations that would otherwise limit the amount of advancement. Maximum advancement of the facial skeleton and maintenance of a functional occlusion and acceptable esthetics are the goals of surgical-orthodontic correction.

The osteotomies are rigidly fixed with miniplates and bicortical screws (Figure 63-10). With large advancements (> 7 mm), skeleton suspension wires and a short course of maxillomandibular fixation (1 wk) can be used to reduce surgical relapse. Potential complications of MMA include surgical relapse, non-union, bleeding, malocclusion, infection, unfavorable changes in facial appearance, and permanent or temporary sensory disturbances of the inferior alveolar and infraorbital nerves.

The long-term skeletal stability of MMA has been shown to be quite good.

Louis and colleagues showed a mean relapse of 0.9 ± 1.8 mm among 20 maxillary advancement patients who underwent MMA for obstructive sleep apnea.⁸³ The mean follow-up period was 18.5 months (range 6 to 29 mo). When the patients were divided into three groups reflecting small (6 mm or less), medium (7 to 9 mm), and large (10 mm or more) advancements, there was no statistical difference in the measured relapse among the groups. Rigid fixation was achieved with four miniplates and no bone grafts were used in any of the maxillary advancements. Nimkarn and colleagues reported on 19 obstructive sleep apnea patients who underwent MMA with simultaneous genioplasty and found relatively stable long-term (> 12 mo) surgical stability of the maxilla and mandible.⁸⁴ Maxillary and mandibular advancement was stable over the long term in both the vertical and horizontal planes. With the exception of gonion in the vertical plane, there was no statistically significant correlation between the amount of surgical advancement and the amount of postsurgical instability.

Mandibular Setbacks In a small number of patients, a mandibular setback procedure can be the initiating factor in the development of obstructive sleep apnea. Riley and associates reported on two women who developed obstructive sleep apnea syndrome after mandibular osteotomies for correction of Class III malocclusion and skeletal prognathism.⁸⁵ Neither patient had any symptoms of sleep apnea prior to surgery. Postoperatively both patients began to snore loudly. Evaluation by polysomnography confirmed the presence of obstructive sleep apnea syndrome. A comparative examination of the preoperative and postoperative lateral cephalograms of each patient showed a more inferiorly positioned hyoid bone and a narrowing of the pharyngeal airway as a result of the mandibular setback procedure.

FIGURE 63-10 Preoperative (A) and postoperative (B) radiographs of a two-jaw surgery and genial tubercle advancement for sleep apnea. Reproduced with permission from Tiner BD, Waite, PD. *Surgical and nonsurgical management of obstructive sleep apnea*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1546.

In an attempt to identify those patients potentially at risk for obstructive sleep apnea, all patients who are planned for mandibular setback procedures should be questioned preoperatively and postoperatively about the presence or absence of snoring, excessive daytime sleepiness, or observed apneas during sleep. Although the vast majority of patients who undergo

Table 63-2 Results of Maxillomandibular Advancement for Obstructive Sleep Apnea

Results	RDI	Desaturation*	No. of Patients	Percent of Total
Excellent	≤ 10	0	20	28.2
Good	≤ 10	≤ 20	26	36.6
Satisfactory	≤ 10	> 20	15	21.1
Poor	> 20	> 20	10	14.1

RDI = respiratory disturbance index.
*Number of oxygen desaturations below 90%.

mandibular setbacks are able to adapt to the changes in the skeletal and muscular apparatus, there is a subset of patients who may be at risk for developing overt signs of obstructive sleep apnea following mandibular setbacks.

Summary

Because the obstructive sleep apnea syndrome is a complex disorder, the type of treatment selected should be tailored to the individual patient based on the relative risks and benefits of the therapy and the severity of the disease. Although a subset of the patients who present with obstructive sleep apnea have an identifiable craniofacial anomaly, care must be used in choosing a simple mechanistic therapy. The success of the chosen therapy should be evaluated both subjectively and objectively. There is no clear agreement on what constitutes a cure of sleep apnea. Most authors use the RDI in assessing severity of disease and success of treatment. However, all agree that the potentially significant physiologic consequences that can be life threatening result from hypoxemia. In some cases patients after treatment have no oxygen desaturations below 90%, but in terms of RDI they are considered not cured and are deemed treatment failures.

A more reasonable approach would be to define the concept of success in terms of excellent, good, fair, and poor and to avoid using the term “cured” in assessing treatment outcomes. These terms could be quantitatively approached assigning low-

est oxygen desaturation and RDI parameters to each one. In Table 63-2 the results of 71 patients treated by maxillomandibular advancement are assessed by these criteria. In managing patients with severe sleep apnea, a “cure” is seldom achieved with a single surgical or medical treatment (tracheostomies excluded). However, maxillomandibular advancement may significantly improve a patient to the point that nonsurgical therapies are more efficacious, if needed at all.

FACIAL ESTHETIC SURGERY

Blepharoplasty

Heidi L. Jarecki, MD

Mark J. Lucarelli, MD

Bradley N. Lemke, MD

Current blepharoplasty techniques were at least two thousand years in the making. Reports from as early as AD 25 to 35, such as *De Re Medica* by Roman encyclopedist and philosopher Aulus Cornelius, demonstrated appreciation of upper eyelid skin excision in the treatment of upper eyelid disorders.¹ Early descriptions of surgery involving eyelid reconstruction by Carl Ferdinand von Graefe, often regarded as the founder of modern plastic surgery, in 1818, and Johann Karl George Fricke, a student of von Graefe's, in 1829, represent the first reported uses of the term blepharoplasty.^{1,2} A.W. Sichel first accurately described "herniated orbital fat" in 1844.¹ Sidney Fox originated the term dermatochalasis in 1952 to describe age-associated excess in eyelid skin.²

Cosmetic surgery was not embraced until the early twentieth century when Charles Conrad Miller penned the first book dedicated to cosmetic surgery in 1907 entitled *Cosmetic Surgery: The Correction of Featural Imperfections*.¹ Shortly thereafter Frederick Kolle published a text on plastic and cosmetic surgery in which he detailed the value of preoperative eyelid skin marking to determine the proper amount to excise during surgery.² The value of preoperative and postoperative photography was introduced in 1926 by Parisian A. Suzanne Noël, one of the first

female pioneers in cosmetic surgery.² These landmark contributions spawned current blepharoplasty techniques, which continue to be further refined and optimized to achieve superior functional and cosmetic results.

Blepharoplasty is frequently performed either as an adjunctive procedure or as a freestanding operation. A 2002 American Academy of Cosmetic Surgery (AACS) survey reported 27,503 blepharoplasty surgeries performed by AACS members, making blepharoplasty the tenth most frequently performed cosmetic procedure in the United States (K. Rybarczyk, personal communication, January 2003). Common indications for blepharoplasty are dermatochalasis, blepharochalasis, orbital septum weakness with resultant fat pad herniation, hypertrophic orbicularis oculi muscle, eyelid laxity with malposition, and other adnexal abnormalities (ie, herniated lacrimal gland, varicose veins, eyelid skin lesions). Dermatochalasis is simply an excess of eyelid skin, often the result of age- or ultraviolet (UV)-associated decreases in collagen and changes in elasticity and composition of the dermis and epidermis.³ Recurrent angioedema of the eyelid results in characteristic laxity, fullness, and episodic edema known as blepharochalasis. Acquired blepharoptosis indicates a drooping eyelid that usually

results from disinsertion of the aponeurotic insertion of the levator palpebrae superioris into the upper eyelid. Blepharoptosis may be present in the setting of dermatochalasis or blepharochalasis. Orbital septal weakness is evident when "bulges," which represent herniation of orbital fat, are present in the eyelids. A hypertrophic orbicularis oculi muscle presents as a horizontal prominence of the lower eyelid immediately beneath the palpebral margin. Eyelid laxity may manifest as ectropion, canthal angle alterations, and epiphora.

The ensuing chapter is intended as a survey of important information for the blepharoplasty surgeon to consider. On completion of the chapter the surgeon should understand pertinent anatomy, be able to identify good blepharoplasty candidates, be capable of developing a surgical plan, and understand the major complications and how to avoid them. This information should serve as a springboard to direct the surgeon in routes of appropriate inquiry.

Anatomy

A thorough understanding of the topography of the upper two-thirds of the face is requisite for successful eyelid surgery. Eyelids should not be viewed in isolation but rather in context of the relationship to the eyebrow above and midface below.

Forehead and Eyebrow

Understanding the normal or idealized brow position is important during evaluation for blepharoplasty.^{4,5} In general men tend to have lower flatter brows at the level of the superior orbital rim. The typical female brow rests 1 cm above the superior orbital rim and peaks between the lateral corneal limbus and lateral commissure, creating a higher and gently arched appearance. Figures 64-1 and 64-2 demonstrate the typical position of the female and male brow, respectively, in youth. Women frequently alter eyebrow position and shape by epilating eyebrow hair so as to approximate the more idealized arched brow.

The eyebrow provides vertical support to the upper eyelid, contributing to the architecture of the eyelid. Eyebrow position is significantly influenced by the elevators and depressors of the brow as well as underlying connective tissue attachments. The frontalis muscle, which originates within the galea aponeurotica, is the main elevator of the eyebrow. The corrugator supercilii, depressor supercilii, procerus, and orbicularis oculi depress the medial brow, whereas the orbicularis muscle is the main lateral brow depressor. Corrugator contraction compresses the medial eyebrows toward the midline with slight depression, forming vertical or oblique

FIGURE 64-1 Typical female brow position. Note the relationship of the brow relative to the superior orbital rim.

glabellar furrows. Contraction of the procerus depresses the glabella, creating horizontal rhytids across the dorsum of the nose. Depressor supercilii contraction causes medial eyebrow depression and formation of oblique glabellar furrows. At its insertion point into the eyebrow the frontalis muscle interdigitates with the orbicularis oculi muscle.

Beneath the frontalis lies the eyebrow fat pad, a structure composed of loose fibrous septae with fat-filled interseptate spaces. The eyebrow fat pad is continuous inferiorly with the filmy areolar posterior orbicularis fascia on the undersurface of the orbicularis muscle.⁶ On the underside of the eyebrow fat pad, dense connective tissue attachments fasten the superficial muscle plane to the supraorbital ridge, thereby supporting the medial one-half to two-thirds of the eyebrow.⁶ Similar attachments for the lateral third of the brow are lacking, thus explaining the preferential ptosis of the temporal brow with aging.⁶ In addition the elevating frontalis muscle does not extend to the lateral-most portion of the eyebrow, further contributing to temporal brow ptosis.

The eyebrow provides vertical support to the anterior upper eyelid structures below, therefore ptosis of the eyebrow increases the amount of apparent upper eyelid dermatochalasis may result in excessive eyelid skin removal, further exacerbation of inferior brow displacement, and an inability to close the eyelids. With mild temporal brow ptosis as the only brow position abnormality, more eyelid skin can be removed laterally during blepharoplasty to provide a satisfactory result. With more severe eyebrow and forehead ptosis, consideration of eyebrow and forehead lifting is important.

Midface

Comprising the area from the inferior orbital rim to the mouth, the midface pos-

FIGURE 64-2 Typical male brow position. Note that relative to the female brow the male brow position is lower and flatter.

sesses structures and landmarks important to the planning of a successful lower lid blepharoplasty. Nasojugal and malar folds separate the thin lower eyelid skin from the thicker skin of the cheek. The superficial musculoaponeurotic system (SMAS) is a fibrous fascial network interconnecting the muscles of facial expression, which acts as a force distributor of facial muscle contractions to the skin to allow for facial expression.⁷ The SMAS divides the subcutaneous fat into two layers and possesses fibrous septae connecting to the dermis. The orbitomalar and zygomatic ligaments provide connections between the periosteum and dermis.^{8,9}

In youth the eyelid cheek contour is a smooth single convexity from the tarsus inferiorly to the cheek. With age numerous soft tissue and skeletal changes occur in the eyelid and midface. The orbital septum weakens permitting orbital fat prolapse, orbital rim exposure, and a prominence of the cheek. Inferolateral aging-associated descent of the orbicularis oculi muscle can also disrupt the eyelid cheek contour.¹⁰ Descent of the malar fat pad contributes substantially to midfacial ptosis.^{11,12} Anatomic studies demonstrate attenuation or abnormal inferior displacement of the subcutaneous insertions of the orbitomalar, masseteric cutaneous, and zygomatic ligaments in the setting of midfacial

ptosis.^{12,13} Important changes of the maxilla, as described by Pessa and colleagues, also contribute to midfacial aging.^{14,15}

Ocular Adnexa

The eyelid margin is traditionally divided into anterior and posterior lamellae. The anterior lamella is composed of the skin, orbicularis oculi muscle, muscle of Riolan, and glands of Zeis and Moll, whereas the posterior lamella is composed of the palpebral conjunctiva, tarsal plates, and associated meibomian glands. A cross-section of the upper and lower eyelid structures demonstrates the composition of the anterior and posterior lamellae (Figure 64-3). The anterior and posterior lamellae are divided by the orbital septum, a structure occasionally referred to as the middle lamella.

Eyelid Skin Thickness Eyelid skin possesses a minimal subcutaneous fibroadipose layer and an attenuated dermis, contributing to its status as the thinnest skin in the body. Subcutaneous fat is completely absent in the pretarsal area. An abrupt transition to thicker skin with a correspondingly more dense fibroadipose layer is encountered near the orbital rim. Care must be taken to minimize surgical incisions laterally beyond the thin eyelid skin as scar appearance may markedly differ. The eyelid skin of Asians tends to be slightly thicker than that of Caucasians primarily due to a thicker dermis and subcutaneous fat.¹⁶

Aging Skin Changes Aging skin changes, such as pigmentary aberrations (dyschromia) and wrinkling (rhytids), result from a combination of UV-induced photodamage, mechanical forces from gravity, and facial muscle contraction and altered chemical environment.³ Decreases in the synthesis of Type I collagen have been demonstrated in aged human eyelid skin.¹⁷

Eyelid Topography Fissure Heights, Upper Eyelid Crease The adult vertical interpalpebral fissure measures 9 to 12 mm,

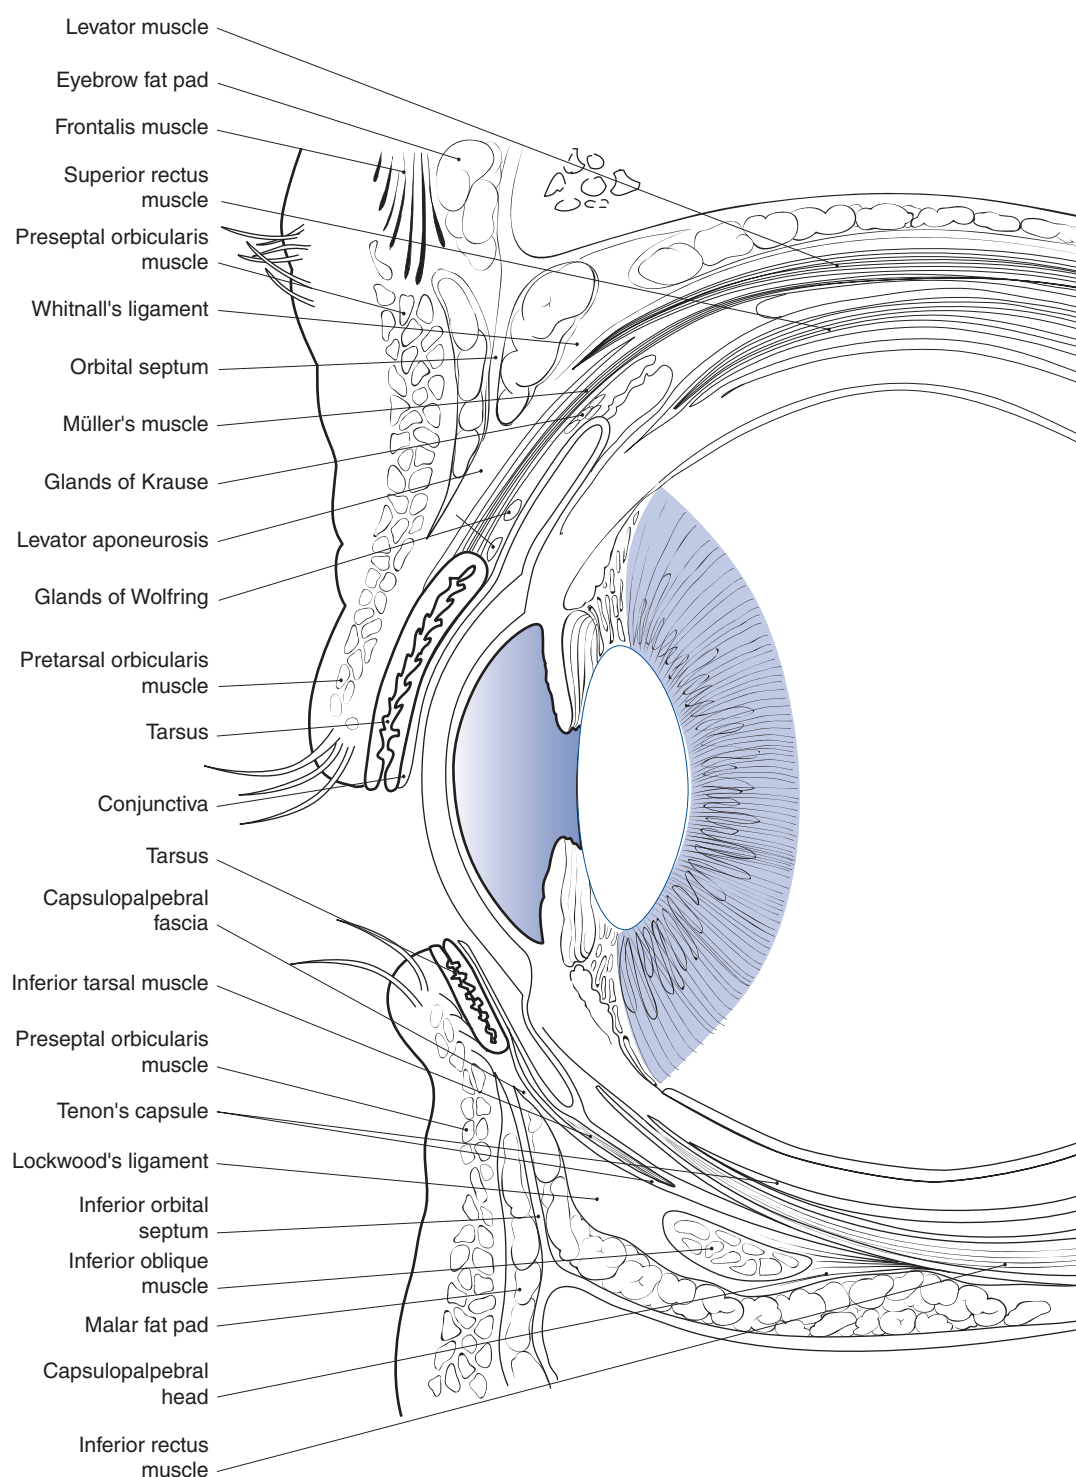

FIGURE 64-3 Cross-sectional view of the structures composing the upper and lower eyelid. Adapted from Kikkawa DO and Lemke BN.⁴¹

whereas the horizontal interpalpebral fissure is 28 to 30 mm. With age the horizontal fissure shortens by approximately 10%.¹⁸ The lateral canthal angle lies 1 to 2 mm superior to the medial canthal angle,

giving the youthful eye a subtle lateral inclination. The apex of the upper eyelid margin rests slightly nasal to the pupil at the level of limbus in children and 1.0 to 2.0 mm below the limbus in adults, yielding

a margin reflex distance of 4 to 5 mm. The lower eyelid margin peaks inferiorly directly beneath the pupil. Figure 64-4 demonstrates the normal upper and lower eyelid position. As depicted in Figure 64-5 dermal and conjoined fascia attachments of the levator palpebrae superioris aponeurosis form the upper eyelid crease, an important anatomic and surgical landmark often used as an incision site.^{6,19,20} Position of the upper eyelid crease varies with age, gender, and, to some degree, ethnicity.²¹ The youthful eyelid crease is approximately one-third of the distance from the eyelid margin to the lower edge of the brow.²² Elevation of the upper eyelid crease may signify disinsertion or attenuation of the levator muscle attachments due to age-related lipid infiltration. Concomitant upper lid blepharoptosis is commonly present in the setting of an elevated upper lid crease. In general upper eyelid creases in Caucasian females are 9 to 10 mm above the upper lid margin, whereas in Caucasian males they are 7 to 8 mm above the upper lid border. A cross-sectional study demonstrated upper lid crease heights lower than traditionally purported values, although small sample size and variation in measuring technique may account for the inconsistency.²¹ Upper eyelid crease position in African Americans has not been documented extensively in the literature, although clinical experience suggests a position similar to that found in Caucasians.

FIGURE 64-4 Normal position of the upper and lower eyelids.

Asian Upper Eyelid In individuals of Asian ethnicity three main variations of upper eyelid crease anatomy exist: single eyelid, low eyelid crease (inside-fold type of crease), and double eyelid with lid crease parallel to lid margin (Figure 64-6).^{16,23-25} In patients with a single eyelid or low eyelid crease the levator aponeurosis fuses with the orbital septum near the eyelid margin below the supratarsal border, creating an essentially absent or low upper lid crease.¹⁶ In the Asian double eyelid the level of fusion of the orbital septum with the levator aponeurosis is higher than in the Asian single eyelid.¹⁶ Aside from the orbital

septum fusion site, thicker fat layers and a lower primary insertion of the levator aponeurosis to the upper eyelid skin contribute to the characteristic topography of the Asian eyelid.

Lower Eyelid Crease The lower eyelid crease, formed by connective tissue fibers extending anteriorly from the capsulopalpebral fascia into the subcutaneous tissues, is less prominent than its upper eyelid counterpart and is often most noticeable in children.²⁶ The lower lid crease begins medially 4 to 5 mm inferior to the lower lid margin and slopes inferiorly as it proceeds laterally.

Eyelid Connective Tissue **Orbital Septum**

The orbital septum, an anatomic boundary between the eyelids and orbit, is a multilaminar layer of dense connective tissue arising from the arcus marginalis, a thickened white fibrous line on the periosteum of the bony orbital margin.²⁷ The orbital septum forms the anterior boundary of the orbit. Medially the septum splits to cover the posterior aspect of Horner's muscle and adhere to the lacrimal fascia, inserting on the posterior lacrimal crest and anterior lacrimal crest, respectively. Laterally the septum inserts anteriorly on the lateral canthal ligament and posteriorly on Whitnall's tubercle of the lateral orbital rim. In the upper eyelid the orbital septum joins the levator aponeurosis 2 to 5 mm above the superior tarsal

border.²⁷ In the lower lid the septum fuses with the inferior tarsal border after joining the lower lid retractors 4 to 5 mm inferior to the tarsus.²⁶ A cadaver demonstration with artist's depiction of the orbital septum is shown in Figure 64-7. Orbital septal strength varies among individuals and with age. Attenuation of the septum allows for anterior orbital fat prolapse.

Tarsus Composed of dense fibrous tissue the tarsal plates contribute structural integrity to the eyelids. Approximately 1.0 to 1.5 mm thick the tarsal plates measure approximately 25 mm in length and range from 10 to 12 mm in height in the upper lid and 3 to 5 mm in the lower lid, with no difference noted between gen-

ders.²⁸ The tarsal plates taper convexly medially and laterally to conform to the globe (Figure 64-8). Within the tarsal plates are the meibomian glands, holocrine sebaceous glands responsible for the lipid layer of the tear film. The meibomian glands are branched acinar glands with long central ducts opening at the eyelid margin just posterior to the gray line. There are approximately 25 glands in the upper eyelid and 20 in the lower eyelid.

Medial and Lateral Canthal Ligaments

The medial and lateral tarsal borders are firmly attached to the orbital rims via the fibrous medial and lateral canthal ligaments, respectively (see Figure 64-8). The medial canthal ligament is more complex anatomically due to its often tripartite attachment as well as its relationship with the lacrimal system. The anterior arm inserts onto the maxillary bone, anterosuperior to the lacrimal crest. The posterior arm attaches to the posterior lacrimal crest in a fanlike fashion and may partially fuse with the posterior surface of the lacrimal sac. The superior arm inserts onto the orbital process of the frontal bone, contributing to the formation of the lacrimal sac fossa roof.²⁹ The lateral canthal ligament inserts on the zygomatic bone at Whitnall's tubercle 1.5 mm inside the lateral

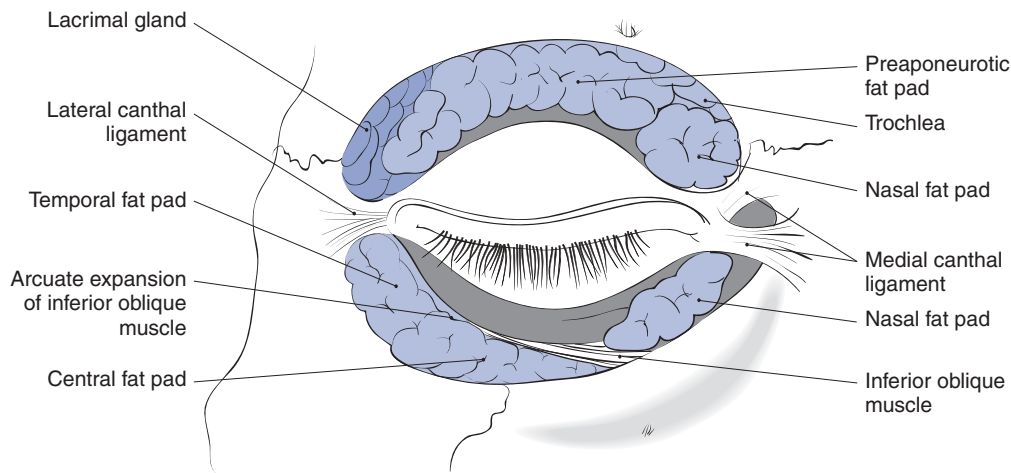

FIGURE 64-8 Skeletonized anterior view of tarsus, canthal ligaments, and fat pads. The medial canthal ligament possesses a complex tripartite attachment. Adapted from Kikkawa DO and Lemke BN.⁴¹

orbital rim and serves as both a stabilizer of the lids and a mobilizer of the lateral canthal angle via attachments to the lateral rectus check ligaments.^{30,31} Whitnall's tubercle is a key surgical landmark as it is the site of lateral lid attachment when performing a canthopexy. Approximately 2 mm of temporal movement of the lateral canthal angle is afforded on lateral gaze due to the fusion of the lateral rectus check ligaments with the lateral canthal ligament.³⁰

Whitnall's Superior Transverse Ligament

The junction of the levator muscle and levator aponeurosis is encircled by a transverse fibrous condensation known as Whitnall's superior transverse ligament, a supporter of the superior anterior eyelid. Although originally thought to serve as a check ligament for the levator, Whitnall's ligament has also been postulated to function as a suspender providing vertical support for the orbit (Figure 64-9).^{32,33} Whitnall's ligament inserts superomedially within the orbit on the frontal bone behind the trochlea and superolaterally near the frontozygomatic suture after attaching to the posterior fibers of the lacrimal gland capsule.³⁴ During ptosis surgery Whitnall's ligament is a key landmark, often corresponding to the transition from levator muscle to aponeurosis.

Lockwood's Ligament The lower lid counterpart to Whitnall's ligament is Lockwood's ligament, a product of the conjoined fascia of the inferior rectus and inferior oblique. Inserting on the medial and lateral canthal ligaments as well as the bony orbital rim, Lockwood's ligament serves as a suspensory sling for the inferior anterior orbit. Lockwood's ligament is strongest anterior to the inferior oblique muscle.²⁶

Eyelid Musculature *Orbicularis Oculi*

Part of the anterior lamella of the upper

eyelid, the orbicularis oculi is a ring-shaped superficial sphincter muscle that can be thought of in three concentric portions: pretarsal, preseptal, and orbital. Figure 64-10 demonstrates the orbicularis oculi muscle in the setting of the superficial facial muscles. Adherent to the tarsus the pretarsal orbicularis requires sharp dissection for isolation. Posterior to the preseptal orbicularis, a thin fibrofatty inferior extension of the eyebrow fat pad, the postorbicularis fascia facilitates dissection of the preseptal orbicularis from the orbital septum. The peripheral-most orbital orbicularis covers the orbital rims. Together the pretarsal and preseptal orbicularis comprise the palpebral orbicularis, responsible for reflexive eyelid closure. The clinical implication of the palpebral orbicularis' function is evident in the postoperative period when the reflexive blink response is temporarily decreased as a result of preseptal orbicularis removal in the blepharoplasty skin muscle flap. The patient must be reminded to blink fully and frequently during postoperative healing to adequately moisten the cornea. Orbital orbicularis contraction produces forceful voluntary eyelid closure. The orbicularis has firm attachments to under-

FIGURE 64-9 Whitnall's ligament of the eyelid, levator palpebrae superioris, and the lower eyelid retractors. Adapted from Nerad JA.⁷⁶

lying structures at the lateral palpebral raphe, medial canthal region, and upper and lower eyelid retractor insertions. The muscle of Riolan, a small portion of the orbicularis separated from the pretarsal orbicularis fibers by the cilia, creates the gray line of the lid margin. The lacrimal (Horner-Duverney) muscle, formed by the deep pretarsal head of the orbicularis as it inserts on the posterior lacrimal crest and lacrimal fascia, is thought to play a role in lacrimal outflow, although the exact nature of its function is controversial.³⁵ Contraction of the lacrimal muscle results in medial and posterior movement of the lower eyelid with the blink.

Levator Palpebrae Superioris The levator palpebrae superioris, the main retractor of the upper eyelid, arises from the lesser wing of the sphenoid deep in the bony orbit, coursing anteriorly above the superior rectus muscle and forming an aponeurosis with several important bony, dermal, and tarsal attachments. As mentioned above, the dermal and conjoined fascial attachments of the levator aponeurosis are responsible for the superior lid crease location (see Figure 64-9).^{19,20}

Müller's Muscle Müller's muscle, a sympathetically innervated minor retractor of the upper lid arising from the undersurface of the levator palpebrae superioris muscle, inserts into the superior tarsal border. Shortening of this muscle from the posterior aspect may be performed as an adjunct ptosis repair during blepharoplasty.³⁶⁻³⁸ Approximately 2 mm of upper lid lift are provided by contraction of Müller's muscle, practically evidenced by the mild upper lid lift experienced with a rush of sympathetic excitation (ie, during the fight-or-flight response).

Lower Eyelid Retractors The lower lid counterparts of the levator and Müller's muscles are the capsulopalpebral fascia and the inferior tarsal muscle, the retractors

FIGURE 64-10 Selected musculature of the eyelid. Orbicularis oculi in the setting of the superficial facial muscles. Adapted from Nerad JA.⁷⁶

tors of the lower lid (see Figure 64-9). The terminal fibers of the inferior rectus muscle give rise to a fibrous extension known as the capsulopalpebral head of the inferior rectus which splits to encompass the inferior oblique muscle, forming the inferior tarsal muscle and the capsulopalpebral fascia.²⁶ These layers fuse anterior to the inferior oblique muscle, forming Lockwood's suspensory ligament, the analog to Whitnall's ligament of the upper lid. Continuing anteriorly the lower lid retractors insert on Tenon's fascia, the inferior tarsal border, and the orbital septum at a level 4 to 5 mm below the tarsal border.

Eyelid Fat Pads **Orbital Relations** In the anterior orbit, distinct fat compartments can be identified, although the majority of the anterior orbital fat pads remain continuous with posterior orbital fat (Figure 64-11).³⁹ This continuity prompted concern that excessive traction on orbital fat was responsible for orbital hemorrhage complicating blepharoplasty with fat removal.⁴⁰ Most surgeons implicate faulty hemostasis of fat pads, rather than traction, as the cause of postblepharoplasty orbital hemorrhage. Careful hemostasis is essential when performing eyelid fat removal.

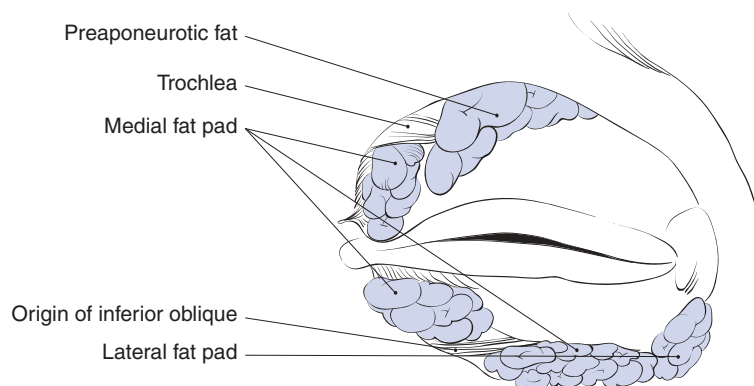

FIGURE 64-11 Artist rendition of the eyelid fat pad. Adapted from Lemke BN and Della Rocca RC.¹¹²

Aging Changes In the youthful face, orbital fat is held in check by a hearty orbital septum. Weakening of the septum associated with aging, chronic allergic swelling, or medical problems resulting in fluid retention (ie, hypo- or hyperthyroidism) may permit anterior prolapse of orbital fat, resulting in steatoblepharon. Aging may also cause atrophy of eyelid fat, creating a superior sulcus deformity. Dietary deficiency alone, however, has not been shown to result in orbital fat loss.⁴¹

Upper Eyelid Fat Pads The upper eyelid contains central and medial fat pockets anterior to the levator muscle and aponeurosis. Immediately posterior to the orbital septum lies the yellow central or preaponeurotic fat, which is not continuous with posterior orbital fat. Medially and inferior to the trochlea is the firmer and more pale fibrous medial fat pad.³⁹ Manipulation of the medial fat pad often requires placement of additional anesthesia into the fat pad itself, as more superficial anesthesia will not adequately infiltrate this structure. Laterally the superior anterior orbit houses the lacrimal gland. Orbital fat does not herniate in the lateral upper eyelid. Care must be taken to avoid removal of lacrimal tissue when fat pad excision is intended. Inspecting for color difference between the pink lacrimal gland and yellow fat is helpful in differentiation. Note that lacrimal gland prolapse may occur as an involutional change or in association with thyroid orbitopathy, making the position of the gland more anterior than usual.

Lower Eyelid Fat Pads The lower lid contains medial, central, and lateral fat pads, which may prolapse separately. Between the medial and central compartments resides the arcuate expansion of the inferior oblique muscle. Care must be taken to avoid damage to the inferior oblique muscle during lower lid blepharoplasty as vertical or torsional diplopia will result.

Eyelid Vasculature Arteries The eyelid vascular supply is rich, allowing for excellent healing and infection resistance, while mandating the surgeon to be cognizant of vascular relationships to avoid excessive bleeding. Both internal and external carotid arteries contribute to eyelid blood supply via the ophthalmic artery and the facial and infraorbital arteries, respectively (Figure 64-12). The facial artery becomes the angular artery in the medial canthal region and then perforates the orbital septum to anastomose with branches of the ophthalmic artery medial and anterior to the lacrimal sac. Arising from the maxillary artery the infraorbital artery travels within the infraorbital sulcus and canal to emerge from the infraorbital foramen and aid in arterial supply of the lower lid. The ophthalmic artery terminates in the lacrimal, frontal, supraorbital, supra-trochlear, and nasal arteries.

Several anastomotic networks, known as arcades, exist in the eyelids. The peripheral arcade of the upper lid lies superior to the tarsus and directly anterior to Müller's muscle, supplying the superior aspect of the upper lid and superior conjunctival

fornix. The marginal arcades of the upper and lower lids lie 2 to 4 mm from the eyelid margin, directly anterior to the tarsi. A peripheral arcade may be present in the lower lid, although it is less well developed.⁴¹

Veins The eyelid venous supply possesses deep and superficial anastomoses. The facial vein, the principal vein of the eyelids, forms a deep anastomosis with the superior ophthalmic vein via the supraorbital vein and a second deep anastomosis with the deep pterygoid plexus via the deep facial vein. Both anastomoses are potential routes for cavernous sinus spread of superficial infection.

Lymphatics Recent anatomic studies demonstrate the lymphatic system of the upper and lower eyelids to consist of superficial subcutaneous and deep pre-tarsal plexuses.⁴² Using lymphoscintigraphy to characterize drainage pathways, parotid lymph node drainage from the upper eyelid, medial canthus, and lateral lower eyelid was shown.⁴³ Similar studies demonstrated medial and central lower

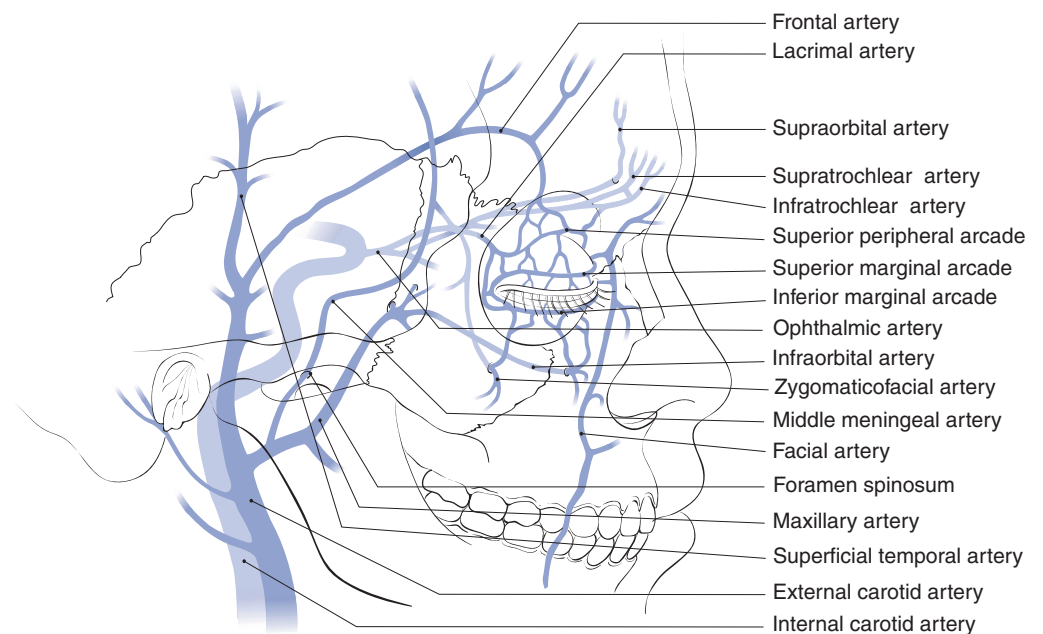

FIGURE 64-12 Orbital arterial blood is supplied from both internal and external carotid arteries. Adapted from Kikkawa DO and Lemke BN.⁴¹

eyelid drainage to the submandibular lymph nodes and a dual drainage of the central upper eyelid to both submandibular and parotid nodes.⁴³

Innervation Motor Cranial nerve VII, the facial nerve, supplies motor innervation for all the facial muscles (Figure 64-13). The facial nerve arises from the pons, eventually dividing into temporal, zygomatic, buccal, mandibular, and cervical branches. The temporal branch innervates both frontalis and orbicularis oculi, whereas the zygomatic and buccal divisions also contribute in an overlapping fashion to innervation of the orbicularis oculi.⁴⁴

The levator palpebrae superioris receives motor innervation from the terminal branches of the superior division of cranial nerve III, the oculomotor nerve, which travels within the muscle cone and enters the superior rectus inferiorly 15 mm from the orbital apex and subsequently enters the levator. Müller's muscle is sympathetically innervated by postganglionic fibers that arise in the superior cervical ganglion, enters the cavernous sinus surrounding the internal carotid artery, and subsequently joins nerve branches to enter the orbit.

Sensory Sensory innervation of the eyelids is via the ophthalmic and maxillary divisions of the trigeminal nerve (cranial nerve V), which give rise to the lacrimal, frontal, and nasociliary nerves, and the infraorbital, zygomatic, sphenopalatine, and posterosuperior alveolar nerves, respectively (Figure 64-14). The lacrimal nerve courses superotemporally to supply the lacrimal gland, conjunctiva, and lateral upper lid and send an anastomotic branch to the zygomaticotemporal nerve. The frontal nerve divides into supraorbital and supratrochlear branches near the orbital rim. The supraorbital nerve exits the orbit via a notch or foramen in the superior orbital rim to provide sensation for the majority of the forehead and scalp. The

FIGURE 64-13 Anatomy of cranial nerve VII, the source of motor innervation for the face. Adapted from Knize DM.¹¹³

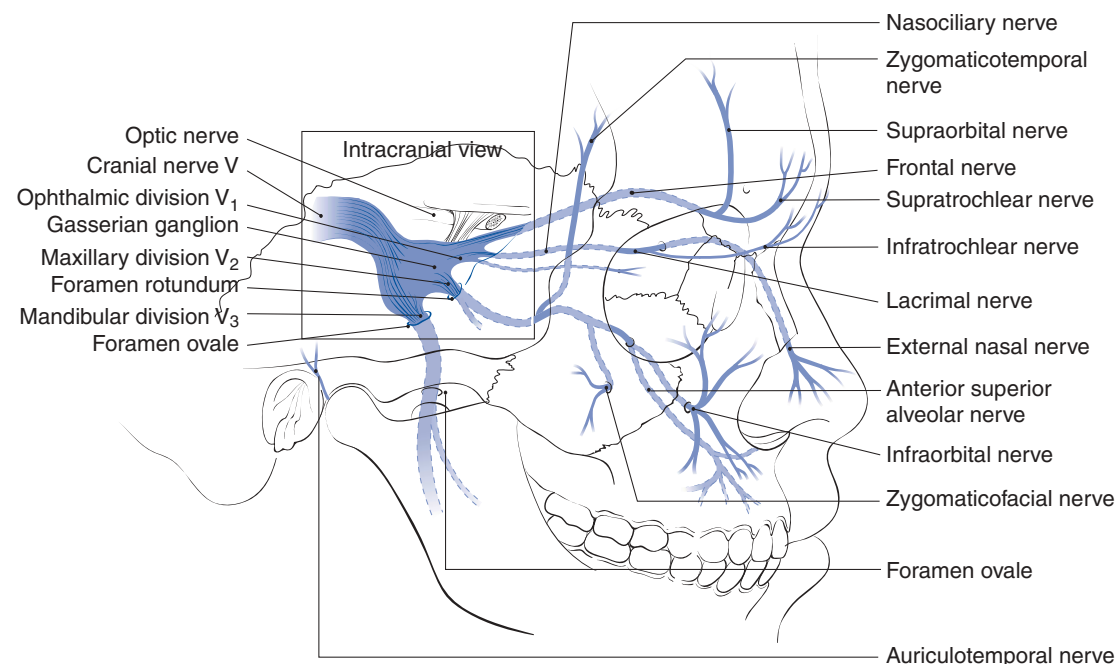

FIGURE 64-14 Cranial nerves V₁ and V₂ supply sensory innervation to the periorbital region. Adapted from Kikkawa DO and Lemke BN.⁴¹

supratrochlear nerve, exiting the orbit lateral to the corrugator muscle, conveys sensory input from the bridge of the nose and

medial aspect of the upper eyelid and forehead.^{45,46} The nasociliary nerve gives rise to the anterior and posterior ethmoidal

nerve, the long ciliary nerves to the globe, and a sensory root to the ciliary ganglion and terminates as the sensory root to the infratrochlear nerve.⁴¹ Emerging from the infraorbital foramen the infraorbital nerve supplies the skin and conjunctiva of the lower eyelid, nasal skin and septum, and upper lip skin and mucosa via the inferior palpebral, lateral nasal, and superior labial nerve terminal branches, respectively. The zygomatic nerve divides into the zygomaticofacial and zygomaticotemporal nerves. The former travels along the inferolateral orbit, traversing the zygomaticofacial foramen before innervating the cheek skin, whereas the latter exits the orbit to the temporal fossa and supplies the lateral forehead.

Lacrimal System and Tear Film Composition *Lacrimal Glands* The lacrimal gland, incompletely divided by the lateral horn of the levator into orbital and palpebral lobes, lies in a shallow depression of the superotemporal frontal bone. In the superior and inferior conjunctival fornices are the accessory lacrimal glands of Krause and Wolfring.

Lacrimal Drainage System The lacrimal drainage system is diagrammed in Figure 64-15. The upper and lower lid puncta lie 8 and 10 mm lateral to the tear sac, respectively, and are normally well apposed to the globe. Initially vertical for 2 mm the canaliculi make a 90° turn and travel 8 mm within the orbicularis muscle just beneath the lid margin to join, forming the common canaliculus. The common canaliculus then joins the lacrimal sac, which is found within the bony lacrimal fossa. Ten percent of the population lacks a common canaliculus, and the canaliculi simply lead to the lacrimal sac. The nasolacrimal duct drains beneath the inferior turbinate into the inferior meatus.

Tear Film Composition The precorneal tear film is comprised of three layers:

FIGURE 64-15 The lacrimal system of the eyelid. Adapted from Lemke BN and Lucarelli MJ.¹¹¹

mucin, aqueous, and lipid. The inner mucin layer, produced by conjunctival goblet cells, stabilizes the tear film while lubricating the corneal surface. Accessory and main lacrimal glands account for the middle aqueous layer, the thickest portion of the tear film. The most superficial lipid layer, secreted by the meibomian glands and glands of Zeis and Moll, further stabilizes the tear film and prevents evaporation. Reflex tearing prompted by emotion or an ocular irritant is produced by the main lacrimal gland. Deficiency of any component of the tear film leads to dry eye symptoms.

The tear layer must be regularly redistributed by the eyelid blink mechanism to maintain ocular surface comfort and integrity. Postoperative lessening of the magnitude and frequency of the blink may temporarily elicit dry eye symptoms in predisposed individuals. Blepharitis, conjunctivitis, and corneal irritation symp-

toms are also amplified by this temporary postblepharoplasty eyelid dyskinesia.

Patient Evaluation: History

Eliciting the Chief Concern

Whether primarily cosmetic or functional, patient selection for blepharoplasty requires careful consideration of history elements, physical features, and patient expectations as well as investigation into potential clinical pitfalls. The blepharoplasty surgeon must thoroughly explore the goals of the patient. Patients needing a functional blepharoplasty owing to severe dermatochalasis often describe frontal headache or fatigue from frontalis contraction, impairment of superior visual field, or a need to raise the chin or use manual elevation of the brow or lids to enhance vision. Symptoms are frequently exacerbated by fatigue and are generally worse in the evening (ie, while reading in downgaze

before bedtime). Patients may relate needing to raise their lid skin to see better. Patients seeking cosmetic blepharoplasty may lament they “look tired all the time” or describe a sagging change in their lid and eyebrow position compared with the lid and brow position of their youth. Documentation of lid effect on patient quality of life is valuable. Information on the impact on occupation, hobbies, driving, and other activities of daily living is essential both for better understanding of the patient’s goals and for third party reimbursement.

The patient is encouraged to demonstrate the problem areas while looking at a handheld mirror. Patients are also asked to bring old photographs that reveal eyebrow position at an earlier age. Asian blepharoplasty candidates are encouraged to present photographs demonstrating the desired upper eyelid crease type. Some surgeons use computer modeling programs to illustrate possible results to patients. An immediate demonstration of the effect of eyebrow elevation or the impact of aging can be achieved through use of digital photography of the patient with comparison to prior photographs.

In functional and cosmetic patients, especially in the latter group, expectations must be well defined. Ideal cosmetic candidates can describe which physical parameters they find problematic. It is helpful to have the patient point out, either in a mirror or a photograph, the objectionable features. Vague complaints or withdrawal from the decision-making process often predict inadequate understanding and unrealistic expectations. The issues under discussion should be those of the surgical candidate, not issues generated by others. An open patient-physician relationship and thorough dialogue remain key building blocks to a successful surgical outcome.

Important History Elements

Historic questions on the initial evaluation are designed to clarify the patient’s issues while identifying factors that can alter

treatment or contraindicate blepharoplasty. A complete past ocular history, including documentation of contact lens use or intolerance, tearing abnormalities, dry eye history, and previous surgery, as well as a thorough past medical history are necessary. Any history of dry eye symptoms, such as ocular scratchiness, blurred vision, foreign body sensation, or pain, should be investigated, as blepharoplasty may aggravate these symptoms. Ophthalmology consultation should be considered. Epiphora, ocular irritation with ambient wind, or current use of artificial tears all raise the possibility of postoperative dry eye symptoms. Keratoconjunctivitis sicca or cicatricial conjunctival disease should make the surgeon wary of proceeding with blepharoplasty.

Prior facial, and especially lid and brow, surgeries should be discussed. If upper eyelid blepharoplasty has been previously performed and the patient complains of a persistent skin fold, evaluate the eyebrow position to rule out forehead ptosis. Similarly the appearance of medial fat pad fullness can be mimicked by medial eyebrow ptosis. A descended eyebrow fat pad or a prolapsed lacrimal gland may also be mistaken by the patient as “residual upper eyelid fat” for which a secondary upper lid procedure is sought. The patient is shown their upper eyelid appearance with the forehead supported in the normal position. If a significant effect is noted the patient must compromise on the final blepharoplasty result or accept concomitant forehead lifting. Previously performed lower blepharoplasty may leave the patient desiring more fat removal, treatment of an accentuated nasojugal fold, skin laxity or deformity, eyelid malposition, or a lateral canthal deformity. A surgeon performing a transcutaneous lower blepharoplasty reenters the muscle later with an increased risk of postoperative lid retraction.

Although rare with blepharoplasty given the thin nature of the eyelid skin, the possibility of hypertrophic scar formation

should be discussed, especially with higher Fitzpatrick skin types.⁴⁷ The possibility of pigmentary change of the surgical wound should also be addressed. Any history of periocular trauma should be explored as to the timing and nature of the injury.

Clinical course and physiologic stability should be documented in patients with thyroid eye disease, as eyelid retraction associated with thyroid ophthalmopathy may worsen after poorly executed blepharoplasty. Eyelid retraction, eyelid edema, and any herniated fat measurements in patients with thyroid disease should be stable for at least 6 months prior to consideration of surgery.⁴⁸ Excessive proptosis in patients with thyroid eye disease is generally treated with orbital decompression prior to any eyelid surgery. Patients with thyroid orbitopathy often exhibit persistent eyelid fat herniation, eyebrow fat pad hypertrophy, and a glabellar grimace (Figure 64-16).

A full medication history should be documented, especially the use of aspirin, nonsteroidal anti-inflammatory medications, anticoagulants, homeopathic herbal

FIGURE 64-16 Patient displaying features characteristic of thyroid orbitopathy.

preparations, and vitamin E, as patients will need to discontinue these medicines preoperatively for 1 to 2 weeks. Warfarin is generally held for 4 days preoperatively. Inquiry regarding cigarette, alcohol, and illicit drug use should be made as the former may influence skin quality and healing and the latter two may affect the patient's ability to complete postoperative care.

Physical Examination

The preoperative physical examination of a patient requesting blepharoplasty focuses on eyelid function (ocular protection, tear film distribution, and clearance of the visual axis) as well as structure and regional anatomy that may necessitate adjunctive procedures for a superior result.

The Eyebrow Examination of the forehead and eyebrow seeks to define brow position as a contributor to apparent upper lid skin redundancy. Findings may be demonstrated to the patient with a mirror. Eyebrow position below the supraorbital rim yields a T-type configuration to the nasal-eyebrow angle, whereas the youthful female brow position creates a Y-type nasal-eyebrow angle configuration.⁴⁶ Measuring the distance from the central inferior eyebrow to the inferior corneal limbus while the patient is in primary gaze can aid in identification of patients with brow ptosis. A value less than 22 mm, especially in women, may warrant consideration of brow elevation as an adjunctive procedure.⁴⁸ Quantitative grading of brow ptosis can be obtained by placing a millimeter ruler vertically over the eyebrow and measuring the difference in millimeters between current location and ideal position when the eyebrow is elevated by the clinician's finger. Performing the measurement over the medial, central, and lateral brow is beneficial to quantify brow ptosis, which is often segmental. Adjunctive brow elevation must be considered if more than mild brow ptosis is present.

Upper Eyelid The skin quantity, quality, and resilience are important in determining the amount of skin to excise and use of adjunctive procedures. With the patient's eyes closed and gentle elevation of the brow to smooth out the upper eyelid skin, an objective measurement of the amount of eyelid skin can be obtained. Generally 18 to 21 mm of eyelid skin is retained during upper lid blepharoplasty.⁴ Eyelid skin should be examined for dermatopathology (ie, eczema), inflammation, pigmentary inconsistencies, and prior surgical scars. Any suspicious skin lesions suggestive of neoplasia should be documented and dealt with prior to surgery. Rhytids should be assessed. Orbital fat herniation, manifested as lid fullness, can be appreciated in the medial and central upper lid by palpation. Fullness in the lateral upper lid may signify lacrimal gland prolapse, which may necessitate repositioning during blepharoplasty.

The upper eyelid crease is identified by gently lifting the eyebrow and asking the patient to look down, then slightly up, and then down again while inspecting upper lid skin for a dynamic crease that retracts with slight upgaze. Static eyelid skin creases may or may not reflect this dynamic infolding produced by levator muscle activity. The distance from the central upper lid crease to the upper lid margin is normally 9 to 11 mm in women and 7 to 8 mm in men, except for the aforementioned variation in Asian eyelid crease location. Greater values than expected may indicate levator aponeurosis disinsertion and possible blepharoptosis. Lesser values may indicate preaponeurotic fat pad incursion into the pretarsal space. Lid crease reformation may be considered when desired.

It is critical that the upper eyelid position, evaluated with the forehead relaxed, be assessed preoperatively in the blepharoplasty candidate and that the measurements be recorded in the chart. The margin reflex distance (MRD), the distance from the middle of the pupil to the upper

lid margin, is determined by shining a penlight in the patient's eyes to obtain a pupillary light reflex while the patient is in primary gaze. Should the patient's upper lid ptosis preclude visualization of the light reflex, the lid should be raised until the reflex is seen and the number of millimeters of lift needed is recorded as a negative value. A normal MRD is 4 to 4.5 mm (Figure 64-17). Care must be taken to distinguish between genuine lid ptosis and severe dermatochalasis wherein the draped skin obscures the light reflex. An MRD greater than 5.5 mm and superior scleral show are indicative of upper lid retraction. Investigation of possible thyroid disease should be considered. Upper eyelid position with the eyelids gently closed should be inspected for lagophthalmos (incomplete lid closure), which may herald dry eye symptoms if greater than 2 mm. Special attention to lagophthalmos is warranted in patients who have undergone prior blepharoplasty.

Levator palpebrae superioris function is key to upper lid position and should be objectively measured. While holding a vertical millimeter ruler lateral to the greatest diameter of the palpebral fissure, the upper lid margin is measured in extreme downgaze and extreme upgaze. Care must be taken to immobilize the brow so as to avoid the influence of frontalis recruitment. Repeating the measurement several times is useful to obtain an average, which is recorded. Lid lag, evidenced by lack of

FIGURE 64-17 The margin reflex distance measures the distance between the center of the pupil and the margin of the upper eyelid. Adapted from Putterman AM.⁴⁸

smooth pursuit of the upper lid margin with the superior corneal limbus while the patient moves from upgaze to downgaze, can alert the examiner to possible thyroid disease. The presence of excessive upper lid laxity, upper lash ptosis, and papillary conjunctivitis in a patient with ocular irritation and injection suggests floppy eyelid syndrome. Lash ptosis is an altered trajectory of the lashes whereby cilia project inferiorly rather than anterosuperiorly. If floppy eyelid syndrome is suspected, examination findings will confirm abnormally easy distraction of the upper lid off the ocular surface. Horizontal tightening of the upper eyelids, performed by lateral shortening and re-insertion of a tarsal strip within the orbital rim, may be indicated.

The eyelid margin should be inspected. Evidence of blepharitis, such as collarettes along the lashes, thickened lid margins, and plugged meibomian glands, should be noted and lid hygiene (ie, warm washcloth soaks with gentle baby shampoo eyelid cleansing) prescribed to resolve the blepharitis prior to surgery.

Lower Eyelid Careful skin examination is equally as important in the lower eyelid area as in the upper lid. Rhytids, especially “crow’s feet,” should be noted, as prominence may necessitate adjunctive topical retinoic acid, chemical peels, laser resurfacing, and botulinum toxin A injections. Assessing for extra lower lid skin is best performed in upgaze. The pinch test uses an angled forceps, such as a Brown-Adson, to grasp a redundant fold of lower lid skin without altering lid position while the patient is in upgaze with his or her mouth open (to allow for maximal necessary excursion of lower lid skin). The amount of skin grasped approximates the amount to excise. Orbital fat prolapse is noted in the medial, central, and lateral lower lid. Facile differentiation of orbital fat from edema is achieved by gentle ballottement of the upper eyelid; fat herniation will result in distinct anterior movement of the

fullness whereas edema will not. Hypertrophied orbicularis muscle is most prominent when the patient smiles.

Lower lid position can be quickly assessed by examining the lower eyelid margin position relative to the inferior corneoscleral limbus. Any inferior scleral show in primary gaze is objectively measured from the inferior corneoscleral limbus to the lower eyelid margin, or using the margin reflex distance-2 (MRD₂), the distance from the pupillary light reflex to the lower lid margin in primary gaze. Together the MRD and MRD₂ compose the palpebral fissure height. Normally the lower lid rests at or slightly above the inferior corneal limbus. An increased MRD₂ raises concern of lower lid retraction from thyroid ophthalmopathy, lower lid laxity, mechanical forces, or cicatricial causes. A hypoplastic maxilla causing decreased prominence of the inferior orbital rim may contribute to postoperative susceptibility to lower lid retraction and ectropion.

Abnormal lower lid position and rounding of the lateral canthal angle often result from lower lid laxity. Laxity is assessed by distraction and the snap-back test. By gently grasping the lower lid centrally, the lid is distracted off the globe anteriorly. Normal distraction is less than 6 mm. Greater distraction suggests laxity. To perform the snap-back test the lower lid is pulled inferiorly and released while the patient refrains from blinking. A normal lid returns to the globe quickly with one or fewer blinks. A lax lid requires several blinks to resume its former position and may remain inferiorly displaced and everted, indicating ectropion. Laxity of the lateral canthal tendon is the most common cause of lower lid laxity. The ability to displace the punctum greater than 2 mm laterally indicates laxity of the medial canthal tendon.⁴⁹ Lower lid horizontal tightening procedures should be performed at the time of blepharoplasty surgery for the lax lower lid to prevent postoperative ectropion and recreate the

youthful, slightly elevated, well-defined lateral canthal angle.

Midface Architecture Midfacial ptosis, festoons, and malar mounds are important aspects to note on evaluation, as separate procedures are necessary to address these concerns. Midfacial ptosis encompasses a host of changes caused by attenuation of the subcutaneous portions of the orbitomalar, masseteric cutaneous, and zygomatic ligaments, including soft tissue inferior migration of the lower eyelid structures, cheek, and midface, as well as concomitant prominence of the nasolabial fold (Figure 64-18).¹² When attenuation of the lower lid orbicularis oculi and laxity of orbicularis attachments to deep fascia develop, the orbicularis may sag or form redundant folds known as festoons.⁵⁰ Several levels of festoons have been described including pretarsal, preseptal, orbital, and malar, and composition varies to include one or more of the following: skin, muscle, suborbicularis fat,

FIGURE 64-18 Profile of a patient with descent of the cheek prominence characteristic of midfacial ptosis.

and herniated orbital fat.⁵⁰ Malar mounds, projections of skin and fat in the area of the malar eminence, are areas of altered inferior orbital orbicularis fibers that allow abnormal communication between subdermal and suborbicularis fat.⁵⁰ Malar mounds often prove challenging to resolve.

Lacrimal Secretion and Ocular Surface Evaluation Dry eye symptoms are frequent following blepharoplasty, and preoperative evaluation of the lacrimal system may direct surgical intervention and patient education, thereby avoiding significant morbidity. The tear meniscus, tear break-up time, Schirmer testing, and/ or fluorescein corneal staining are often used. The tear meniscus may be measured using a thin cross-sectional beam of light of a slit lamp biomicroscope focused on the patient's lower lid. The beam height is changed to match the height of the tear meniscus on the lower lid. Normal values are approximately 0.2 to 0.3 mm. The tear break-up time test requires instillation of 2% fluorescein dye on the cornea and examination with a cobalt blue light. The patient is asked to blink once and then refrain from blinking. Any loss of the tear film continuity (evidenced as a streaky dry spot and color change from green to blue) in less than 10 seconds is considered abnormal. The tear break-up test measures tear stability, which is largely due to the lipid component of the tear film. The Schirmer tests, the gold standards for lacrimal testing, quantify the aqueous tear secretory component. After blotting the inferior cul de sac and palpebral conjunctiva, a bent filter paper strip (ie, a Schirmer strip), is placed in the lateral third of the lower eyelid with the strip notch at the eyelid margin such that the strip proceeds anteriorly. The room lights are dimmed to avoid reflex tearing. The strip is removed after 5 minutes and the amount of strip wetting measured. Topical anesthesia is

generally used in the basic secretion test, which indicates basal tear secretion. The normal value is approximately 15 mm. Tear hyposecretion is indicated with 5 to 10 mm of wetting and less than 5 mm suggests dry eye. Interpalpebral corneal and conjunctival staining with fluorescein (Figure 64-19) is characteristic of keratitis sicca, while inferior corneal staining suggests exposure keratopathy or blepharitis.^{51,52} The extent of evaluation for dry eye varies among surgeons and often from patient to patient with the same surgeon.⁵³ There is controversy in the literature regarding the most appropriate evaluation, although the general consensus is that historic and physical examination elements suggestive of dry eye warrant more thorough evaluation and an especially conservative blepharoplasty.⁵⁴⁻⁵⁶ Patient education should stress the role of ocular lubrication.

One of the important ocular surface protective mechanisms is the Bell's phenomenon, or the normal "rolling back" of the eyes with lid closure. This may be tested by asking the patient to tightly close their eyes while the examiner manually opens the lids to assess corneal position. A poor Bell's phenomenon indicates a risk of postoperative corneal exposure and irritation.

Corneal sensation is another key aspect of ocular surface protection. It may be tested by touching a wisp of cotton to the peripheral cornea while the patient is in upgaze. A blink response is normal. Patients who wear contact lenses or who have undergone refractive surgery may have decreased corneal sensation.⁵⁷⁻⁵⁹ Individuals seeking cosmetic corneal surgery often seek cosmetic blepharoplasty.

Ocular Motility Evaluation Diplopia may result spontaneously after blepharoplasty or be due to iatrogenic injury of the superior or inferior oblique muscles. A baseline evaluation of extraocular motility is therefore warranted. Using a muscle light or the examiner's finger, the patient is

FIGURE 64-19 Punctate staining of the cornea typical of keratitis sicca.

directed to look in the nine positions of gaze: superotemporal, superior, superonasal, lateral, medial, inferotemporal, inferior, inferonasal, and straight ahead. Any ocular motility deviations should be evaluated prior to surgery. Patients with thyroid ophthalmopathy having impaired ocular motility are generally recommended to have their strabismus surgery prior to any eyelid surgery.

Visual Acuity A vital sign of ocular function, the best-corrected visual acuity of both eyes, should be documented prior to surgery. If visual acuity is subnormal, ophthalmologic evaluation is especially important. In addition postoperative visual complaints can be more accurately assessed when the baseline visual acuity has been recorded. Visual decline postoperatively may be wrongly attributed to blepharoplasty if preoperative visual acuity has not been documented.

Ancillary Studies

Both visual field testing and photography aid in demonstrating preoperative changes in visual function and appearance. Visual field testing is necessary for patients wishing to determine insurance benefits for surgery.

Visual Field Evaluation Peripheral visual field testing is performed to document visual field loss, usually of the superior field, due to upper eyelid dermatochalasis

or blepharoptosis. Several different perimeters may be used, such as the automated Humphrey or manually operated Goldmann perimeter or tangent screen. Perimetry is performed with the patient's eyelid unaltered and repeated with the eyelid skin or ptotic lid elevated.

Photographic Documentation Preoperative photography is key when performing eyelid surgery. Documentation of preoperative appearance serves as a benchmark from which postoperative change can be determined and is a valuable reference when initially unforeseen postoperative complications arise. Minimum photographs recommended include frontal primary, upgaze and downgaze, and lateral views. Discussion of photographic specifics is beyond the scope of this chapter and the reader is referred to alternate texts for a more complete discourse.⁶⁰

Anesthesia

The majority of blepharoplasty surgery is performed in an outpatient surgical environment or an office procedure room, under local anesthesia, with or without intravenous sedation. Oral anxiolytics such as diazepam are often employed when intravenous sedation is not used. Adjunctive procedures performed at the time of blepharoplasty may warrant general endotracheal anesthesia, and the anesthesia and sedation needs may vary on an individual basis.

The blepharoplasty surgeon should be familiar with topical and local infiltrative anesthesia options. Commonly used topical ocular anesthetics include the ester-type compounds, proparacaine (0.5%) and tetracaine (0.5%). Commonly used local infiltrative anesthesia choices are all amides and include lidocaine (0.5 to 2.0%), mepivacaine (1 to 2%), and bupivacaine (0.25 to 0.75%). Lidocaine and mepivacaine have an onset of action from 3 to 6 minutes and a comparable duration of action (120 minutes) when epinephrine

is mixed with lidocaine. Bupivacaine has a slower onset of action (10 minutes) and a longer duration of action (8 to 12 hours). Epinephrine is added to promote hemostasis through vasoconstriction and slow absorption, thereby prolonging duration of the anesthetic and increasing the maximum safe anesthetic dosage. No additional therapeutic benefit is gained by adding concentrations of epinephrine greater than 1:100,000. A mixture of 2% lidocaine with 1:100,000 epinephrine and 0.5% bupivacaine with epinephrine allows for rapid onset of prolonged anesthesia. Overdose toxicity of the amide-type anesthetics manifests as mild hypertension and tachycardia, lightheadedness, mild agitation, and confusion. Severe toxicity is marked by seizures, coma, respiratory depression, bradycardia, ventricular dysrhythmias, and asystole. Maximal doses based on milligram per kilogram and total daily dose are 7 mg/kg and 500 mg for lidocaine with epinephrine, 4.5 mg/kg and 300 mg for lidocaine without epinephrine, and 7 mg/kg and 1,000 mg for mepivacaine. Bupivacaine daily dose should not exceed 175 mg and maximal daily dose with epinephrine is 225 mg.

Hyaluronidase, an enzyme that degrades the polysaccharide hyaluronic acid, may be added to local anesthetics to aid in anesthetic diffusion and tissue permeability. Duration of anesthetic action is decreased when hyaluronidase is used concomitantly.

Sodium bicarbonate has been advocated as a local anesthetic adjunct to reduce the discomfort associated with anesthetic infiltration.⁶¹ A base, sodium bicarbonate, partially neutralizes the acidic nature of local anesthetics with epinephrine, thereby decreasing the irritation that the acidic anesthetic pH induces.

Anesthesia injection is performed from the temporal aspect with the needle bevel up. Keeping the needle as parallel as possible to the eyelid skin and carefully stabilizing the patient's head during injection

guard against inadvertent globe penetration. Injection sites are placed within the skin area to be excised, thereby allowing removal of the occasionally produced microhematomas. Milking the injected fluid medially aids in minimizing the number of sites injected. Injection depth is at the level of the orbicularis muscle.

Upper Eyelid Blepharoplasty

Preoperative Concerns

On the day of surgery, review of the surgical plan and examination of the patient in an upright position are helpful.

Once in the operating room, skin incision lines are marked with a methylene blue surgical marking pen prior to skin preparation or immediately thereafter. The former has the advantage of allowing full view of the patient's face during the marking process and providing several minutes of anesthesia infiltration while the surgeon is scrubbing for the surgery and the patient is being draped. Injection prior to surgical marking is not recommended unless the surgeon waits for the injected volume to diffuse as the injected volume may influence placement of surgical marks. The patient's periocular area should be thoroughly prepared with a 5% povidone-iodine or pHisoHex solution. Care should be taken to not allow pHisoHex solution to contact the corneal or conjunctival surfaces. Irrigate the ocular surface well if contact occurs. Care must be taken to avoid removing the surgical marking during preparation if marking is performed prior to the prep. Topical ocular anesthesia drops (ie, proparacaine or tetracaine) are instilled onto the ocular surface and a protective corneal contact may be inserted.

Surgical marking requires that the patient be supine with the surgeon intermittently elevating the brow manually so as to flatten any redundant upper eyelid skin. If the brow is not elevated, erroneously high surgical marking may result. Special care is

taken to provide vertical traction on the pretarsal skin to remove any redundancy as the inferior incision is designed. The initial surgical mark extends from the punctum to the lateral canthus and lies along the upper eyelid crease or where the intended lid crease will be. The location of the upper eyelid crease should be measured with calipers to confirm proper placement of the inferior aspect of the incision. In women the initial surgical mark is generally 8.5 to 10 mm above the superior lid margin centrally. The corresponding value in men is 7 to 8 mm. The crease may be designed 0.5 mm lower than ultimately desired as vertical traction will stretch the skin somewhat and provide desired lash eversion. Surgical marking in the Asian patient varies from these values and will be discussed below. The superior surgical mark is placed next. Approximately 18 to 21 mm of upper eyelid skin should be left after the intended skin is removed. Care should be taken to avoid confusing epilated inferior eyebrow skin for true eyelid skin. Excessive skin removal will result in difficulty with eyelid closure and impair ocular surface protection. Excessive skin removal might also preclude future correction of eyebrow or forehead ptosis. The upper and lower surgical marks are connected in a curvilinear manner (Figure 64-20). To test the adequacy of lid skin remaining, the upper and lower marks should be approximated using a pinching technique with forceps. The forceps should grasp all excessive skin without altering the closed eyelid margin. Slight elevation of the eyelashes with the pinch may be desired. Any opening of the lids during medial, central, and lateral pinch assessment should warrant modification of intended incision lines.

Local anesthesia is next injected subcutaneously into the skin intended for removal. Gentle pressure may be used to diffuse the injected fluid.

Excision of the Skin-Muscle Flap After sufficient anesthesia infiltration has

occurred and a corneal protector has been placed on the operative eye if desired, the eyelid skin is held taut for the incision. Careful traction perpendicular to the incision site can be provided by the surgical assistant. A no. 15 Bard-Parker blade, straight iris scissors, carbon dioxide (CO₂) laser, electrosurgical microdissection needle, or radiosurgical unit is used to incise the skin and orbicularis muscle along the previously placed surgical marks.

The skin-muscle flap is next dissected off the orbital septum by elevating the lateral aspect of the flap superiorly with forceps while the assistant provides perpendicular traction at the superior and inferior margins of the flap. A gentle painting motion is used, with care to avoid violating the orbital septum. The edges of the flap should be angled at approximately 45° to avoid a bulky muscular ridge when the edges are reapproximated during closure. Angulation of the edge is especially important temporally where the muscle layer is thicker. Hemostasis should be achieved with cautery after flap dissection and, if no fat excision is planned, the skin can be closed at this point.

Fat Debulking Upward traction is used to lift the orbital septum prior to opening the septum in the superomedial aspect with Westcott scissors, electrosurgical microdissection needle, or CO₂ laser. The septal opening is extended laterally to comprise the full width of the flap. The herniated orbital fat pads should be evident medially and centrally. Color as well as location can be helpful in differentiation, as the medial fat pad is a more pale lemon color as opposed to the brighter yellow central fat pad. The connective tissue capsule overlying the medial fat pad is opened. Gentle ballottement of the globe through the upper lid aids in herniating the fat through the incised capsule. The medial fat pad may require additional anesthetic injection to facilitate comfort during manipulation. The fat is gently grasped

with straight forceps and teased out, then clamped at the base exiting the capsule. Cautery is used to separate the fat from the clamp. Care should be taken to achieve excellent fat pad hemostasis as postoperative bleeding may contribute to the rare but vision-threatening complication of orbital hemorrhage. Herniation of the central or preaponeurotic fat pad is addressed in a similar fashion by incising the overlying capsule, teasing out the fat, and clamping and cauterizing the herniated fat.

Over the last decade emphasis has been placed on removing less fat during both upper and lower blepharoplasty. In male blepharoplasty patients, fat excision should be especially judicious as the superior sulcus in men is generally more full than in women and excessive fat excision may feminize appearance by creating an unnaturally hollow-appearing superior sulcus. With a bilateral upper eyelid blepharoplasty, attention should be directed toward leaving rather than resecting symmetric amounts of fat. Alternatively fat may be thermally sculpted to improve the eyelid contour.

Lacrimal Gland Prolapse A fullness to the lateral upper eyelid may suggest prolapse of the orbital lobe of the lacrimal gland, which is seen as a pink to tan firm lobulated structure intraoperatively after the septum is opened. Care should be taken not to resect lacrimal gland tissue as postoperative dry eye may result. Repositing the prolapsed lacrimal gland in the lacrimal gland fossa should be easily achieved. Difficulty in repositing may suggest a neoplastic or infiltrative process and warrant a biopsy. A double-armed 5-0 polypropylene suture may be used to refixate the prolapsed gland to the orbital roof periosteum.^{62,63}

Eyelid Crease Reformation and Skin Closure Reformation of the upper eyelid crease seeks to establish a connection between the levator aponeurosis and the orbicularis oculi muscle. In most instances

FIGURE 64-20 A, Upper eyelid transcutaneous blepharoplasty. Surgical marking. B, Pinching technique to assess adequacy of amount of remaining lid skin. C, Dissection of the skin-muscle flap. D, Completion of skin-muscle flap dissection showing intact orbital septum. E, Opening of the orbital septum. F, Fat pad debulking. G, Closure of the orbicularis. H, Closure of the skin. I, Completed result.

the inferior tissues are sufficiently adherent posteriorly such that a lid reformation suture may not be required. Prior to eyelid crease reformation, meticulous hemostasis should again be checked. Reformation is performed using buried interrupted sutures with an intermediate duration absorbable suture (ie, polyglactin) passed through both upper and lower orbicularis edges and the

levator aponeurosis at the level of the top of the tarsus. Care should be taken to achieve symmetric upper lid creases bilaterally.

The orbicularis is next approximated with several buried interrupted sutures of 7-0 polyglactin or a similar suture material. Placement of these interrupted sutures should allow facile reunion of the upper eyelid skin edges with a smooth contour.

Redundant skin causing cutaneous standing defects should be excised using Burow's triangle technique. The skin is closed using 6-0 fast-absorbing gut suture in a running fashion, beginning medially and progressing laterally. Alternative suture options for skin closure include nylon, polypropylene, or silk, although sutures that are not absorbable require removal approximately 5 to 7 days

postoperatively. Greater duration of suture retention is required if CO₂ laser resurfacing is performed concomitantly with blepharoplasty. Skin closure sutures should have only minimal tension. Recent evidence suggests the tissue adhesive octyl-2-cyanoacrylate is a viable alternative to sutures.⁶⁴ Several key steps of transcutaneous upper eyelid blepharoplasty are shown in Figure 64-20.

Transconjunctival Upper Lid Blepharoplasty Reserved for patients with isolated medial fat pad herniation and minimal or no wrinkling of the upper eyelid skin is the transconjunctival approach, which is relatively new.^{65,66} The transconjunctival approach is a valuable one for patients in whom a noticeable scar would be unavoidable with the transdermal approach (ie, young patients), patients who have residual medial fat pad prominence after traditional upper lid blepharoplasty, or as an adjunct to a brow lift and periorbital laser for periorbital rhytids. Patients with severe blepharoptosis, dermatochalasis or prominent upper lid asymmetry are not candidates for this approach.⁶⁵

After instilling tetracaine on the corner of the operative eye a corneal protective lens is inserted. Local anesthesia is next injected into the medial aspect of the upper fornix. A Desmarres retractor is used to expose the upper lid palpebral conjunctiva. An incision is made 3 to 4 mm above the upper tarsal margin, and medial dissection toward the contralateral parietal bone is carried out using angled scissors. Once the connective tissue of the medial fat pad is opened the fat protrudes outward. The fat is next gently grasped, clamped, and cauterized at the excision base. When fat excision is complete the lid is released without closure of the incision site.^{65,67}

Asian Upper Eyelid Blepharoplasty Originally described in 1896 by the Japanese physician M. Mikamo, the double eyelid procedure creates a superior palpebral crease in Asian patients with single eye-

lids.⁶⁸ This frequently performed cosmetic procedure seeks to create a defined crease parallel to the eyelid margin or an arcing crease that begins at the medial canthal area and gradually fans away from the lid margin laterally.⁶⁹ Consideration of the patient's facial features should guide surgical planning of the lid crease.⁷⁰ Because lid crease asymmetry is the most frequent complication, careful surgical planning and marking are critical to ensure proper crease placement.⁷¹

The patient is prepared in the manner described for a transcutaneous blepharoplasty. The lower surgical mark, which indicates the final desired crease location, should be 5 to 8 mm from the ciliary margin, thereby approximating the superior tarsal margin.²⁴ Vertical tarsal height can be ascertained by lid eversion. The lower surgical mark shape depends on whether a parallel or arcing crease is planned.²⁴ The amount of skin excised, as determined by the superior surgical mark, should be conservative. The skin-muscle flap is next dissected. A suborbicularis fat pad may be encountered, which can be carefully excised to reveal the orbital septum.¹⁶ The orbital septum is next gently opened to allow for any necessary preaponeurotic fat pad treatment and to access the levator aponeurosis. Two options are frequently employed for lid crease creation, which requires an adhesion between the skin and levator aponeurosis. Direct suturing of the pretarsal orbicularis to the levator aponeurosis is accomplished via multiple small interrupted sutures that incorporate bites of the levator aponeurosis and the pretarsal orbicularis in the area of the desired final lid crease. A running suture would then be used to close the skin. Alternatively the skin edges can be directly sutured to the levator aponeurosis by picking up the lower skin edge, incorporating a small bite of levator aponeurosis in the desired crease location, and finishing by passing through the upper skin

edge. Placing several such sutures can fix the crease location and the remainder of the skin incision can be closed using sutures performed in a running fashion.²⁴ Figure 64-21 depicts the latter variation in Asian eyelid crease reformation.

Lower Eyelid Blepharoplasty

Selection of Approach Blepharoplasty of the lower eyelid can be approached via an anterior transcutaneous or a posterior transconjunctival approach depending on the abnormalities to be addressed. The traditional transcutaneous route provides excellent visualization of lower lid fat pads and allows for excision of excessive skin, hypertrophic orbicularis muscle, and herniating fat. The risk of lower lid malposition, however, is not insignificant using an

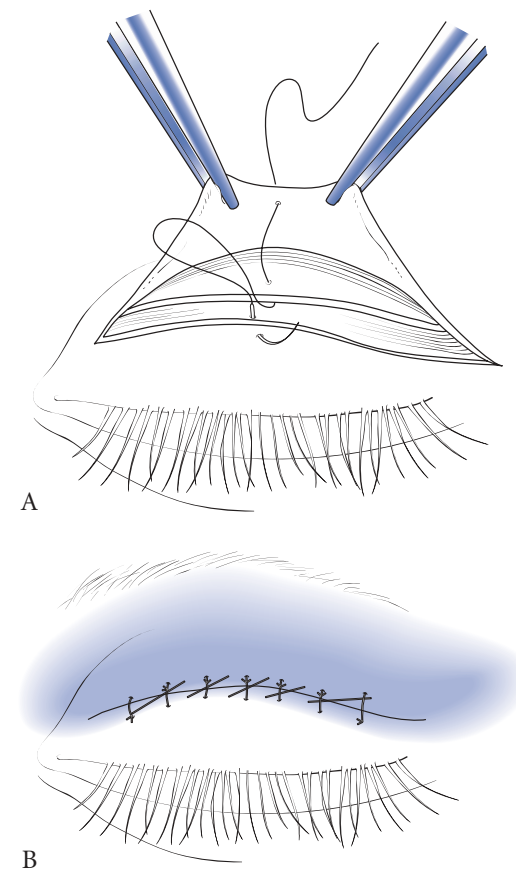

FIGURE 64-21 Asian lid crease reformation. A, Direct suturing of the orbicularis to the levator aponeurosis. B, A continuous suture is used to approximate wound edges. Adapted from Chen WP.²⁴

anterior approach. The transconjunctival approach carries a significantly lower risk of postoperative lower lid malposition and does not create an external scar. The transconjunctival approach is ideal in the setting of isolated fat herniation with minimal skin redundancy. The darkly pigmented patient predisposed to altered pigmentation or scar formation may also be a good transconjunctival blepharoplasty candidate. Patients with thyroid eye disease, who are prone to lower eyelid retraction, are potential posterior blepharoplasty candidates provided enough lid laxity is present to allow conjunctival access. Adjunctive procedures such as chemical peels, CO₂ laser skin resurfacing, or pinch skin excision are commonly performed in association with transconjunctival lower lid blepharoplasty. These adjunctive procedures have expanded the lower lid pathologies successfully treated by the transconjunctival approach to include most patients.⁷²

Presence of lower eyelid laxity calls for an adjunctive horizontal lower lid tightening procedure at the time of lower eyelid blepharoplasty. Failure to perform such a procedure heightens the risk of lower lid retraction, lateral canthal abnormalities, and inferior scleral show.

Transcutaneous Approach An infraciliary surgical mark is drawn approximately 1.5 mm beneath and parallel to the lower lash line extending from the punctum to the lateral canthus. Temporal to the lateral canthus the mark is continued laterally within a preexisting “laugh line” for approximately 5 mm. Care should be taken to avoid an inferiorly sloping termination of the incision as an unnatural surgical scar will result. Subcutaneous anesthesia is next injected and the patient is prepared for surgery in a similar manner to that described for upper eyelid blepharoplasty.

A no. 15 Bard-Parker blade, CO₂ laser, microdissection needle, or other incising instrument is used to make the skin incision. A 4-0 silk traction suture

may be placed through the skin, orbicularis, and superficial tarsus to aid in upward displacement of the lower eyelid. Subcutaneous dissection is carried out taking care to minimize trauma to the pretarsal orbicularis. Next the orbicularis is incised below the inferior tarsal border with Westcott scissors or other appropriate instrument for the full length of the incision. A skin and muscle flap is dissected inferiorly toward the orbital rim. Excellent hemostasis should be obtained with judicious use of cautery. The orbital septum is next opened with Westcott scissors where it overlies the lower eyelid fat pads. The fat pad capsules are subsequently incised beginning with the lateral fat pad, which is the more difficult compartment to visualize. Gentle ballottement of the globe is used to aid in fat prolapse. The herniated fat is grasped, clamped, and excised. Meticulous hemostasis of fat is essential to avoid retrobulbar hemorrhage. Conservative fat resection is recommended, as over-resection results in a hollow appearance rather than a youthful one. The central and medial fat pads are debulked as needed in a similar fashion. Fat removal is compared bilaterally for symmetry.

A horizontal tightening procedure is indicated in nearly all cases of anterior approach lower lid blepharoplasty. The lateral tarsal strip procedure is a secure time-honored method of resuspending the lower eyelid but requires opening of the lateral commissure.⁷³ Alternative procedures addressing lower lid laxity include suspension of the lateral retinaculum and canthal-sparing lateral canthopexy.^{74,75}

The skin and muscle flap are draped over the edge of the lid margin while the lid is not held in traction and the patient is looking upward and opening his or her mouth. These latter maneuvers simulate the lower eyelid's maximally extended position and aid in preventing excessive skin removal.⁷² The redundant skin and muscle flap is drawn superolaterally,

marked with a surgical marking pen, and subsequently excised. A conservative approach to skin and muscle excision is crucial to prevent postoperative lower lid malposition. Rarely should more than 2 to 3 mm of the skin muscle flap be excised in total.⁷² Special care should be taken to avoid creating lateral canthal rounding by not removing excessive skin laterally. Suturing the muscle flap to the zygomatic periosteum prior to excision of excess skin and orbicularis muscle may provide better appreciation of final tissue location and permit modifications prior to permanent tissue alteration. If hypertrophic orbicularis was earlier noted, a strip of orbicularis muscle should be excised in the affected area prior to closure of the skin. The muscle is later closed with interrupted buried absorbable suture (ie, 7-0 polyglactin). Alternatively, should greater support be desired, the muscle may be anchored to the zygomatic periosteum, if not already performed. The skin is closed with a running 6-0 fast-absorbing gut suture proceeding from the medial to lateral aspect. Figure 64-22 demonstrates several of the important aspects of transcutaneous lower eyelid blepharoplasty.

Transconjunctival Approach Formal marking is not performed for transconjunctival lower eyelid blepharoplasty, although marking the herniating fat pads may be of benefit.⁷⁶ Topical anesthesia is instilled onto the ocular surface and a corneal protective contact is inserted. Local anesthesia is injected subcutaneously in the central lower lid just beneath the lashes and into each fat pad. The skin is next prepared with 5% povidone-iodine or pHisoHex as in the previously described fashion.

The inferior palpebral conjunctiva is exposed using a Desmarres retractor or a 4-0 silk traction suture placed through the skin, orbicularis, and superficial tarsus in the central lower eyelid. The traction suture may be placed through the

FIGURE 64-22 Transcutaneous lower eyelid blepharoplasty. A, Surgical marking. B, Skin incision along previously placed surgical marks. C, Subcutaneous dissection. D, Orbicularis incision beneath the inferior tarsal border. E, Extension of orbicularis incision to achieve full length of skin incision. F, Gentle globe ballotement to expose herniated fat after orbital septal incision. G, Herniated fat treatment after incision of overlying fat pad capsule. H, Determination of redundant skin and orbicularis. I, Excision of redundant tissue. J, Skin closure after orbicularis fixation and orbicularis closure. Adapted from Putterman AM.⁴⁸

inferior conjunctiva and lower lid retractors and fixed superiorly to aid in exposure. An incision through the conjunctiva and the lower eyelid retractors is made approximately halfway from the inferior border of tarsus and the inferior fornix. The incision is extended medially beneath the punctum and laterally nearly to the lateral canthus. The lower lid is next retracted anteriorly and inferiorly to facilitate isolation of the three fat pads, which are further defined by blunt dissection through the capsulopalpebral fascia. The inferior oblique muscle should be identified between the central and medial fat pads. Care should be taken to avoid aggressive or sharp dissection that may induce injury to the muscle. Fat removal or sculpting is next performed beginning with the lateral fat pad. As described above gentle ballottement of the globe aids in orbital fat prolapse. The herniating fat is carefully grasped and excised. Some surgeons favor clamping the fat during excision. Meticulous hemostasis is essential during fat pad excision. After fat pad debulking the anterior border of the fat pads should be flush with the inferior orbital rim. Overzealous fat pad excision risks a postoperative hollow appearance.

The superior traction suture is removed prior to closing the conjunctiva. Complete hemostasis should be confirmed before closure is attempted. The conjunctiva and lower eyelid retractors are reapproximated with two or three buried interrupted sutures of 6-0 or 7-0 polyglactin or other suture. Several important aspects of transconjunctival lower eyelid blepharoplasty are demonstrated in Figure 64-23.

Skin Pinch Excision Transconjunctival lower lid blepharoplasty does not address excess lower lid skin, making skin pinch excision a useful adjunct for small amounts of excess lower lid skin. Significant excessive lower lid skin is identified using the aforementioned pinch test. Local anesthesia is next injected and the pinch

test is performed again, taking care to place the tine of the forceps within a pre-existing skin fold and create a pinched off ridge of tissue to be removed. The redundant skin is then excised using curved scissors. The skin is closed using 6-0 fast-absorbing gut suture in a running fashion.

Lateral Canthopexy A time-honored procedure for lateral canthopexy is the lateral strip procedure, which entails determining the amount of horizontal excess of lower eyelid (part of which is used as the tarsal strip), dividing the lower lid of the strip at the gray line, and removing the anterior lamella, conjunctiva, cilia, and lid margin-associated glands.⁷³ Desired lower lid position is determined and a suture on a semicircular needle is used to fasten the tarsal strip to the periosteum inside the lateral orbital rim at a level to yield the optimal postoperative lower lid location and apposition of lower eyelid to the globe. A canthal reformation suture is passed through the gray line of the upper eyelid and the tarsal strip to recreate the lateral canthal angle. The orbicularis is closed using buried interrupted absorbable suture. Fast-absorbing gut suture is used to close the skin.

Midfacial Rejuvenation Standard lower eyelid blepharoplasty does not address midfacial aging changes often present in the blepharoplasty patient. Hamra proposed an arcus marginalis release procedure to recreate the contour of the youthful lower lid and cheek.⁷⁷ The procedure entails creating a skin-muscle flap, incision of the arcus marginalis at the orbital rim, and removal of a portion of the inferior orbital septum, with subsequent reposition and fixation of the orbital fat over the orbital rim.⁷⁷ A transconjunctival approach to the arcus marginalis with similar transposition of orbital fat has recently been advocated.⁷⁸ Elevation of the soft tissue of the midface by suture plication using transcuta-

neous, subperiosteal, transconjunctival, and supraperiosteal routes has also been described.^{79,80}

Steinsapir recently reported the use of a hand-carved expanded polytetrafluoroethylene orbital rim as both a site for resuspension of the midfacial soft tissues and a mechanism to compensate for lost midface volume.⁸¹

Postoperative Management

Postoperative instructions seek to limit edema and ecchymosis and prevent postoperative bleeding.

Ice-cold compresses are placed over the operative site immediately on arrival in the postoperative recovery area. These compresses should be used continuously for 36 to 48 hours after the procedure with cessation only for dining and bathroom breaks. After 48 hours warm compresses may be used for comfort and to hasten resolution of edema. Up to 4 weeks should be allowed for resolution of bruising, although the majority of patients note limited discoloration beyond 1 week. Complete resolution of edema may require several weeks.

During the first 48 to 72 hours minimal physical activity is recommended. Patients should remain supine with approximately 30 degrees of head elevation provided by pillows or a recliner. Walking and low impact activities can be resumed after postoperative days 2 to 3, although refraining from strenuous physical activity for the first week postoperatively is strongly recommended. During weeks 2 and 3, activity may gradually be increased. In general most patients require 1 to 2 weeks off from work including the operative day. For patients with physically intense occupations, longer time away is required.

Application of a combination antibiotic and steroid ointment to any dermal incision site is recommended. Keeping the absorbable sutures moist allows for their timely dissolution. A typical schedule includes three times per day application for

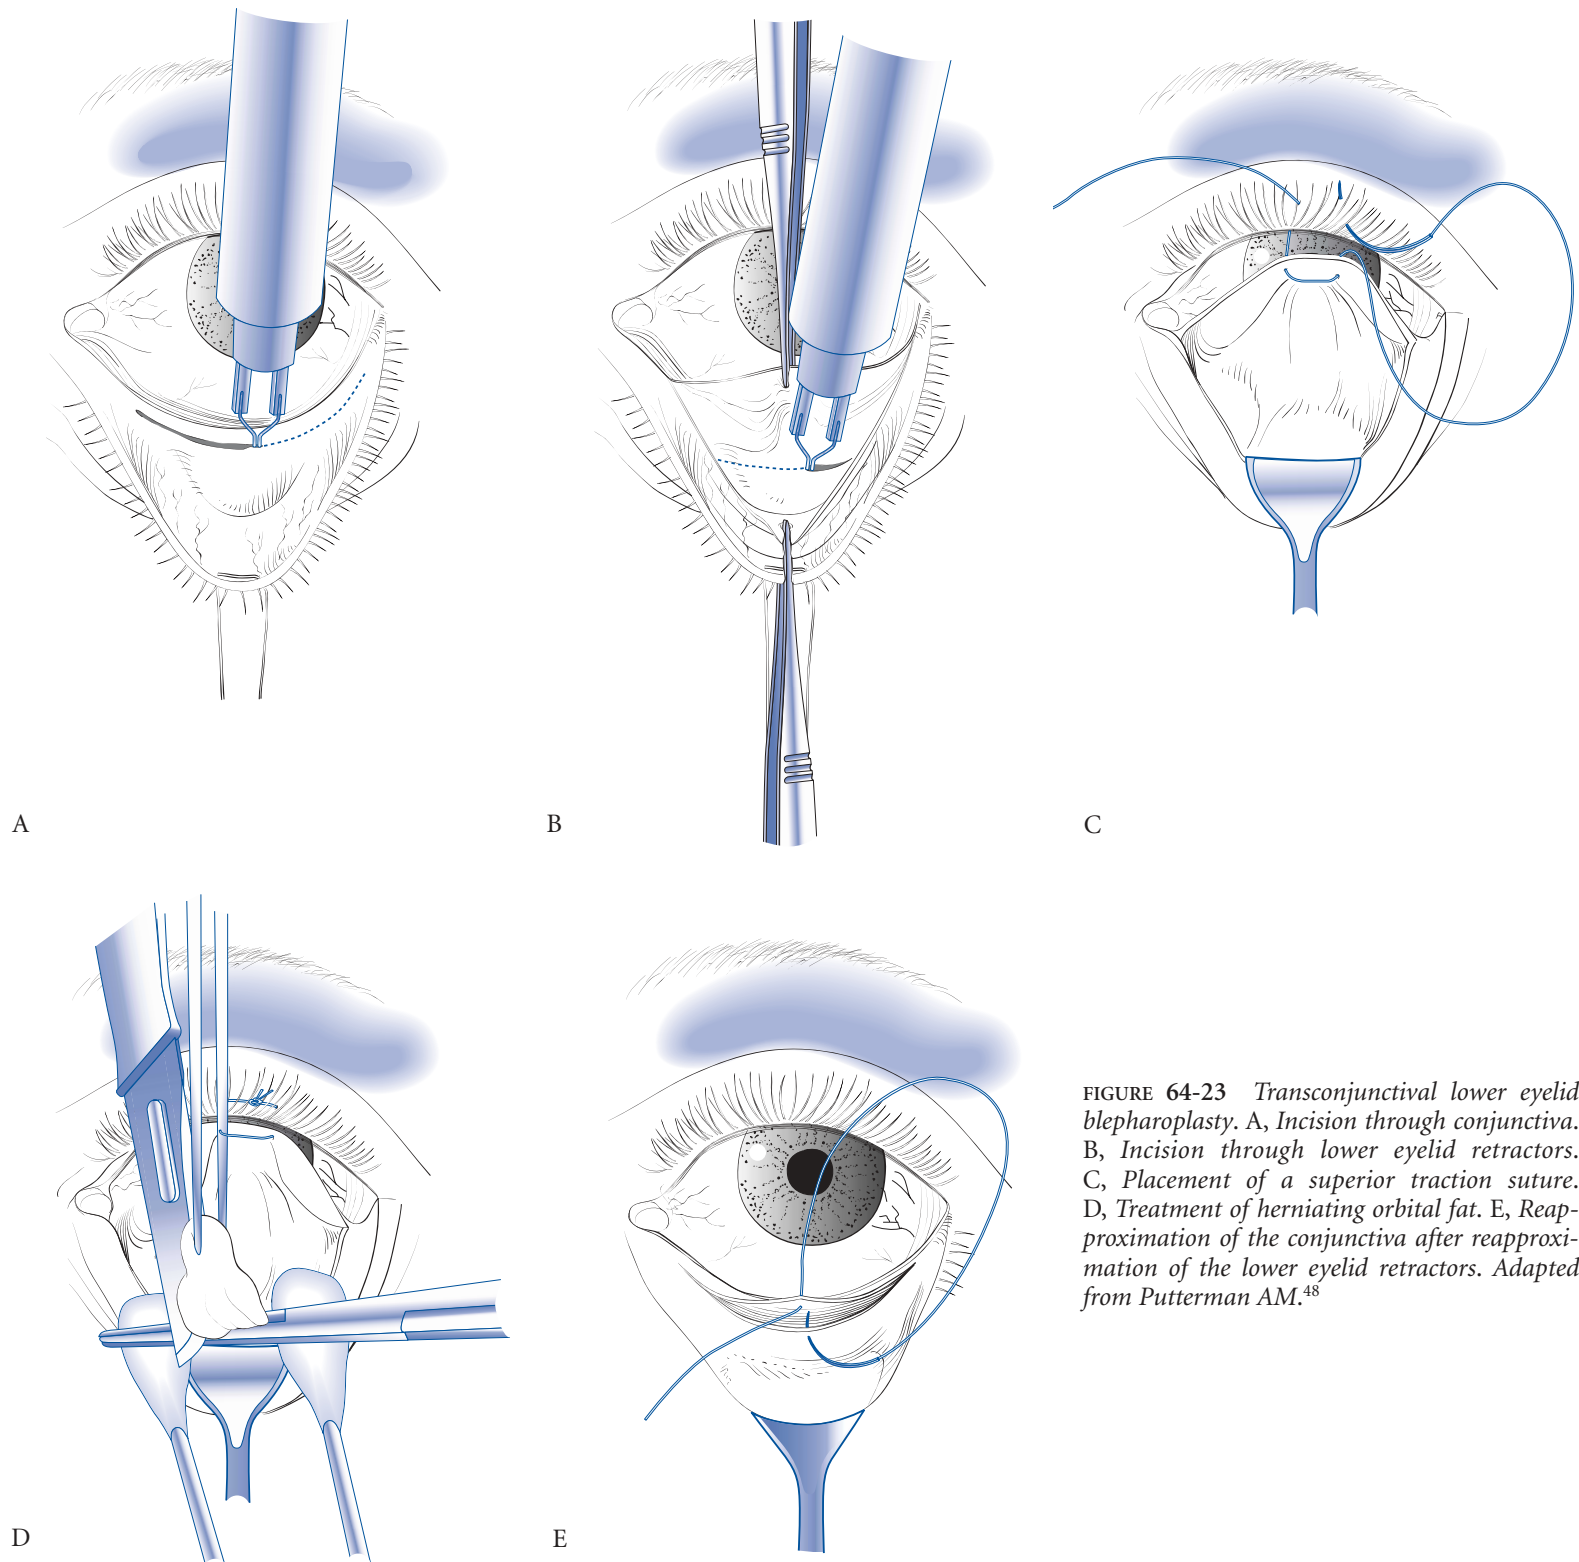

FIGURE 64-23 Transconjunctival lower eyelid blepharoplasty. A, Incision through conjunctiva. B, Incision through lower eyelid retractors. C, Placement of a superior traction suture. D, Treatment of herniating orbital fat. E, Reapproximation of the conjunctiva after reapproximation of the lower eyelid retractors. Adapted from Putterman AM.⁴⁸

the first week, with taper to twice daily application in the second week and application four times daily in the third week. Transconjunctival incision sites should be lubricated with an antibiotic ointment in a

similar schedule. Application of makeup to the incision sites should be deferred 1 week.

Postoperative pain is usually not a significant concern. Nonetheless a prescription for several tablets of a low potency

opioid and acetaminophen combination analgesic may be provided. Acetaminophen should be sufficient for the majority of patients. Routine aspirin and nonsteroidal anti-inflammatory drug use

can be resumed several days postoperatively. Warfarin may be restarted on the day after surgery. Excessive postoperative discomfort should be investigated as it may herald an orbital hemorrhage or other complications.

The patient is advised to trim short loose absorbable skin sutures. Care should be taken to avoid rubbing the incisions or vertically stressing the incisions with digital traction when attempting to open the eyes. The buried absorbable sutures may occasionally be palpated postoperatively as small nodules along the incision for as long as 5 to 6 weeks. Occasionally these buried sutures may surface and require trimming.

Follow-up evaluation 1 week postoperatively is typical, with additional visits scheduled as needed. Postoperative photography is typically obtained approximately 4 months after the procedure.

Management of Complications

Complications following blepharoplasty are either cosmetic, functional, or vision-threatening. The majority of complications can be readily prevented by clear preoperative communication, careful preoperative and intraoperative measurements, and meticulous surgical technique. Prior to pursuing surgery all the major possible complications should be discussed with the patient.

Complications of Upper Eyelid Blepharoplasty

Inadequate Skin Excision A common postoperative cosmetic concern, inadequate skin excision manifests as a second fold superior to the upper eyelid crease. Previously unrecognized eyebrow ptosis may contribute to the appearance of excess skin, especially laterally, and should therefore be assessed. When a true excess of upper lid skin is present, careful additional resection of skin and orbicularis is indicated. In general revision blepharoplasty should be delayed for several months to allow resolution of edema.

Excessive Skin Excision Overzealous removal of upper eyelid skin may result in cosmetic as well as functional concerns. Patients may describe a tight sensation in their lids, demonstrate lagophthalmos, or display symptoms and signs of exposure keratitis. Like most complications, excessive skin excision is best prevented as subsequent management is challenging. Lid massage, consisting of vigorous downward massage on the anterior tarsal surface, instituted 1 to 2 weeks postoperatively, can resolve mild cases. The patient is advised to blink fully and use artificial tears during the day and ophthalmic ointment at night. More significant over-resection of skin may require full-thickness skin grafting, commonly performed after 6 months to allow for more complete wound healing. Retroauricular skin is frequently used as a graft site for eyelid reconstruction. Care must be taken to properly thin the graft. If possible the graft placement should be superior to the lid incision to lessen cosmetic impact.

Lid Crease Asymmetry Raising an inferior lid crease is easier than lowering an excessively high crease; therefore, unless the higher crease is abnormally elevated, the lower crease should be raised to achieve symmetry. Removing a crescent of skin and muscle above the low crease, with care to make the inferior edge (the new location of the lid crease) symmetric with the opposite crease, lysing any attachments inferior to the new crease location, and closing the ellipse by incorporating several stitches through the levator aponeurosis recreates the new lid crease.⁴⁸

High Lid Creases Successfully lowering an excessively high lid crease is difficult. The adhesions forming the current lid crease must be interrupted and an incision made for the new crease closed by suture bites through the levator aponeurosis and the new incision wound edges. In some cases orbicularis muscle transposition

from above can prevent the original skin crease adherence to the underlying fibrous tissue. A fat graft between the orbital septum and levator aponeurosis may be required to prevent adhesions.⁸²

Excessive Fat Removal A deep medial concavity or superior sulcus results from aggressive medial fat removal. Injection of autogenous fat or dermal fat grafting has been attempted to augment an excessively hollow superior sulcus. Careful conservative fat excision is warranted to avoid superior sulcus syndrome, especially in males, as creation of a deep sulcus feminizes the eyelid.

Wound Dehiscence Wound dehiscence is best handled by resuturing the eyelid if the area of dehiscence is greater than several millimeters in length. Small areas of dehiscence can be allowed to granulate if granulation does not impair final scar cosmesis. If re-approximation is performed the wound bed should be scraped free of granulation tissue and the edges trimmed to expose fresh tissue prior to the second closure. Surgical closure should include adequate muscular closure to minimize this complication.

Suture Milia Suture milia are small cystic epithelial inclusions occurring at suture entrance points into the skin. Common and temporary, suture milia appear approximately 1 week postoperatively and disappear over the ensuing months. Hot compresses may hasten milia resolution. Alternatively a large bore needle or scissors can be used to create an opening in the cyst to aid in healing.

Postoperative Ptosis Injury to the levator aponeurosis through direct intraoperative trauma or from stretching by postoperative hematoma may result in postoperative ptosis.⁸³ Recent anatomic dissections evidencing terminal branches of the superior division of the oculomotor nerve far anterior in the levator palpebrae superioris

muscle prompted speculation that infiltrating local anesthetics affecting these end branches may induce transient ptosis.⁸⁴ Mild postoperative ptosis (2 mm or less) from eyelid edema can be observed for spontaneous resolution. Poor levator function or severe ptosis warrants timely surgical exploration, as the fibrotic phase of healing will complicate repair. Surgical correction of prolonged ptosis can be accomplished with a conjunctival Müllerectomy, or external levator repair in mild cases, and levator aponeurosis advancement in more extensive cases.

Dry Eye Symptoms Dry eye symptoms are a frequent complication of blepharoplasty due to altered lid function and decreased spontaneous blink rate and magnitude. Topical artificial tears and lubricating ointment are often sufficient for symptom control, although punctal occlusion may be warranted in the setting of more severe dry eye symptoms. Punctal occlusion at the time of blepharoplasty in patients with dry eye syndrome may be of some benefit in decreasing postoperative exacerbation of symptoms.⁸⁵

Diplopia Injury to the superior oblique tendon or trochlea, although uncommon, has been described following upper blepharoplasty with medial fat excision.^{86,87} Poor visualization during cautery or dissection was implicated during reported cases.^{86,87} Recent anatomic dissections confirm a consistent relationship between the trochlea and superior orbital foramen and the superior oblique tendon and the frontozygomatic suture.⁸⁸ Direct visualization during cautery and dissection coupled with familiarity of associated anatomy decreases the risk of tendon or trochlear damage.

Bleeding Intraoperative and postoperative bleeding can be vision-threatening complications. Patients should be instructed to discontinue aspirin, nonsteroidal anti-inflammatory drugs, and

other platelet-impairing medications 1 to 2 weeks preoperatively. Warfarin is generally withheld 4 days preoperatively. Intraoperative bleeding often results from the orbicularis muscle. Recent evidence suggests a prominent arterial branch, which pierces the orbital septum and levator aponeurosis at the upper aspect of the tarsus, may account for excessive bleeding if damaged when the septum is opened for fat excision.⁸⁹

Aside from causing significant ecchymosis, insufficient hemostasis can result in retrobulbar hemorrhage or hematoma and concomitant loss of vision.^{90,91} Many patients will describe a small degree of bruising and swelling postoperatively, often beginning after a sneeze, cough, or in the setting of hypertension. Significant pain, proptosis, marked upper lid swelling, restricted extraocular motions, and/or any decrease in vision raises suspicion for a retrobulbar hemorrhage, a true emergency requiring immediate bedside wound release with or without a lateral canthotomy and cantholysis, hyperosmotic agents, and systemic corticosteroids.

Hematoma presents with severe ecchymosis and eyelid edema. Visual compromise may be present if the lids are tense. Since compression of the globe and optic nerve is of concern, intraocular pressure (IOP) should be measured. If no visual deterioration or increase in IOP is found, conservative management with ice-cold compresses can be used. Visual compromise or increased IOP may necessitate a return to the operating room to reopen the incision site, evacuate any clots, and address the source of bleeding.

Vision Loss Most cases of vision loss after blepharoplasty are due to hemorrhage or hematoma formation with resultant optic nerve damage or central retinal artery occlusion.^{90,92} Angle-closure glaucoma following blepharoplasty has also been reported.⁹³ Instructing patients to monitor their vision and promptly

responding to all patient reports of excessive pain best detect these complications.

Complications of Lower Eyelid Blepharoplasty

Lower Eyelid Retraction Eyelid malposition after lower lid blepharoplasty has several etiologies: excessive anterior lamella removal, scarring of the orbital septum, inadequate treatment of lower eyelid laxity, or hematoma-associated fibrosis. Delayed lower eyelid retraction resulting from scarring of the orbital septum is largely associated with the anterior approach to lower eyelid blepharoplasty. A posterior approach avoiding incision of the orbital septum has been demonstrated to minimize lower eyelid retraction.⁹⁴ Lower eyelid retraction is a more frequent complication in patients with shallow orbits and prominent eyes.

Initial treatment of lower eyelid retraction varies with extent and duration of altered lid position. Early identification of retraction warrants conservative treatment such as vigorous upward massage, placement of temporary traction sutures, or a temporary tarsorrhaphy suture.⁹⁵ Postoperative edema may contribute to early postoperative retraction, emphasizing the importance of a period of watchful waiting and conservative therapy.

Persistent retraction resistant to conservative measures can be treated with septal scar tissue lysis and lateral canthopexy. Scar lysis is accomplished by dissection between the orbicularis and septum via an incision associated with a lateral canthotomy.⁹⁶ Lateral canthopexy is usually performed using the lateral tarsal strip approach as described previously.⁷³ Temporary suspension of the lower eyelid to the brow has been proposed to provide further upward traction.⁹⁶

Severe lower eyelid retraction may necessitate posterior lamella extension with a hard palate mucosal or ear cartilage graft, often with a horizontal tightening

procedure.^{96–99} The palpebral conjunctiva and lower eyelid retractors are incised and recessed. Through a palpebral conjunctival incision inferior to the lower tarsal border, the orbicularis is exposed and the graft sutured inferior to the tarsus in the recipient bed.

Lower Eyelid Ectropion Often symptomatic due to drying of the exposed conjunctiva, lower lid ectropion may exist alone or in combination with lower lid retraction. If previously unappreciated lid laxity is present, horizontal tightening is performed as previously described. A deficit of anterior lamella is addressed using a full-thickness skin graft harvested from the upper eyelid or retroauricular area. Grafts must be sized larger than the ideal final size to accommodate postoperative contracture.

Inadequate Fat Removal Further excision of lower eyelid fat should be addressed through a posterior approach to avoid excessive cutaneous scar formation and lower lid malposition. Often the lateral lower eyelid fat pad is implicated.

Excessive Fat Removal A tear trough deformity, the lower lid analog to the upper lid superior sulcus syndrome, describes a prominent inferior orbital rim and nasojugal fold that may result from aggressive lower lid fat removal. Injection of autologous fat into the deformity, particularly directed at the underlying musculature, has been attempted to address the tear trough deformity.^{100,101} Eyelid fibrosis with decreased mobility is associated with excessive fat removal and multiple surgical interventions.

Diplopia Diplopia may result after both transcutaneous and transconjunctival lower lid blepharoplasty due to direct and indirect injury of the inferior oblique and inferior rectus.^{87,102} Inferior oblique injury should be suspected in patients

complaining of vertical diplopia increasing in gaze contralateral to the operated eye. Recent anatomic dissections demonstrate a consistent relationship between the inferior oblique muscle and the inferior orbital rim, infraorbital foramen, and supraorbital notch.¹⁰³ Precise anatomic knowledge coupled with avoidance of an excessively inferior conjunctival incision and care when treating prolapsed fat are recommended to avoid extraocular muscle injury.

Bleeding As previously discussed with complications of upper lid blepharoplasty, hemostasis is critical in blepharoplasty to avoid postoperative retrobulbar hemorrhage and hematoma formation.

Vision Loss Causes of vision loss after lower eyelid blepharoplasty are similar to those described with upper eyelid blepharoplasty.

Adjunctive Procedures

Chemical Peeling

Chemical peeling, or chemexfoliation, involves using a chemical agent to wound the epidermis and dermis, thereby evoking an inflammatory healing response that acts to improve skin texture. The level of the peel is dictated by the depth of penetration, nature of destruction, and inflammatory response. A variety of agents may be employed, most commonly trichloroacetic acid (TCA), glycolic acid, or phenol, and the concentration of the chemical agent varies depending on the depth of peel desired.¹⁰⁴ In general more severe rhytids or skin texture problems require a deeper peel to achieve the desired effect. Medium-depth TCA chemexfoliation in conjunction with transconjunctival lower eyelid blepharoplasty has been demonstrated to achieve excellent results in improving lower eyelid skin appearance.¹⁰⁵

Evaluating a blepharoplasty patient for chemexfoliation requires additional

appreciation of skin pigmentation, often using the Fitzpatrick skin pigment type classification, inquiry into history of herpes simplex infection, and knowledge of the patient's need to return to social activities.⁴⁷ Previous herpes infections may require prophylaxis with antiviral agents. Patients with higher Fitzpatrick skin types, extensive sun exposure, or diffuse freckling may have unacceptable scarring, hypopigmentation, or noticeable demarcation borders of treated skin and hence should be considered with caution.¹⁰⁶

Chemexfoliation relies on even application of the peeling agent to the intended treatment area. Pretreatment of the treatment area with retinoic acid can be performed to enhance uptake. Any skin oil or greases will impair even chemical treatment, making careful soap and water skin cleansing and acetone degreasing crucial to a successful peel. Chemical peeling should follow completion of blepharoplasty surgery. The peel is applied to the skin using sturdy cotton-tipped applicators, with care taken to achieve symmetric application, avoid inadvertent corneal application, and treat more lightly those areas with the thinnest skin (ie, medial canthal and pretarsal skin). Initially a white frost becomes apparent after chemical application, which gives way to deep erythema. Cold compresses to the treated area after the skin has dried may decrease discomfort. A bland lubricating ointment should be applied to treated skin prior to the patient leaving the postoperative recovery area. Postoperative care for patients undergoing chemical peel requires twice to four times daily mild soap cleansing, gentle patting to dry, and ointment re-application until all treated skin has reepithelialized. Sun exposure, which may cause skin burning and hyperpigmentation, should be avoided meticulously by wearing a hat and dark sunglasses during the first month. Careful sunscreen application is advised thereafter.

Complications of chemexfoliation include pigmentary change, scarring or

other textural changes, corneal damage, lid position abnormalities, infection, prolonged erythema, acne, and cold sensitivity.

Laser Skin Resurfacing

Laser skin resurfacing employs a CO₂ or erbium laser to thermally remove a defined layer of dermal tissue and shrink collagen, prompting improved skin appearance through collagen contraction, new collagen formation, and remodeling and epidermal growth. The number of passes taken determines the depth of treatment. Laser resurfacing is ideal for patients with minimally pigmented skin who seek improvement of skin with photodamage or acne scarring.¹⁰⁷ Adjunctive CO₂ laser resurfacing of the lower eyelid in conjunction with transconjunctival lower lid blepharoplasty has been demonstrated to successfully address lower eyelid wrinkling that may result from transconjunctival blepharoplasty alone.¹⁰⁸ When compared to a phenol chemical peel, CO₂ laser resurfacing was found to be equally as efficacious in diminishing rhytids in thin-skinned facial areas and more effective at improving texture in thicker glandular facial areas.¹⁰⁹ The erbium:yttrium-aluminum-garnet (YAG) laser has been recently introduced as an alternative method of laser skin resurfacing.

History and physical elements to be explored are similar to those described for patients being evaluated for chemexfoliation. Additionally past use of isotretinoin (accutane) should be obtained, as the drug-induced elimination of glandular architecture contraindicates laser resurfacing for the subsequent 1 to 2 years following drug discontinuation.¹¹⁰ Prior to undergoing laser resurfacing, patients predisposed to hyperpigmentation are typically treated for several weeks with a skin bleaching agent. Prophylactic antivirals and antibiotics are also commonly employed.

Surgical marking plays a critical role in successful laser resurfacing by providing a

roadmap to direct treatment application. After carefully marking all significant rhytids, general anesthesia or monitored sedation coupled with proper local or regional nerve block anesthesia is achieved. Resurfacing is performed using laser settings determined by the area of interest. Resurfacing is carried out methodically, taking care to wipe the ablated tissue away prior to re-treatment to avoid excessive heat absorbance in any given location. Generally one or two passes with lower power are performed on periocular skin.¹¹⁰ Color change indicates depth of treatment, progressing from pink to orange to yellow-orange to yellow-white as more passes are made or more energy is used per pass. Excessive treatment risks hypertrophic scarring. After procedure completion the skin is irrigated, gently patted dry, and a dry occlusive or wet dressing is applied. Many surgeons have abandoned occlusive dressings in favor of simply keeping the face well lubricated with a bland lubricant such as petroleum jelly. Dilute vinegar and water soaks are favored by many for cleansing. Dressings are changed daily with additional lubrication ointment applied until reepithelialization occurs, generally after 10 to 14 days. Antibiotic ointment is occasionally used; however, the risk of inducing allergies to the applied antibiotic has lessened the frequency of this practice. Ice packs are used postoperatively to reduce edema. Complications are similar to chemexfoliation.

Basic Principles of Rhinoplasty

James Koehler, DDS, MD

Peter D. Waite, MPH, DDS, MD

For many cosmetic surgeons rhinoplasty is one of the most challenging surgical procedures. A clear understanding of nasal anatomy is critical in order to provide an esthetic result that does not compromise nasal function. Developing a pattern of analysis of the nose is vital for proper diagnosis and for determining the most appropriate treatment plan. Numerous rhinoplastic techniques have been described. Some surgeons favor an endonasal approach whereas others believe that an external approach is more desirable. Each surgeon must become familiar with all technique options in order to address the wide variety of challenges of rhinoplasty surgery.

The goal of this chapter is to give a broad overview of the diagnosis and treatment of nasal deformities. It is by no means exhaustive since multiple textbook volumes have been written on this subject. The reader should gain an understanding of nasal anatomy and determine how to systematically analyze the nose. Both endonasal and external rhinoplasty will be described.

Nasal Anatomy

A clear understanding of nasal anatomy is important to successfully perform nasal procedures and decrease the incidence of complications.

Surface Anatomy

The terms used to describe the surface anatomy of the nose are important in

nasal form analysis and for treatment plan formulation (Table 65-1). For descriptive purposes the spatial relationships are described as cephalic, caudal, dorsal, basal, anterior, posterior, superior, and inferior (Figure 65-1).

Skin and Soft Tissue

The soft tissue that overlies the bone and cartilage may influence the final result of rhinoplasty. The thickness of the skin will determine how it will re-drape after performing a rhinoplasty. The skin thickness varies along the dorsum of the

nose. The skin is fairly thick and mobile in the region of the nasion. It quickly thins over the nasal dorsum and is generally thinnest and most mobile in the mid-dorsal region (rhinion). In the distal third of the nose the skin tends to be more thick and adherent and has an increased sebaceous content.

A patient with thin skin will show dramatic changes with alteration of the underlying bone and cartilage, and this limits room for error since little is camouflaged by the thickness of the skin. Conversely for thick-skinned individuals more

Table 65-1 Surface Anatomy of the Nose

Glabella: the most forward projecting point of the forehead in the midline at the level of the supraorbital ridges
Radix: the junction between the frontal bone and the dorsum of the nose
Rhinion: the anterior tip at the end of the suture of the nasal bones
Dorsum: the anterior surface of the nose formed by the nasal bones and the upper lateral cartilages
Supratip break: the slight depression in the nasal profile at the point where the nasal dorsum joins the lobule of the nasal tip
Infratip lobule: the portion of the tip lobule that is found between the tip-defining points and the columellar-lobular angle
Tip-defining points: there are four tip defining points, which include the supratip break, the columellar-lobular angle, and the most projected area on each side of the nasal tip formed by the lower lateral cartilages
Alar sidewall: the rounded eminence forming the lateral nostril wall
Alar-facial junction: the depressed groove formed on the face where the ala joins the face
Columella: the skin that separates the nostrils at the base of the nose

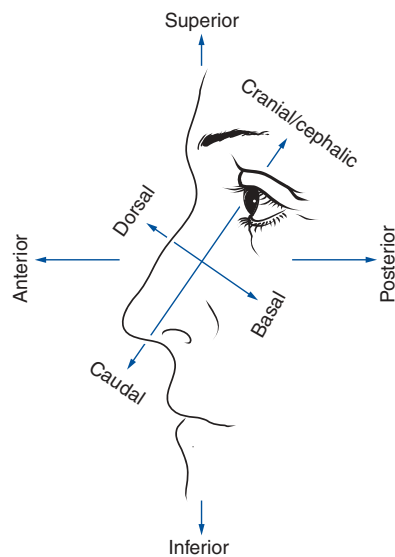

FIGURE 65-1 Spatial descriptors. In describing the relationship of one anatomic unit to another many terms are used. The standard relationships are anterior, posterior, superior, and inferior. The nose is also described in terms of dorsal, basal, caudal, and cranial (or cephalic) positions. Adapted from Austermann K. *Rhinoplasty: planning techniques and complications*. In: Booth PW, Hausamen JE, editors. *Maxillofacial surgery*. New York: Churchill Livingstone; 1999. p. 1378.

aggressive sculpturing of the nasal skeleton must be performed in order to effect significant changes. Although thick skin may mask imperfections it does not re-drape as well and can result in underlying fibrosis and formation of a polybeak deformity (supratip scarring). Better results are possible with thin-skinned patients, however the margin for error is smaller. The surgeon must sometimes modify the technique depending on the type of skin of the patient.

Superficial Musculoaponeurotic System and Nasal Musculature

The muscles of the nose are encased in the nasal superficial musculoaponeurotic system (SMAS). This is a fibromuscular layer that separates the skin and subcutaneous tissue from the nasal cartilage and bone. The SMAS of the nose is in continuity with the SMAS of the face. During rhinoplastic surgery the dissection is performed

beneath the SMAS. Violating the SMAS will often result in increased bleeding, scarring, and postoperative edema.

The muscles of the nose can be divided into four categories: the elevators, the depressors, the compressors, and the dilators (Figure 65-2). The muscles of significance are the paired depressor septi nasi. These muscles can result in drooping of the nasal tip during smiling. This added tension on the nasal tip must be recognized preoperatively and addressed by resection in order to achieve a cosmetic result.¹

Blood Supply

There is a rich blood supply to the subdermal vascular plexus of the nose that arises from branches of both the internal and external carotid arteries. The blood supply from the internal carotid artery that supplies the external nose includes the dorsal nasal artery and the external nasal artery. The dorsal nasal artery is a branch of the ophthalmic artery. The

external nasal artery is a branch of the anterior ethmoid artery.

The external nose is also supplied by branches of the facial artery and the internal maxillary artery, which originate from the external carotid artery. The facial artery branches include the angular artery, lateral nasal artery, alar artery, septal artery, and superior labial artery (Figure 65-3).

The internal nose is supplied by the internal and external carotid branches. The ophthalmic artery, a branch of the internal carotid, branches into the anterior and posterior ethmoidal arteries. The anterior ethmoidal artery supplies the anterosuperior part of the septum and the lateral nasal wall. The posterior ethmoidal artery supplies the septum, lateral nasal wall, and the superior turbinate.²

The internal maxillary artery branches include the sphenopalatine artery and the greater palatine artery. The sphenopalatine artery supplies most of the posterior part of the nasal septum, lateral wall of the

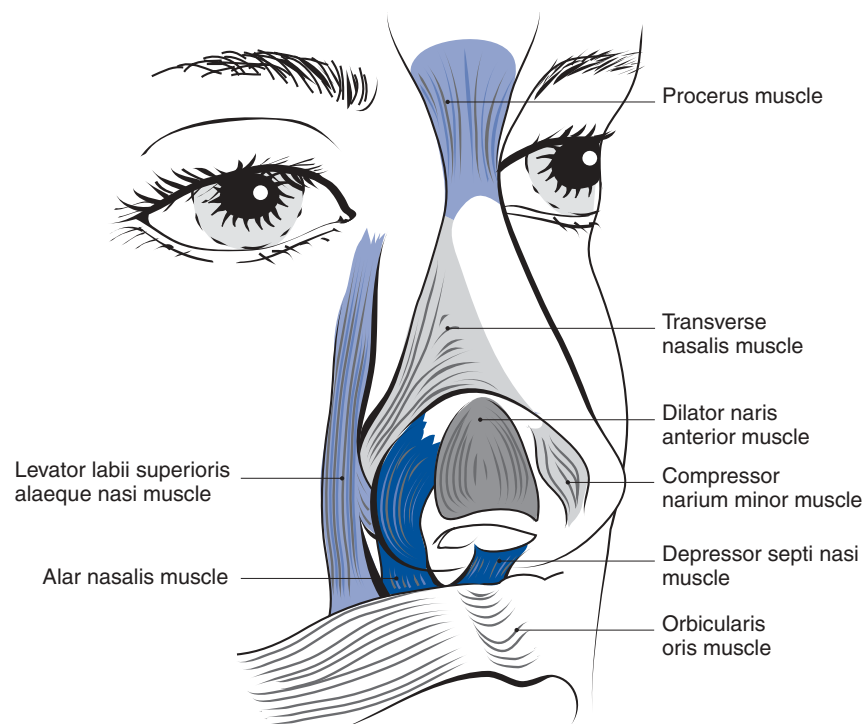

FIGURE 65-2 Nasal musculature. The muscles of the nose are grouped into the elevators (light blue), the depressors (dark blue), the compressors (light gray), and the dilators (dark gray). Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO):Mosby; 2002. p. 17.

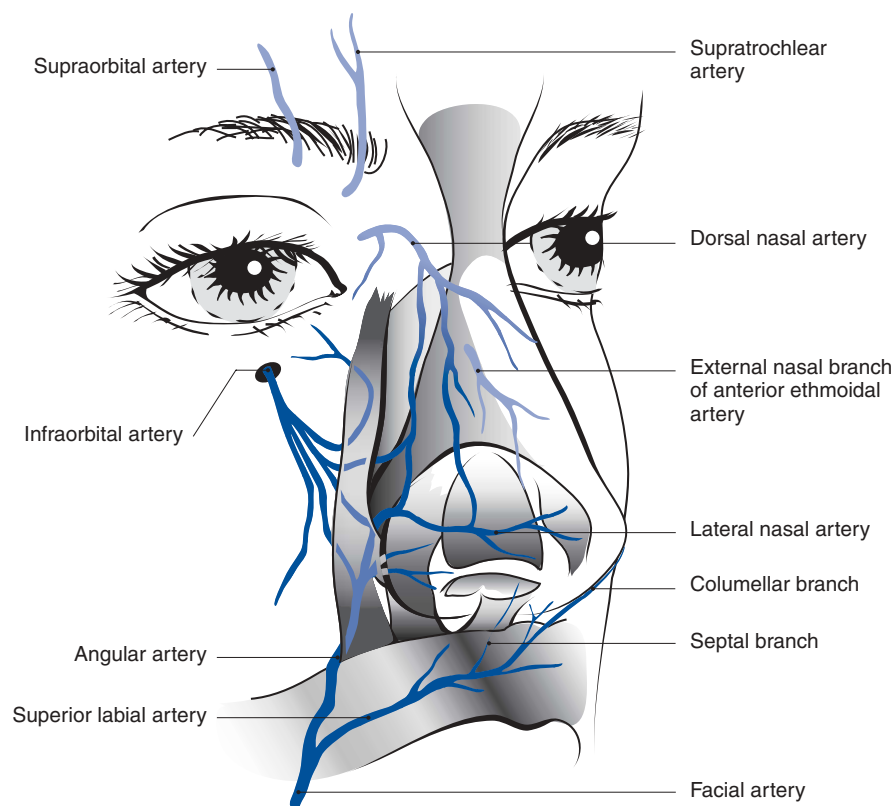

FIGURE 65-3 Arteries of the external nose. The arterial supply of the external nose comes from branches of the external carotid artery (dark blue) and the internal carotid artery (light blue). Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO): Mosby; 2002. p. 18.

nose, roof, and part of the nasal floor. The greater palatine artery supplies a portion of the anterior and inferior portion of the nasal septum (Figure 65-4).²

The surgically significant area for internal nasal bleeding is known as Kiesselbach's plexus (also termed Little's area). This is the area in the anteroinferior part of the nasal septum which is a common site of epistaxis. It is where the sphenopalatine, greater palatine, superior labial artery, and anterior ethmoid arteries anastomose (Figure 65-5).² The venous drainage of the nose is primarily from the facial and ophthalmic veins.

One concern during nasal surgery is the possibility of compromised blood flow to the nasal tip if the surgeon performs an external rhinoplasty. The blood supply to the nasal tip has been analyzed by lymphoscintigraphic studies, cadaver dissections, and histologic sections.^{3,4} The

conclusion is that the primary blood supply to the nasal tip comes from the bilateral lateral nasal arteries that course in a plane superficial to the alar cartilages in the subdermal plexus approximately 2 to 3 mm above the alar groove. Thus a columellar incision does not compromise tip blood supply. Also there are no significant veins and minimal lymphatics in the columellar region.^{3,4} Some surgeons believe that external rhinoplasty remains more edematous for longer postoperative periods than an endonasal rhinoplasty.

Bone and Cartilage

The structure of the nose consists of the paired nasal bones as well as the frontal process of the maxilla. The bone is thickest near the junction with the frontal bone and tapers as it joins with the upper lateral cartilages.

The upper lateral cartilages are in intimate contact with the nasal bones and underlie the nasal bones for approximately 6 to 8 mm. The connection between the

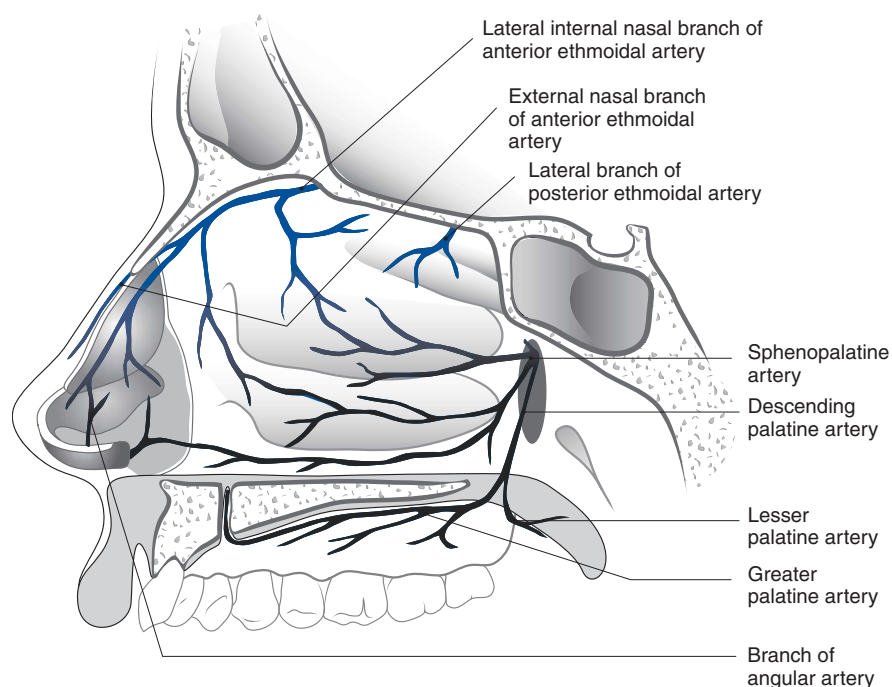

FIGURE 65-4 Arteries of the lateral nasal wall. The arterial supply of the lateral nasal wall arises from branches of the external carotid artery (black) and the internal carotid artery (blue). Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO): Mosby; 2002. p. 23.

FIGURE 65-5 Arteries of the nasal septum. The arterial supply of the nasal septum arises from branches of the external carotid artery (black) and the internal carotid artery (blue). Kiesselbach's plexus is formed by the sphenopalatine artery, greater palatine artery, superior labial artery, and anterior ethmoid arteries. It is a common site of epistaxis. Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO): Mosby; 2002. p. 23.

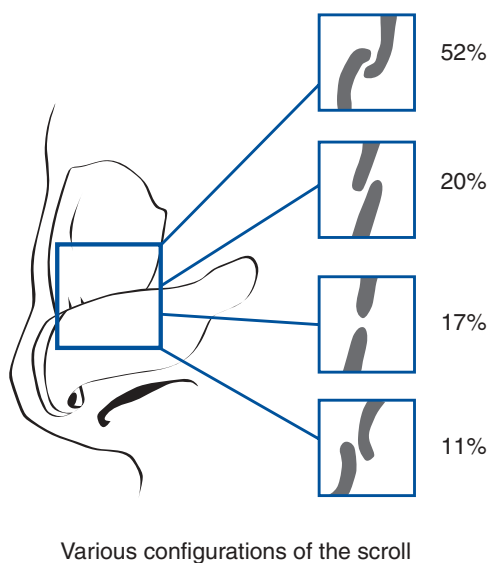

FIGURE 65-6 Configurations of the scroll. The relationship of the upper lateral and lower lateral cartilages is termed the scroll. Anatomic studies have identified four common configurations: interlocked (52%), overlapping (20%), end to end (17%), and opposed (11%). Adapted from Lam SM and Williams EF III.⁵

nasal bones and upper lateral cartilages should not be violated since this may disrupt the internal nasal valve causing nasal obstruction and asymmetry. The internal nasal valve is formed by the junction of the upper lateral cartilages and the nasal septum.

The lower lateral cartilages comprise the lower third of the nose and connect to the upper lateral cartilages in a union described as the scroll. There are various configurations of the scroll.^{5,6} The scroll is described as interlocked (52%), overlapping (20%), end to end (17%), or opposed (11%) (Figure 65-6). The scroll provides significant support to the nasal tip. When performing an endonasal rhinoplasty this area is violated by the intercartilaginous incision (Figures 65-7–65-9). The lower lateral cartilage is divided into medial and lateral crura. The medial crura are in intimate contact with the nasal septum and

provide tip support. The lateral crura extend superiorly and form dense fibroareolar tissue attachments with the pyriform aperture. The intermediate crus is the diverging of the medial crus before turning to become the lateral crus proper. The highest point of the intermediate crus is an important surgical landmark known as the tip-defining point (Figure 65-10).

The nasal septum is formed by both bone and cartilage. The ethmoid and vomer provide bony support posteriorly. The quadrangular cartilage provides support anteriorly (Figure 65-11).

Support for the nasal tip is classified into major and minor divisions. The major tip support comes from the size, shape, and strength of the lower lateral cartilages, the attachment of the medial crura of the lower lateral cartilage to the caudal septum, and the fibrous attachment of the lower lateral cartilage to the upper lateral cartilage. The minor tip support comes from the nasal spine, the membranous septum, the cartilaginous dorsum, the sesamoid complexes, the interdomal ligaments, and the alar attachments to the skin (Table 65-2).⁵

Nerves

The sensory nerve supply to the skin of the external nose is supplied by the ophthalmic and maxillary divisions of the

FIGURE 65-7 Partial transfixion. The partial transfixion incision through the membranous septum and short of the medial crural foot pads.

FIGURE 65-8 Intercartilaginous incision. The intercartilaginous incision, between the upper and lower cartilage, allows access to the nasal dorsum. Note the incision does not violate the nasal valve.

FIGURE 65-9 Connecting intercartilaginous and partial transfixion incisions. The intercartilaginous incision extends along the upper edge of the lateral crus to connect with the transfixion incision. This will provide access for a septoplasty during internal rhinoplasty.

FIGURE 65-11 Anatomy of the nasal septum. The nasal septum is composed of the perpendicular plate of the ethmoid, the vomer, and the quadrangular cartilage. Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO): Mosby; 2002. p. 22.

trigeminal nerve. Branches of the supra-trochlear and infratrochlear nerves supply the skin in the region of the radix and rhinion. The lower half of the nose is supplied by the infraorbital nerve and the external nasal branch of the anterior ethmoidal nerve (a branch of the nasociliary nerve that arises from the ophthalmic branch of the trigeminal nerve) (Figure 65-12).

The main sensory nerve supply to the nasal septum comes from the internal nasal nerve (a branch of the anterior ethmoidal nerve) and the nasopalatine nerve (Figure 65-13). The lateral nasal wall sensation is supplied by the anterior ethmoidal nerve, branches of the pterygopalatine ganglion, branches of the greater palatine nerve, the infraorbital nerve, and the anterior superior or alveolar nerve.

FIGURE 65-10 A–C, Anatomy of the lower lateral cartilages. The lower lateral cartilages are often described as having a lateral crus, medial crus, and an intermediate crus. The intermediate crus is the most projected portion of the lower lateral cartilages and these form two of the tip-defining points seen on nasal tip analysis. Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO): Mosby; 2002. p. 21.

Table 65-2 Tip Support Mechanisms

The three major tip support mechanisms include

1. The size, shape, and strength of the lower lateral cartilages
2. The attachment of the medial crura to the caudal septum
3. The attachment of the lower lateral cartilages to the upper lateral cartilages

The minor tip support mechanisms include

1. The interdomal ligament
2. The sesamoid complex extending the support of the lateral crura to the piriform aperture
3. The attachment of the alar cartilages to the overlying skin
4. Cartilaginous septal dorsum
5. Nasal spine
6. The membranous septum

Parasympathetic innervation is derived from branches of the pterygopalatine ganglion which are derived from cranial nerve VII. Some sympathetic branches reach the nasal cavity via the nasociliary nerve.^{2,7}

Nasal Valve

The airflow through the nose is regulated by the internal and external nasal valves. The external nasal valve is comprised of the lower lateral cartilage and the nasal septum and floor. Collapse of the external nasal valve can sometimes be noted when the nares become occluded on even gentle inspiration. This problem is seen in patients with narrow nostrils, a projecting nasal tip, and thin alar sidewalls. External nasal valve collapse is usually seen in patients who have had previous rhinoplasty surgery and excessive trimming of the cephalic portion of the lower lateral cartilages. It is also seen with increased age and in facial nerve paralysis. The external nasal valve collapse can be corrected by deprojecting the overprojected nose, realigning the lateral crura into a more caudal orientation, and placing alar batten grafts to provide structural support and prevent collapse.⁸

The internal nasal valve is formed by the junction of the septum with the upper lateral cartilages. The angle formed should be a minimum of 10° to 15° to maintain

patency. Deviation of the nasal septum or separation of the upper lateral cartilages from the nasal bones can lead to obstruction. This problem is also seen after rhinoplasty if the patient has had weakening of the upper and lower lateral cartilages. These patients often have a pinched

appearance in the supra-alar region. The Cottle test is used to evaluate obstruction at the internal valve by using a finger to distract the check and lateral wall of the nose thereby opening the valve. If nasal airflow is dramatically improved, then the internal valve may require correction. These patients often have symptomatic relief by the use of external taping devices. Surgical correction involves the placement of spreader grafts between the septum and upper lateral cartilages to increase the angle at this junction.⁸⁻¹⁰

Cosmetic Evaluation

The cosmetic evaluation begins in the same way as with any examination, by eliciting the chief complaint of the patient. The patient should be given a mirror and cotton-tipped applicator to point out specific cosmetic concerns. Following this a thorough medical history should be obtained. Specific attention should be directed toward

FIGURE 65-12 Sensory nerves of the external nose. The sensory innervation of the nose is derived from the V₁ (ophthalmic; colored black) and from V₂ (maxillary; colored blue) divisions of the trigeminal nerve. Adapted from Jewett B. *Anatomic considerations*. In: Baker SR, editor. *Principles of nasal reconstruction*. St. Louis (MO): Mosby; 2002. p. 19.

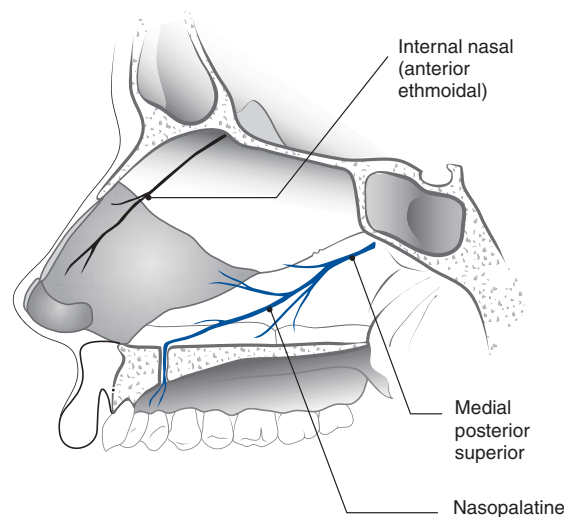

FIGURE 65-13 Sensory nerves of the nasal septum. The main sensory nerve supply comes from the internal nasal nerve (a branch of the anterior ethmoidal nerve V_1 (black) and the nasopalatine nerve V_2 (blue). obtaining a history of nasal trauma, nasal obstruction, previous nasal surgery, and medications (including over-the-counter and herbal medications).

Psychiatric Stability

In addition to analyzing the nose the surgeon needs to assess if the patient is psychologically prepared for a cosmetic procedure. Patients should have realistic expectations and motivations. A patient who is internally motivated (eg, wishes to improve their self-esteem) to have the procedure is a better candidate than one who desires the procedure for external reasons (eg, spouse wants them to have it done).^{11,12}

The surgeon should beware of patients who are indecisive, rude, uncooperative, depressed, have unrealistic expectations, or have significant personality disorders because they may never be satisfied. Other warning signs of poor patients are those who overly flatter, are talkative, consider themselves to be a very important patient, have minimal or no deformity, are surgeon shoppers, price hagglers, or involved in litigation. Most importantly, do not operate on a patient that you do not like.¹¹⁻¹⁴

General Facial Analysis

Prior to performing a specific analysis of the nose, a global assessment of the face

and its proportions should be done. Refer to Chapter 54, “Database Acquisition and Treatment Planning,” for additional information on facial analysis in orthognathic surgery.

Nasal Analysis

The nasal examination should be performed in a systematic manner so that the proper diagnosis is attained (Figures 65-14 and 65-15).

General Assessment

Skin

The skin should be assessed for its thickness, mobility, and sebaceous gland content. Any pigmentations or scars should also be noted. Thick skin does not redrape well after rhinoplasty.

Symmetry

Any gross asymmetries in all views should be noted.

Lateral View Nasofrontal Angle The nasofrontal angle is defined as the angle formed from lines that are tangential to the glabella and the nasal dorsum and intersect through the radix as seen on a profile view. The normal angle is between 125° and 135° (Figure 65-16).

FIGURE 65-14 Preoperative rhinoplasty. A, Preoperative frontal view shows the width of the nose and alar base. B, Preoperative lateral view shows the nasal profile and dorsum in relation to the nasofrontal angle and nasolabial angle. C, Preoperative three-quarter, or oblique view, is most natural and often revealing for harmony of the orbital rims and gull wings that flow into the nasal dorsum. D, Preoperative basal view is either taken from above or below the patient and is a good view of tip and base morphology.

FIGURE 65-15 Postoperative rhinoplasty. A, Postoperative frontal view shows the change in the width of the nose. This is the patient's most critical analysis. B, Postoperative lateral view shows the change in dorsal reduction and tip position. C, Postoperative three-quarter, or oblique view, demonstrates the symmetry and graceful balance of the nose with the face. D, Postoperative basal view shows the width of the nose and any tip deviation from the dorsal midline.

The position of the radix should then be assessed in terms of its anteroposterior and vertical positions from a profile view. The radix should lie in a vertical plane

FIGURE 65-16 Position of the nasal dorsum and radix. The nasal dorsum is typically 2 mm behind a line drawn from the radix to nasal tip in women. In men the nasal dorsum typically lies on this line. The radix should lie between the upper eyelid margin and the supratarsal folds in a vertical plane and approximately 4 to 9 mm anterior to the corneal plane. Adapted from Austermann, K., *Rhinoplasty: planning techniques and complications*. In: Booth PW, Hausamen JE, editors. *Maxillofacial surgery*. New York: Churchill Livingstone; 1999. p. 1380.

somewhere between the lash line and the supratarsal folds. In addition it should be 4 to 9 mm anterior to the corneal plane (see Figure 65-16).

Nasal Dorsum In women the nasal dorsum should lie approximately 2 mm posterior to a line drawn from the radix to the nasal tip. In males the nasal dorsum should lie on this line or slightly in front of it (see Figure 65-16).

The length of the nose (radix to tip) can be measured clinically or on photographs taken during the initial examination. The ideal nasal length should approximate the distance from stomion to menton if the lower facial height is proportionate to the middle facial height (glabella to subnasale). If the lower face height is not proportionate it is best to estimate the nasal length as 0.67 times the middle facial height.

Nasal Tip Definition The nose should have four tip defining points which when drawn on the nose in the frontal view appear as two equilateral triangles (Figure 65-17). These points include the supratip break, the columellar-lobular angle, and the two tip-defining points (the most projected portion of the nasal tip)

Nasal Tip Projection Nasal tip projection can be defined as the distance that the tip (pronasale) projects anterior in the facial plane.¹⁵ Perception of nasal tip projection can be influenced by many factors: upper lip length, nasolabial angle, nasofrontal angle, dorsal hump, and

FIGURE 65-17 Nasal tip-defining points. A nose should have four tip-defining points. These are defined by the supratip, columellar-lobular angle, and the tip-defining points of each intermediate crus of the lower lateral cartilages.

chin projection. There are several methods to determine if the nasal tip projection is adequate. Most cosmetic rhinoplasty procedures are designed to preserve tip projection.

The simplest method to remember is Simons' method, which states that the lip-to-tip ratio is 1:1. Essentially the length of the upper lip (from subnasale to labrale superioris) should equal the nasal projection (measured from subnasale to pronasale). This method may be invalid because of the wide variation in lip lengths.¹⁶

The Goode method is another way of determining nasal projection. Using the Goode method a line is drawn from the radix to the nasal tip. A second line is drawn from the radix to the alar columellar junction. A third line is drawn perpendicular to this and passes through the nasal tip. Goode's analysis states that if the nasofrontal angle is between 36° and 40°, then the length of the perpendicular line passing through the nasal tip should be 0.55 to 0.6 of the length of the nasal dorsum (Figure 65-18).¹⁶

Rohrich describes another technique of assessing nasal tip projection. If the nasal dorsal length is appropriate, the tip projection should be 0.67 times the ideal nasal length. The ideal nasal length should be equal to the distance from stomion to menton or 1.6 times the distance from the nasal tip to stomion. The tip projection is measured from the alar facial junction to the nasal tip.¹⁷ This method is subject to a great deal of facial variation.

Additionally a vertical line drawn from the most projected portion of the upper lip should divide the nose in two equal halves between the alar facial groove and the nasal tip. If the anterior portion is greater than 60%, then the nose is likely to be overprojected (Figure 65-19).¹⁷

Nasal tip Rotation The nasal tip rotation is evaluated by the nasolabial angle and the columellar-lobular angle. Nasolabial angle is defined as the angle formed by lines that are tangential to the columella of the nose

and the philtrum of the lip and intersect at the subnasale. In women this should be approximately 95° to 110°, whereas in men this should be 90° to 95°. Lip position may be dependent on tooth position. The columellar-lobular angle is defined as the angle formed by the intersection of a line tangential to the columella and a line tangential to the infratip lobule. This angle is normally between 30° and 45°.

Tip Support The strength of the cartilage in the tip of the nose is apparent when one presses on the tip. A nose with poor support may require cartilaginous struts to counteract the inherently weakened tip from the rhinoplasty. The effect of facial animation should also be noted. Some patients have overactive depressor septi nasi muscles, which result in a drooping nasal tip on smiling. The columella show on a lateral view should be 3 to 4 mm below the inferior alar rim.¹³

Frontal View Width of Nasal Dorsum

The width of the nasal body and tip should be approximately 80% of the alar base width. This is assuming that the alar base is in proper anatomic proportions. The alar base width should approximate the intercanthal distance. If the width of the nasal dorsum is significantly greater than 80%, then lateral nasal osteotomies should be considered. The eyebrows should gracefully flow into the nasal dorsum analogous to a gull wing in flight.

The alar rims and columella should also be a gently curving line that appears as a bird in flight.

Alar Width The alar base width should approximate the intercanthal distance. Seldom is the nasal width less than the intercanthal dimension.

Basal View From a basal view the columella-to-lobule ratio should be 2:1. Nostril size and shape should also be noted. An esthetic nostril is teardrop

FIGURE 65-18 Goode method of nasal projection. This method is sometimes used to determine adequacy of nasal projection. If the nasofrontal angle is between 36° to 40°, then the length of a perpendicular line through the nasal tip should be 0.55 to 0.6 the length of the nasal dorsum. x = nasal length. Adapted from Austermann, K., *Rhinoplasty: planning techniques and complications*. In: Booth PW, Hausamen JE, editors. *Maxillofacial surgery*. New York: Churchill Livingstone; 1999. p. 1380.

FIGURE 65-19 Nasal projection. A vertical line through the most projected part of the upper lip should divide the nose into two equal parts. If the nasal tip comprises > 60%, then the nose may be overprojected.

shaped, but there is a great amount of ethnic variation (Figure 65-20).

Oblique View The oblique view is most natural and sometimes more revealing than standard photographs. It demonstrates the flow of subunits and facial harmony. The three-quarters view is how we usually see each other in routine interaction.

Functional Considerations

Although the patient desires cosmetic correction of their nose, the functional significance of the nose should be closely considered. Nasal airflow through both the internal and external nasal valves should be evaluated. The septum should be evaluated for deviation and perforations. The septum is often a good site for harvesting autogenous cartilage for grafting. The turbinates should be evaluated for hypertrophy. Rhinoscopy with a nasal speculum can be performed both before and after the administration of a topical decongestant.

Photographs

The examination is not complete without standardized facial photographs. The standard facial photographs should include frontal, right, and left lateral views; right and left oblique views; and a high and low basal view. Close-up views are taken if warranted. The photographs are beneficial from a medicolegal standpoint, and they also allow the surgeon to

FIGURE 65-20 *Columella-to-lobule ratio.* The columella-to-lobule ratio should be 2:1.

study the nose in more detail and to develop a surgical plan.

Anesthesia

Proper anesthesia of the nose is important to ensure minimal distortion of the tissues as well as to provide adequate hemostasis. Prior to injecting the nose, cottonoids or cotton-tipped applicators soaked in 4% cocaine or oxymetazoline are placed in each nostril to constrict the mucous membranes of the turbinates. If the rhinoplasty is to be performed under sedation, then cocaine is preferred because of its anesthetic properties. If the procedure is performed under general anesthesia, then oxymetazoline is sufficient.

Three cottonoids are placed in each nostril: one along the middle turbinate, one along the superior nasal vault, and one along the inferomedial septum.

Local anesthesia is achieved with 2% lidocaine with 1:100,000 epinephrine. In an endonasal rhinoplasty the following areas are injected:

- 0.5 cc deposited at the junction of each upper and lower lateral cartilage (intercartilaginous area)
- 0.5 cc deposited in the region of each marginal incision
- 3 cc along the nasal dorsum and lateral nasal bones (hugging periosteum)
- 1 cc along the nasal septum
- 0.5 cc at each alar base
- 1 cc at each infraorbital nerve
- 1 cc at the nasal tip

For external rhinoplasty the following additional area is injected:

- 1 cc to the columella

Incisions/Sequencing

There are multiple incision techniques used to gain access to the cartilage and bone support of the nose.

Complete Transfixion

This incision provides access to the caudal septum, medial crura, and nasal spine.

The incision is made with a no. 15 blade, beginning just caudal to the superior caudal end of the nasal septum. The incision extends inferiorly through the membranous septum, following the cephalic margin of the medial crura (see Figures 65-7 and 65-21A). It results in ptosis and deprojection of the nose.

Partial Transfixion

This incision is similar to the complete transfixion incision except that it stops at the level of the medial footpads of the lower lateral cartilages. The advantage of this incision is that the attachments of the medial footpads of the lower lateral cartilages to the caudal septum are not disrupted (see Figures 65-7 and 65-21B).

Hemitransfixion

This incision is a complete transfixion incision that is performed on only one side of the membranous septum. It does not traverse both mucosal surfaces and therefore some attachments of the medial crura to the caudal septum are maintained. Access to the nasal septum is good with this incision; however, delivery of the lower lateral cartilage on the side opposite to the incision is difficult (see Figures 65-7 and 65-21C).

Killian Incision

This incision is seldom used in rhinoplasty. It is a useful incision to gain access to the nasal septum if only a septoplasty is to be performed. The incision is made several millimeters cephalad to the caudal edge of the septum. It can be extended onto the nasal floor if needed.

Intercartilaginous Incision

This incision is made at the junction of the upper and lower lateral cartilages. The nare is elevated superiorly with a double skin hook. A no. 15 blade should pass below the lower lateral cartilage and above the upper lateral cartilages. This incision is typically made after a transfixion incision. The intercartilaginous incision is then

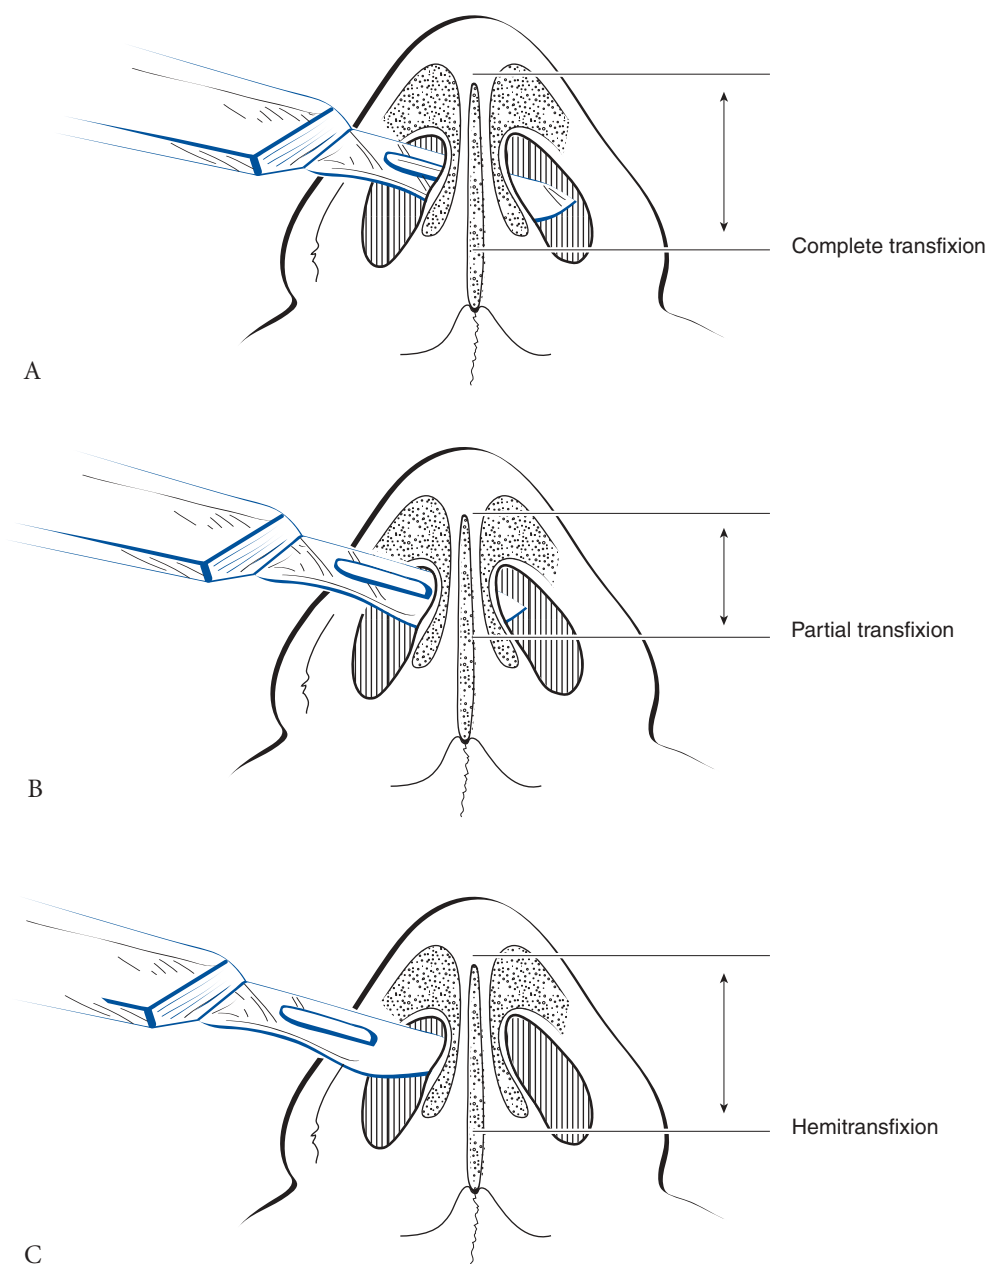

FIGURE 65-21 Transfixion incisions. A, A complete transfixion incision is made caudal to both the medial crura and through the membranous septum. B, A partial transfixion incision is similar except the incision stops short of the medial foot pads of the medial crura. C, A hemitransfixion incision is a complete transfixion incision that is performed only on one side, therefore the other medial crura and footpad is not violated.

connected to the transfixion incision (see Figures 65-8, 65-9, and 65-22).

Intracartilaginous Incision

This incision is made through both the vestibular nasal mucosa and a portion of the lower lateral cartilages. This incision is similar to the intercartilaginous incision except that it is made 3 to 5 mm posterior

to the junction of the upper and lower lateral cartilages. This incision in effect performs a complete cephalic strip of the lower lateral cartilages without the need for delivering the cartilage. The disadvantage is that the lower lateral cartilage is not directly visualized and it may therefore be difficult to achieve symmetry between the right and left sides.

Rim/Marginal Incision

This incision parallels the caudal edges of the lower lateral cartilages. The incision is used in combination with an intercartilaginous incision in an endonasal rhinoplasty. The two incisions allow the lower lateral cartilage to be delivered and visualized. This allows the surgeon to more accurately trim the cartilage if needed. In an open rhinoplasty this incision is combined with a transcolumellar incision in order to gain access to the lower lateral cartilage and nasal dorsum (Figure 65-23).

Transcolumellar Incision

This incision is made through the thinnest portion of the columella at a level just superior to the flaring of the medial crura. The incision can be made with a notched V in the center of the columella or as a “stair step.” This will break up the scar and assist in closure. This incision is connected with a marginal incision bilaterally for open rhinoplasty (see Figure 65-23).

The two principle techniques are the endonasal and external rhinoplasty. Each of these techniques will be described in general terms, in the order in which the authors perform them. Other surgeons may perform the sequence in a different order (Tables 65-3 and 65-4).

Septoplasty

In rhinoplasty surgery there are several reasons to access the nasal septum: (1) to correct nasal airflow obstruction, (2) to assist in the correction of asymmetries, and (3) to harvest cartilage for tip grafting.

Access to the nasal septum in an endonasal approach is through a partial-transfixion incision, which is connected to bilateral intercartilaginous incisions. The partial-transfixion incision can be extended to the nasal floor on the side on which the septoplasty is to be performed. After completing the incisions the caudal aspect of the nasal septum is exposed by dissecting the mucoperichondrium from one

FIGURE 65-22 Intercartilaginous incisions. The intercartilaginous incision is made at the junction of the upper and lower lateral cartilages. The blade should pass below the lower lateral and above the upper lateral cartilage. Adapted from Alexander R. *Fundamental terms, considerations, and approaches in rhinoplasty*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 19.

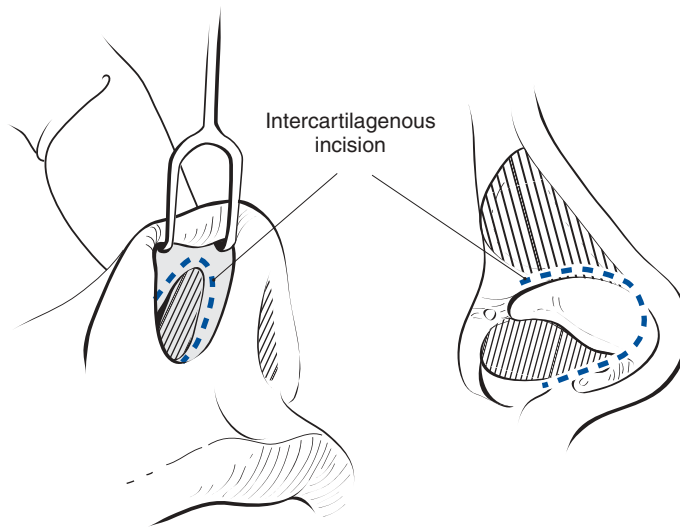

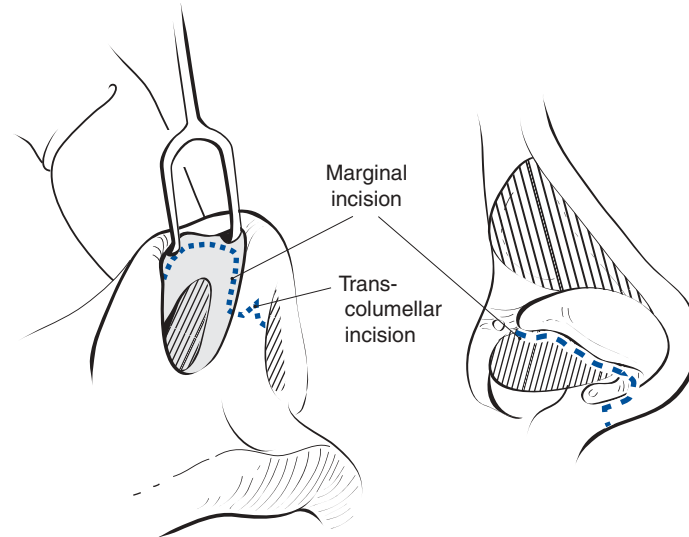

FIGURE 65-23 Marginal incision. This incision is made parallel to the caudal edge of the lower lateral cartilage. This incision can be combined with bilateral intercartilaginous incisions for a cartilage delivery technique in endonasal rhinoplasty or combined with a transcolumellar incision for an external rhinoplasty. Adapted from Alexander R. *Fundamental terms, considerations, and approaches in rhinoplasty*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 19.

side. Two tunnels will be developed, one superior and the other inferior, which will ultimately be joined so that wide exposure of the septum is obtained.¹⁸ Initially sharp dissection is done with a no. 15 blade or scissors to expose a portion of the caudal septum. The perichondrium is gently scored using a no. 15 blade. A dental amalgam condenser is then used in a sweeping motion to develop a plane between the perichondrium and the nasal septum (Figure 65-24). Once this plane of dissection is started a Freer or Cottle elevator can be used to complete the septal envelope (Figure 65-25). The mucoperichondrium is

tightly bound at the junction of the septum and the maxillary crest.

Once the septum is exposed it can be treated in four ways: (1) resection, (2) morselization, (3) segmental transection, and (4) swinging door flaps.¹⁸ Submucosal resection allows a significant portion of cartilage to be harvested for grafting. At least 1 cm should be maintained superiorly and anteriorly in an L-shaped configuration to provide support for the nose (Figure 65-26). In order to resect the cartilage a Cottle elevator is used to cut the cartilage. Fomon scissors may be used to make the superior and inferior cuts

Table 65-3 Surgical Sequence for Endonasal Rhinoplasty

The general sequence is

1. Local anesthesia
2. Partial transfixion incision (see Figure 65-7)
3. Intercartilaginous incision (join with partial transfixion) (see Figures 65-8, 65-9, 65-21, and 65-22)
4. Septoplasty (if needed) (see Figures 65-24 and 65-25)
5. Dorsal reduction (see Figures 65-28–65-30)
6. Lateral nasal osteotomies (see Figure 65-31)
7. Marginal incision (see Figure 65-23)
8. Delivery of lower lateral cartilages (see Figure 65-37)
9. Tip modification (ie, cephalic strips/cartilage grafting/suture techniques)
10. Alar base modification (see Figure 65-41)
11. Closure, taping, and splinting

Table 65-4 Surgical Sequence for External Rhinoplasty

The general sequence is

1. Local anesthesia
2. Bilateral marginal incisions (see Figure 65-23)
3. Columellar incision (see Figure 65-23)
4. Skeletonization of upper and lower lateral cartilages and nasal dorsum
5. Dorsal reduction
6. Dome division if access is needed to the septum for septoplasty or graft harvest
7. Septoplasty (if needed)
8. Turbinate reduction
9. Lateral nasal osteotomies
10. Tip modification (ie, cephalic strips/cartilage grafting/suture techniques)
11. Alar base modification
12. Closure, taping, and splinting

FIGURE 65-24 Identifying perichondrium. The perichondrium is elevated with a dental amalgam condenser. One will notice a slight blue-gray cartilage and a distinct plane of dissection.

FIGURE 65-25 Elevation of mucoperichondrium. The Cottle elevator is specifically designed to elevate the nasal envelope without perforation.

through the bony septum. The cartilage can also be removed with a Ballenger swivel blade. If no cartilage is needed for the rhinoplasty, the resected cartilage can be morselized and replaced. Morselization can be performed in situ. Another technique for aligning the septum is through a segmental transection. In this technique the mucoperichondrium is elevated on one side of the septum. Cross-hatching with a no. 15 blade is performed to weaken the cartilage (Figure 65-27). The mucoperichondrium on the other side of the septum provides support. 4-0 gut mattress sutures can be positioned through the septum to assist in realignment. A septal splint is placed for 1 week. Finally a swinging door type flap can be used to reposition a large segment of flat cartilage

FIGURE 65-26 Resection of cartilage/bone from the nasal septum. This may be done to harvest cartilage for grafting procedures or for removal of grossly deviated septum. It is important to maintain 1 cm dorsally and caudally for nasal support.

FIGURE 65-27 Septal repositioning. A deviated nasal septum can be repositioned by removing the obstruction inferiorly (A) and cross-hatching the cartilage to allow the deviated portion to be repositioned (B). Adapted from Robinson RC. *Functional septorhinoplasty*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 35.

that is improperly angulated. The mucoperichondrium is elevated on one side. Through and through incisions are made on either side of the deviated cartilage. The cartilage is also separated from the maxillary crest so that it can hinge into a more normal position. Septal splints may

be required for 1 week. In all septal procedures a 4-0 gut on a straight needle is routinely used to perform a mattress suture through the septum and mucosa. This decreases the likelihood of a septal hematoma formation and circumvents the need for nasal packs.

Tears in the septal mucosa are not uncommon. However, it is not problematic as long as the tears are only on one side of the septum. Unilateral tears require no elaborate closure. If the tear is through and through, at least one side should be closed. This is best done with a 5-0 chromic gut suture.

Turbinectomy

Although the focus of this chapter is the cosmetic rhinoplasty, some mention needs to be made on maintaining function. Inferior turbinate hypertrophy is a problem that can result in nasal obstruction after cosmetic rhinoplasty, if the problem is not recognized preoperatively. Hypertrophy of the inferior turbinates is the most common cause of nasal airway obstruction.^{19,20} Hypertrophy can be caused by numerous factors. Most commonly it is related to allergic symptoms. Hypertrophy caused by allergy should be managed medically with antihistamines and topical corticosteroids. If this fails, then surgical management can be considered.²¹ In cases of a deviated nasal septum the turbinate on the side at which the nasal passage is enlarged can become hypertrophic with time. In patients with anatomic enlargement of the turbinate, the problem needs to be recognized so that the nasal passage does not become obstructed when the septum is straightened.

Management of inferior turbinate hypertrophy is controversial and outside the scope of this chapter. The surgical procedures used to treat this problem have included corticosteroid injection, turbinate out-fracture, electrocautery, cryosurgery, laser reduction, partial turbinate resection, total turbinate resection, submucous turbinate resection, and vidian neurectomy.²⁰⁻²⁴ Each of these procedures has various advantages and disadvantages and the procedure chosen depends on the patient. The most common complications from turbinate surgery are hemorrhage, atrophic rhinitis, and ozena.

Nasal Dorsum

Reduction

One of the most dramatic changes that can be achieved in rhinoplasty surgery is correction of a dorsal hump. There are many ways to remove the hump. Some surgeons use a scalpel and osteotome, whereas others use rasps, and a few use power rasps. The authors recommend to first incise the cartilaginous convexity below the nasal bones and then to use a Rubin osteotome to remove the bony hump (Figures 65-28–65-31). Care must be taken to keep the osteotome directed superficially, since it can deflect downward and result in over-reduction. After removing the gross hump, sequential

rasping can be used for refinement. After removal of any significant dorsal hump, the patient is left with an open roof deformity. This must be closed with lateral nasal osteotomies (see Figure 65-31).

Augmentation

Augmentation is indicated when there has been excessive reduction from previous rhinoplasty or from a post-traumatic defect. Several techniques are used to augment the nasal dorsum.

Autogenous Augmentation In the setting of acute trauma, cranial bone grafts can be used to provide support. These are cantilevered off the frontal bone with a miniplate. The graft must be properly

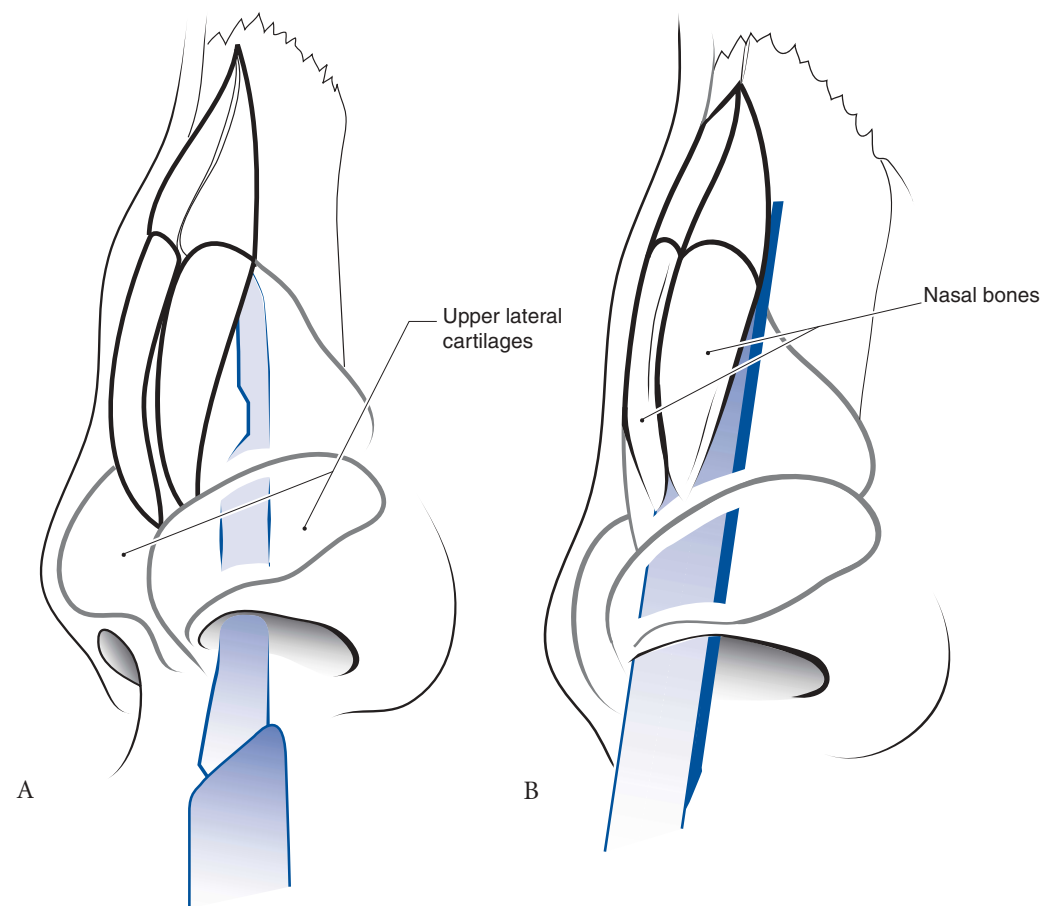

FIGURE 65-28 Removal of a dorsal hump. A, The dorsal hump is removed by first using a scalpel to incise through the upper lateral cartilages. B, Next, a Rubin osteotome is used to reduce the bony prominence. Care is needed to keep the osteotome from being directed too far posteriorly thereby over-reducing the dorsum. Adapted from Austermann, K., *Rhinoplasty: planning techniques and complications*. In: Booth PW, Hausamen JE, editors. *Maxillofacial surgery*. New York: Churchill Livingstone; 1999. p. 1389.

FIGURE 65-29 Dorsal reduction. An Aufricht retractor lifts the dorsal drape and can protect the skin during hump reduction. A no. 15 blade is used to incise the cartilaginous dorsum. Working through this incision, an osteotome or rasp is used to reduce the bone of the dorsum.

FIGURE 65-30 Dorsal reduction. The dorsum should be about two-thirds of the cartilage and one-third of the bone.

FIGURE 65-31 Lateral nasal osteotomies. Removal of a large dorsal hump will often leave a flat open roof deformity, and this can be reduced by lateral nasal osteotomies with an invert chisel, saw, or rasp.

shaped so that it provides support but does not distort the shape of the nose.^{25–27} Rib cartilage can also be harvested for augmentation of the nasal dorsum. Silicone sizers can be used to estimate the size and shape of graft needed. Once the graft is harvested, a 0.035 inch K-wire can be placed in the center of the graft to stabilize it. Rib grafts have a tendency to distort with time and the K-wire may help limit this tendency.²⁸

For a less aggressive augmentation, autogenous cartilage harvested from the nasal septum can be used. This can be layered and sutured together. It is then placed through traditional rhinoplasty incisions.^{29–31}

Alloplastic Augmentation Another technique is to use cadaveric dermis along the nasal dorsum. The advantage here is that no harvesting is required and the material is pliable. However, the resorption of this material is unpredictable. Other implantable materials include silicone and expanded polytetrafluoroethylene (ePTFE) implants. These can be contoured to the appropriate size intraoperatively. The issue with implants is that the grafts can extrude or become infected. Meticulous placement is essential.^{31–34}

Osteotomies

Osteotomies are performed after the nasal reduction has been performed. The purposes of lateral nasal osteotomies include reduction of the open nasal roof, correction of deviated nasal bones, and narrowing of a wide nasal base (see Figure 65-31).

There are two principal types of nasal osteotomy: lateral and medial. The lateral nasal osteotomy can be performed at different levels. It typically begins low on the piriform rim and can end either high or low in its relationship to the nasal bones. Thus the osteotomy is often termed as a low-to-low osteotomy or a low-to-high osteotomy. These osteotomies can be performed via an internal or external tech-

nique. Regardless of which technique is used, limited periosteal dissection is favored so that support is provided to the nasal bones. Medial osteotomies are seldom needed but can be used to obtain a controlled fracture in patients with thick nasal bones or when a low-to-low technique is used. Also, regardless of the osteotomy technique, the osteotomies should not be carried above the intercanthal line. The bone above this point becomes much thicker and mobilization becomes difficult. Care should be taken when performing medial osteotomies, since the thicker portion of the nasal bone can be included in the lateral osteotomy segment and result in widening of the upper nasal dorsum. This is termed a rocker deformity.

Lateral nasal osteotomies are not always required to close an open roof deformity after dorsal hump reduction. Some surgeons believe it is better to place spreader grafts in those patients with short nasal bones so that compromise of the internal nasal valve does not occur. If an osteotomy is performed in a patient with shorter nasal bones, then a low-to-high technique is preferred.

Nasal Tip

Understanding the mechanisms of nasal tip support is critical when performing rhinoplasty. The surgeon must understand both the desired and undesired changes that occur from the surgical approach or technique.³⁵

The three major tip support mechanisms include the following:

1. The size, shape, and strength of the lower lateral cartilages
2. The attachment of the medial crura to the caudal septum
3. The attachment of the lower lateral cartilages to the upper lateral cartilages

The minor tip support mechanisms include the following:

1. The interdomal ligament
2. The sesamoid complex, extending the support of the lateral crura to the piriform aperture
3. The attachment of the alar cartilages to the overlying skin
4. The cartilaginous septal dorsum
5. The nasal spine
6. The membranous septum^{36,37}

Certain surgical procedures can affect tip support. For example a complete transfixion incision will disrupt the fibrous attachments of the caudal septum to the medial crura thus leaving little support for the nasal tip. Suturing techniques and cartilage strut grafts may be necessary to reestablish support if this incision is performed. Intercartilaginous incisions, which are useful to gain access to the nasal dorsum, interrupt the ligamentous connections of the upper and lower lateral cartilages. This can result in cephalic tip rotation, which may or may not be desirable. A cephalic strip procedure creates even further disruption and rotation of the lower lateral cartilages. Most often tip rhinoplasty is designed to refine and decrease the tip lobule while maintaining or even increasing rotation and projection.

The cartilaginous support of the nasal tip is often described in terms of a tripod concept.^{38,39} The medial crura of both the lower lateral cartilages together form one strut of the tripod, and each of the lateral crura of the lower lateral cartilages forms a strut. By selectively shortening or lengthening any of these struts, the tip position can be altered.

The tip position changes are referred to in terms of both projection and rotation. Tip projection is the distance from the tip of the nose to the alar-facial junction. Increasing tip projection is one of the most difficult procedures to perform in rhinoplasty surgery. Nasal tip projection can be increased by both grafting and non-grafting techniques.

Tip Projection *Increasing Tip Projection* Nongrafting techniques to increase nasal projection include the following:

1. Suturing of divergent medial crura: For this technique to be effective there must be diverging medial crura. Intervening soft tissue may require excision prior to suturing with mattress sutures.⁴⁰
2. Lateral crural steal: The lower lateral cartilage is skeletonized and the lateral crura cartilages are sutured with a mattress suture so that the lateral crura now contributes to the medial crura (Figure 65-32). This results in increased projection and some rotation as well.^{41,42}

Grafting techniques to increase projection include the following:

1. Collumellar strut: This technique involves the placement of a strut of septal cartilage between the feet of the medial crura and abutted against the nasal spine. The medial crura are elevated superiorly with double skin hooks and the cartilage strut is sutured to the medial crura via mattress sutures. Only a minor amount of tip projection can be increased with this method.
2. Peck graft: This is an onlay graft in the region of the nasal tip. Layers of cartilage are placed in the domal region to
3. Umbrella graft: This technique involves the creation of a cartilaginous structure that resembles the appearance of an umbrella. It is useful when both tip projection and support of weak medial crura are required. The umbrella graft is constructed from harvested septal, ear, or rib cartilage. It is then sutured in position so that the “handle” of the umbrella is between the medial crura and the “canopy” of the umbrella rests atop the dome. The canopy portion can be modified to incorporate the Peck graft technique by stacking layers of cartilage (Figure 65-34).⁴³
4. Shield graft: This graft was first described by Sheen.³⁰ A piece of septal cartilage is shaped to form a trapezoidal configuration measuring 6 to 8 mm superiorly and 5 mm inferiorly. The graft is usually 10 to 12 mm long and is beveled so that the corners are blunted. The graft is placed in a pocket through an endonasal approach or sutured in position via an open approach. The superior and lateral aspect of the graft forms the tip-defining points (Figure 65-35).³⁰

Adapted from Taylor CO. *Surgery of the nasal tip.* In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty.* Philadelphia (PA): W.B. Saunders; 1995. p. 61.

FIGURE 65-33 Peck graft. This involves the placement of layers of cartilage grafts in the region of the nasal tip to increase nasal projection. Adapted from Taylor CO. *Surgery of the nasal tip*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 62.

Decreasing Tip Projection Decreasing tip projection involves reduction of the tip supporting mechanisms. Achieving acceptable results when decreasing projection can be difficult since nasal definition can be lost.⁴⁴ If the nasal projection needs to be decreased, be certain to first confirm that the problem is not the result of an optical illusion caused by a low radix position. If the problem is a low radix, then a dorsal radix graft is the appropriate treatment.

Methods to decrease projection include the following:

1. Complete transfixion incision: As discussed above, a complete transfixion incision will decrease tip support. Intercartilaginous incisions or cephalic strips will also weaken the tip support but will increase tip rotation.
2. Lower the septal angle: If the septum is providing significant support for the nasal tip, then the septal angle must be lowered. This is done by excision of a portion of the caudal septum. Additionally the medial crura can be separated from the caudal septum to decrease projection.
3. Crural excision: To dramatically decrease tip projection the medial and lateral crura may need to be sectioned, overlapped, and sutured into a new position with less projection. This technique maintains the natural shape of the tip at the domes (Figure 65-36). Excision of a segment cartilage in the domes and suturing them back together can be done, but it will change the shape of the nasal tip.

Sometimes, after decreasing the nasal projection, the patient may have flaring of the ala and increased infratip columellar show. This can be treated with an alar base resection but should be used judiciously.

Tip Rotation Increasing Tip Rotation Understanding the tripod concept and tip supporting mechanisms is important when determining which of the following methods to use to increase tip rotation.

1. Removal of dorsal hump: A subtle way to increase rotation of the tip is to reduce a dorsal hump if present.
2. Resection of the caudal septum: A small triangular piece of caudal septum can be removed. The base of this triangular shape is at the nasal dorsum.
3. Cephalic strips from lower lateral cartilages: A complete strip of cephalic cartilage from the lower lateral cartilages will result in increased tip rotation. Even an intercartilaginous incision will result in some tip rotation (Figure 65-37).
4. Shorten the lateral crura
5. Shield graft: A shield graft gives the illusion of increased tip rotation.
6. Augmentation of premaxilla: Placement of cartilage or ePTFE in the premaxilla region below the anterior nasal spine will also give the illusion of increased tip rotation.

Decreasing Tip Rotation Decreasing tip rotation is done by two methods:

FIGURE 65-34 Umbrella graft. This is essentially a columellar strut graft placed between the medial crura, combined with a tip graft. This technique improves support of the medial crura as well as increases nasal projection. Adapted from Taylor CO. *Surgery of the nasal tip*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 61.

FIGURE 65-35 Shield graft. A, B, This is a grafting technique used to redefine the tip-defining points of the nose. The graft is typically 6 to 8 mm wide superiorly, 5 mm wide inferiorly, and 10 to 12 mm long. Adapted from Taylor CO. *Surgery of the nasal tip*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 62.

1. Trim the caudal septum near the anterior nasal spine
2. Augment the nasal dorsum: this creates the illusion of decreased tip rotation.

Tip Shape In addition to changing the tip position, the tip shape must also be considered. Historically changes to the nasal tip were performed by selective cartilage excision and reapproximation. The Goldman tip is an example of such a technique. The current trend is to preserve and re-orient existing cartilage and place cartilaginous grafts if required.⁴⁵ Excessive grafting can be unpredictable in the long run.

Although cartilage preservation is emphasized there is still sometimes a need to remove cartilage. There are three principal techniques of cartilage excision in the nasal tip region: a complete strip technique, a weakened complete strip technique, and an interrupted strip technique. A greater

FIGURE 65-36 Crural excision. This is used when the nasal tip needs dramatic deprojection. A portion of the lateral crura is excised and the ends are sutured back together.

resection generally results in more dramatic tip narrowing and rotation.

Complete strip techniques involve the removal of a complete piece of cartilage from the cephalic end of the lower lateral cartilages (see Figures 65-37 and 65-38). This procedure is thought to be more stable since it leaves an intact strip of the inferior border of the lower lateral cartilage. Aggressive resection can result in loss of tip support, alar notching, alar retraction, and the appearance of increased columellar show. Most surgeons feel that a minimum width of 6 mm is required to maintain the structural integrity of the lower lateral cartilage.

The weakened complete strip technique involves the removal of a complete cephalic strip followed by weakening of the cartilage by selective morselization of the medial and lateral crura with a scalpel blade.

An interrupted strip involves division of the lateral crura from the dome (Figure 65-39). This technique provides greater rotation than a complete strip but can also result in complications, including loss of tip support, alar notching, and alar retraction. In addition the nasal tip can develop a pinched appearance. The classic Goldman tip is an example of an interrupted strip

FIGURE 65-37 Delivery of lower lateral cartilage. The lower lateral cartilage is best delivered by a marginal incision or exposed through an open rhinoplasty for direct visualization and surgical manipulation. Tip refinement is improved in this case by complete tip reduction to reduce the volume of the tip.

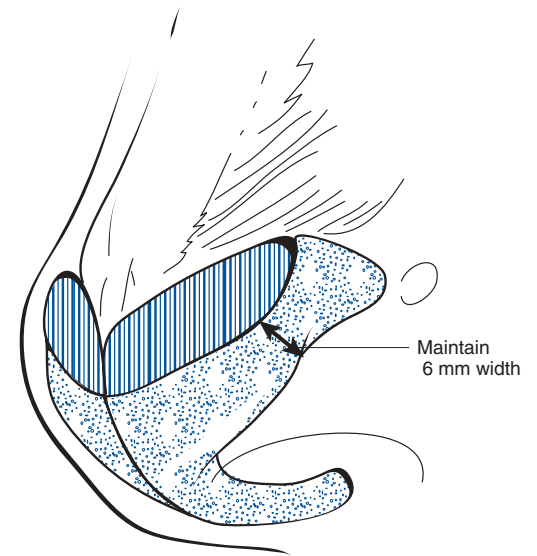

FIGURE 65-38 Complete strip technique. This involves the excision of a strip of cartilage on the cephalic portion of the lower lateral cartilage. This will result in increased tip rotation. It is important to maintain a minimum of 6 mm width of cartilage for structural support of the nose. Adapted from Taylor CO. *Surgery of the nasal tip*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 58.

technique (Figure 65-40). In this technique the lateral crura are divided lateral to the tip-defining points. The medial segments are sutured together, which results initially in increased tip projection. The lateral crural segments are left alone as independent units. This procedure is no longer commonly used because of problems with tip asymmetry, pinched appearance of the nasal tip, and long-term tip ptosis.

For patients with a broad nasal tip, transdomal suturing techniques are often used to narrow the tip. Volume reduction is performed first if needed by cartilage excision as described above. Next, excision of excessive interdomal soft tissue is performed. A 4-0 polydioxanone transdomal suture is placed in a horizontal mattress fashion to narrow and re-orient the alar cartilages. The advantage of this technique is that the suturing can be done multiple times until the surgeon is satisfied with the result. Additionally the long-term results of this technique have been favorable.⁴⁶⁻⁴⁸

FIGURE 65-39 Interrupted strip technique. This is similar to the complete strip except the remaining cartilage is also divided in a vertical fashion. This allows for even greater tip rotation, as indicated by the arrow; however, it can result in a pinched nasal tip and functional problems. The cartilage can be weakened by scoring it in a vertical fashion and this is termed a weakened complete strip technique. Adapted from Taylor CO. *Surgery of the nasal tip*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 59.

Nasal Base Alar Reduction

The alar base should approximate the intercanthal distance and be no more than 1 to 2 mm wider than this. The nostrils should have a symmetric appearance. Asymmetry of the nostril is often due to a deviated nasal septum and this should be reevaluated prior to consideration of an alar base resection.

The primary procedure to reduce the alar base width is an alar base resection. Alar modification is often considered in cases where the nose has to be deprojected or to balance the anatomy in certain ethnic types. It is mandatory to be conservative when performing alar reduction since it is difficult to correct an over-reduction. If there is any doubt, the surgeon should delay the alar base reduction until a later date.⁴⁹

The procedure is performed by excising a small wedge of vestibular mucosa

FIGURE 65-40 Goldman tip. This is an interrupted strip technique in which the lateral crura are divided lateral to the tip-defining points. The medial segments are then sutured together to increase nasal tip projection and to narrow the nasal tip. Adapted from Willis AE, Costa LE. *Surgical management of the nasal base*. In: Waite PD, editor. *Atlas of the oral and maxillofacial surgery clinics of North America: rhinoplasty*. Philadelphia (PA): W.B. Saunders; 1995. p. 61.

and skin. The angulation can be adjusted so that greater reduction of the outer perimeter of the ala is reduced and only limited reduction of the internal perimeter is performed.⁴⁹ The excision should be conservative and will rarely be greater than 3 mm in width (Figure 65-41).

Postoperative Management

After performing the rhinoplasty the surgeon must decide whether intranasal stents or packing is necessary. We generally do not place nasal packing. If the septum requires additional support during healing, then silicone stents are placed. These stents are also used if there are mucosal tears or if a turbinectomy was performed. The stents help reduce the incidence of synechiae formation. The stents are secured to each other by a 3-0 silk suture passed through the columella and are typically left in place for 1 week.

Next the nasal dorsum is splinted. Benzoin or mastisol is painted on the nasal dorsum and $\frac{1}{4}$ inch brown paper tape is applied. After placement of the tape the splint is applied. A metal Denver splint or thermoplastic splint is contoured and applied. Additional paper tape can be placed over the splint.

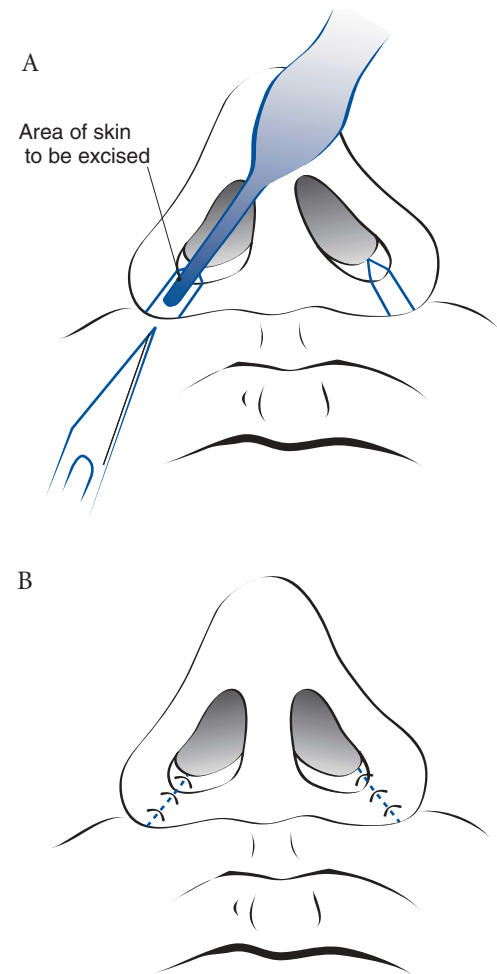

FIGURE 65-41 Alar base reduction (Weir's excision). A, This is used to narrow an overly wide nostril. B, A small amount of vestibular mucosa and skin is excised and sutured together. The excision is usually 1 to 2 mm wide

Rhytidectomy

G. E. Ghali, DDS, MD

T. William Evans, DDS, MD

Face-lifting has received significant attention over the past several decades owing to increasing patient demands for a more youthful appearance. The face undergoes harmonious changes in the facial skeleton, deep soft tissue elements, and skin texture during the aging process. Dissection of cadavers has identified facial ligaments, muscle expansions, and dissection planes that give us a better understanding of facial aging and rejuvenation. Perhaps more importantly, it has also been the catalyst for the evolution of a variety of face-lifting techniques. The goal of facial rejuvenation should be to address all components of aging, leaving the patient with a younger-appearing face and a long-lasting result. If this is accomplished, the patient's face and neck will continue to age harmoniously.¹

Critical evaluation of early techniques and a clear understanding of surgical anatomy have provided insight into the perils and pitfalls of surgical rejuvenation of the face and have resulted in the complexity of various rhytidectomy techniques. Today rhytidectomy is one of the most frequently performed esthetic surgical procedures in the United States.

There are numerous techniques currently used for performing face-lifts but no general agreement as to which of these techniques is most effective²; facial esthetic surgeons have discussed the advantages and disadvantages of superficial and deep

face-lifts for many years. A clear consensus is difficult because patient variables such as past medical history, anatomy, genetic background, social history (eg, smoking, alcohol), motivation to have esthetic surgery, and environment make it virtually impossible to perform a blinded long-term prospective clinical study. Evaluation of facial esthetic surgery is also difficult because most procedures yield satisfactory results initially, often producing enough improvement to be accepted as a good result.

History

Although doubt still exists as to who performed the first face-lift, most authorities date the procedure to the early part of the twentieth century.³⁻¹³ Historically, rhytidectomy procedures may be divided into three main categories: skin excision, subcutaneous undermining, and superficial musculoaponeurotic system (SMAS) manipulation. Early rhytidectomy procedures were limited to skin excision and wound closure without any appreciable subcutaneous undermining.^{3,4,8-10,14} Beginning in the late 1920s, the conventional face-lift operation, consisting of skin dissection with subcutaneous undermining, was established.¹³

The subcutaneous rhytidectomy was the preferred technique for many years. A small amount of subcutaneous tissue is elevated with the skin and is simply redraped, leaving the patient with less

redundancy. However, this technique does not address underlying skeletal deformities, ptotic deep soft tissue structures, or changes in skin texture. Therefore, it usually results in a more unnatural look and increases the likelihood of complications, particularly skin slough.

In an attempt to improve the results obtained with the subcutaneous face-lift, several clinicians described techniques to correct platysmal banding and submental lipomatosis.¹⁵⁻¹⁸ The third historic category came with the advent of SMAS manipulation. Multiple surgeons have described various techniques involving the SMAS and platysma to enhance cervicofacial rhytidectomy.^{1,19-35} In 1974 Skoog described a procedure based on surgical anatomy.¹⁹ At that time the subdermal plane was accepted by most to be the anatomic limit for face-lifting and rejuvenation. Skoog's technique redraped the skin and platysma together, leaving the patient with a more youthful jaw line.

Subsequently Mitz and Peyronie's description of the SMAS provided an anatomic basis for restoration of the face.²¹ Hamra (initially with the deep-plane and later with the composite rhytidectomy) and, later, Owsley (with the multiplanar/multivector approach) modified and improved Skoog's technique by performing a more complete release of the nasolabial fold.^{35,36} Ramirez showed that after subperiosteal release, the soft tissues of the

cheek, forehead, jowls, lateral canthus, and eyebrows can be restored to their youthful relationship with the underlying skeleton.³⁷ Finally, Watson and colleagues described a technique similar to that of Owsley but combined it with laser resurfacing.³⁸ This technique involved a larger plane of subdermal or subcutaneous undermining than that described by Hamra.

Four generations of rhytidectomy techniques are recognized (Table 66-1).³⁹ Current literature has popularized more complex procedures including the deep-plane and composite rhytidectomies.^{1,34,35} These methods have incorporated multiplanar dissections and craniofacial techniques in an attempt to gain better control of the midface soft tissues. Whether these techniques provide longer-lasting results remains to be shown.^{1,34,35,39-42} Multiple authors have cautioned that the more complex deep-plane and composite rhytidectomies typically carry increased morbidity.^{1,40,41,43-49}

Patient Evaluation

When a rhytidectomy is being contemplated, the treatment requirements of the surgeon must be balanced with the desires of the patient (Table 66-2).⁵⁰ These requirements are critical for proper patient selection. The patient evaluation must include general medical and psychological considerations in addition to physical facial features. Neglect of any aspect of the patient evaluation can lead to future problems.⁵¹

Table 66-1 Generations of Rhytidectomy

I	Subcutaneous dissection only with variable skin undermining
II	Subcutaneous dissection + SMAS plication or imbrication
III	Subcutaneous dissection + SMAS plication or imbrication + deep midface section dissection
IV	Composite dissection
SMAS = superficial musculoaponeurotic system.	

Table 66-2 Rhytidectomy Requirements

Patient	Surgeon
Minimal morbidity risk	Safe and predictably consistent outcomes
Long-lasting results	Reasonable operative time
Quick recovery	Reasonable cost to patients
Affordable	Reasonable postoperative recovery period
Performed on outpatient basis; will be ambulatory	Adaptable for revision procedures
	Teachable to residents and fellows

A thorough medical evaluation must be completed prior to surgery. Medical illnesses such as diabetes, hypertension, hypothyroidism, and asthma must be appropriately treated and controlled preoperatively. Medical evaluation is essential for detecting conditions that may adversely affect a patient's ability to tolerate an anesthetic or that may compromise the final surgical result. Appropriate consultations regarding cardiovascular disease, pulmonary disease, coagulopathies, and other active medical problems should be obtained preoperatively. Current medication profiles should be elicited, including aspirin and aspirin-containing compounds, nonsteroidal anti-inflammatory drugs, and herbal drugs, as well as high doses of vitamin E. Examination of prior surgical incisions, such as those resulting from previous thyroidectomies or parotidectomies, is useful in evaluating the wound-healing capacity.

Tobacco and alcohol use, as well as the use of illicit substances, may increase the incidence of surgical complications. Cigarette smoking, diabetes mellitus, and previous head and neck radiation therapy may also impede healing and should be recognized preoperatively. Patients should be told that cigarette smoking significantly increases the likelihood of skin flap necrosis, poor healing, and unsightly scars.^{52,53} Studies have demonstrated a 12-fold greater risk of skin slough in smokers compared with that in nonsmokers.^{52,53} Animal studies involving skin flap experiments have also supported this conclusion.⁵²⁻⁵⁷

A review of the patient's psychological history should focus on motivation for surgery and outcome expectations. Patients seeking surgery based on recent emotional events or with unrealistic expectations should be further counseled and the procedure postponed or cancelled.^{58,59}

The goal of face-lifting is to correct anatomic changes to the face and neck that have occurred as a result of the normal aging process. Patients considered for rhytidectomy present with various degrees of age-related alterations to the facial soft tissues. Ideally, face-lift candidates are 45 to 55 years of age, are in good health, are of normal weight, possess a good bone structure, and possess a thin neck and a deep cervicomental angle. Physical examination of the patient includes a detailed regional evaluation of the face. A face-lift is capable of correcting specific anatomic regions, and a complete and detailed description of the patient's physical characteristics is important. A systematic evaluation allows the surgeon to assess the areas that can be improved with an isolated rhytidectomy and to determine whether other ancillary procedures will be beneficial. Additionally, a detailed regional evaluation provides an opportunity for the surgeon and the patient to understand the limitations of the rhytidectomy; the surgeon can refer to the evaluation when explaining the expected outcome.

Evaluation of the upper facial one-third includes the forehead and upper and lower eyelids. In general, these areas are not affected by the standard rhytidectomy

and are therefore not addressed in this review. Evaluation of the middle facial one-third includes the face and ears. The quality of the skin should be noted, including thickness, redundancy, previous scarring, fine or coarse rhytids, and the location of the hairline. Patients with significant elastosis or actinic damage do not obtain and retain the same quality of results as do patients possessing good skin quality. Assessment of the ear lobe shape and position is critical, and any deviations from normality should be pointed out to the patient preoperatively. Documentation of the nasolabial folds, including length, depth, and symmetry, as well as an assessment of the degree of jowls should be noted. Presence of perioral rhytids is important because they are not corrected with rhytidectomy procedures.

The evaluation of the lower facial one-third includes the chin, jaw line, and neck. A useful preoperative classification of the neck for cervicofacial rhytidectomy divides the neck profile into six distinct classes (Table 66-3).⁶⁰ Using this classification, the clinician can identify each patient's specific abnormality and choose the most appropriate procedure for optimal results (Figure 66-1). Skin redundancy, platysmal banding, cervicomental angle, and submental fat accumulation are important to note in this region. Additionally, the degree of ptosis of the submandibular glands should be assessed and recorded at this time.

Preoperative photographs provide invaluable medicolegal documentation as well as an opportunity to review patient characteristics before and during surgery. The surgeon should obtain the photographs of the full face in repose and smiling, right and left profiles, and right and left three-quarter views. Close-ups of the forehead, eyebrows, and periorbital and perioral regions should be taken, depending on the particular deformity.

An essential component of the patient evaluation includes the preoperative visit.

Table 66-3 Dedo Classification of Facial Profiles

Classification	Comments
I. Normal	Well-defined cervicomental angle Good muscle tone No submental fat
II. Cervical skin laxity	Obtuse cervicomental angle owing to relaxed skin
III. Submental fat accumulation	Requires submental lipectomy
IV. Platysma muscle banding	Requires muscle clipping, plication, or imbrication
V. Retrognathia/microgenia	Requires genioplasty or orthognathic surgery
VI. Low hyoid	Difficult to alter Important to inform patient of limitation

Adapted from Dedo DD.⁶⁰

FIGURE 66-1 Six classes of facial profiles by Dedo. Adapted from Dedo DD.⁶⁰

It is an excellent opportunity to educate the patient regarding various aspects of the procedure, postoperative care, and expectations. It is wise to review any and all patient instructions during the preoperative visit including medications, skin cleaning, and makeup. Patients must discontinue all aspirin-containing compounds, nonsteroidal anti-inflammatory medications, and vitamin E at least 2 weeks prior to surgery. Germicidal shampoo and skin cleaners are used several days before the scheduled date of the procedure to reduce bacterial counts. The patient should wash his or her hair and face and remove all makeup the night before surgery. A written copy of postoperative instructions should be given to and reviewed with the patient (Appendix).

A description of the expected convalescence is appropriate during the preoperative visit. In general, 10 to 14 days is a reasonable time period to wait for ecchymosis to resolve sufficiently to allow camouflage with makeup. Patients should not expect to return to work or social activities before this time. They should be educated regarding expectations in the early postoperative period since those unaware of the slow evolution of results will quickly become frustrated. It should be clearly explained that appearance will continue to improve over a period of several months.

Surgical Technique

Superficial-Plane Rhytidectomy

Once appropriate monitors are placed and the patient is adequately sedated, proposed incision lines and anticipated areas of undermining are marked with a skin marker while the patient is seated in an upright position. The face, neck, and hair are prepped with an appropriate antiseptic surgical scrub. Skin preparations should include the full length of the planned incision and all exposed skin within the surgical field.

Our preference is to perform rhytidectomies under local anesthesia with appropriate sedation and analgesia. Suitable agents include intravenous fentanyl, midazolam, ketamine, and/or propofol. Local anesthesia is provided along the incision line with a 2% lidocaine solution with 1:100,000 epinephrine via a dental syringe. Hydrodissection is performed within the planned plane of dissection with a tumescent anesthetic technique (Figure 66-2).⁶¹⁻⁶⁶

Although multiple techniques exist for mixing the tumescent solution, our preference is to mix 20 mL of a 2% lidocaine with 180 mL of normal saline, creating a solution of 0.2% lidocaine with a 1:1,000,000 epinephrine concentration. This mixture is administered through four trocar sites: temporal, infralobular, mastoid, and submental (Figure 66-3). The solution is deposited subcutaneously in the supra-SMAS plane.

Hydrodissection should extend 1 cm beyond the proposed undermining mark that delineates the anticipated extent of flap

FIGURE 66-2 From left to right: *procar/trocar, infiltrator, and dissector* used for the tumescent technique.

development. Approximately 75 mL of the tumescent anesthetic solution is deposited per side, with an additional 50 mL deposited

FIGURE 66-3 Four trocar sites are typically used: A, temporal; B, infralobular; C, mastoid; D, submental.

in the submental region. The anesthetic is allowed to work for 8 to 10 minutes before proceeding. Typically, the contralateral side is not infiltrated until just prior to initiating closure on the first side.

Following deposition of the anesthetic solution, blunt cannula dissection of the cervicofacial and submental regions is performed. The cervicofacial dissection is generally performed without suction (Figure 66-4), whereas the submental dissection is performed under suction (Figure 66-5). The submental dissection, using the blunt cannula, is accomplished prior to the initiation of the cervicofacial dissection. As previously mentioned, the planned incisions should be marked with the patient seated in an upright position,

FIGURE 66-4 Cervicofacial dissection in the supra-SMAS (superficial musculoaponeurotic system) plane without suction.

FIGURE 66-5 Submental dissection in the supraplatysmal plane under suction.

and prior to administration of the local anesthetic, to prevent distortion of local anatomy. There are numerous modifications of the standard face-lift incision, but several general principles should be followed closely.⁶⁷⁻⁷⁰

It is not necessary to shave the hair in the incision area. If necessary, the hair may be braided along the proposed incision, with the temporal extension placed no more than 2 cm within the hair and parallel to the hairline. Some surgeons recommend a pretrichial incision to prevent the posterosuperior migration of the temporal line.

The incision should be extended inferiorly toward the root of the helix, anterior to the curve of the crus helicis, following the margin of the tragus, and proceed anteriorly just above the base of the incisura intertragica (Figure 66-6). Preservation of the incisura helps to prevent distortion of the tragus postoperatively, providing a more esthetic scar. The incision curves inferiorly 1 to 2 mm below the junction of the lobule with the cheek, rising superiorly onto the back of the conchal bowl approximately 3 to 5 mm and reaching the level of the postauricular sulcus or superior crus of the antihelix. The incision is then directed posteroinferiorly approximately 4 to 5 cm into the scalp of the retromastoid region (Figure 66-7).

If significant cervical skin redundancy is noted, the incision may parallel the posterior hairline for several centimeters before being directed into the hair-bearing skin. This maneuver can prevent a step deformity in the posterior hairline when significant cervical skin is excised. Care must be taken to maintain approximately a 90° angle at the reflection of the posterior flap to prevent skin slough at the tip of the flap.

Several considerations for incision design are important in the male patient.^{18,71} In the temporal region the planned incision is affected by the patient's hair pattern. Individuals with thick temporal hair can tolerate a standard incision. Those with thinning hair,

FIGURE 66-6 Temporal, preauricular, and infralobular components of the typical rhytidectomy incision.

temporal recession, or significant male pattern baldness require a modification of the incision design.

In the preauricular region, the male sideburn must be taken into consideration and the non-hair-bearing skin anterior to the ear must be left intact to prevent an unnatural appearance. Therefore, the incision should extend in a linear fashion, following a natural skin crease adjacent and parallel to the sideburn. This is in contrast to the curved incision used in female patients.

Last, the posterior extension of the incision is placed along the margin of the postauricular hairline. Although this placement has the potential to be slightly more noticeable, the importance of preventing posterior displacement or a step deformity to the hairline must be taken into account. A final consideration in the male patient is the inevitable transfer of hair-bearing skin into the postauricular region or into the ear canal itself.

FIGURE 66-7 Postauricular and mastoid components of the typical rhytidectomy incision.

Management of the cervical region, if indicated, is begun with the placement of a transverse incision in a submental skin crease as an extension of the submental trocar puncture (Figure 66-8). This incision should not be placed in the dominant crease of the “double-chinned” deformity, as scarring may result during the healing process and accentuate the crease. The incision should be approximately 2 cm in

FIGURE 66-8 Submental incision placed to address platysmal banding.

length and placed just inferior to the dominant crease.

Dissection in the submental region proceeds in a subcutaneous plane and joins the lateral subcutaneous neck planes subsequent to the submental dissection. Excess subcutaneous fat may be excised with sharp scissors or a cannula, if indicated. Lipectomy in the submental region should be done cautiously. Overly enthusiastic removal of fat in this region can lead to an atrophic appearance of the cervical facial tissues or a “cobra” neck deformity.¹⁷

Next, the anterior borders of the platysma bands are identified, and excess subcutaneous tissue is removed. The medial borders should be released along their deep surface from the submental region inferiorly to the level of the thyroid

cartilage. The medial borders are then repositioned in the midline, and any overlapping tissue is excised. Plication of the medial platysma borders proceeds from the submental region to the level of the thyroid cartilage with a 2-0 slow-resorbing suture (Figure 66-9).

A horizontal myotomy of the inferior aspect of the platysma may be beneficial in accentuating the cervicomental angle and relieving tension along the anterior surface of the neck. Partial horizontal transection is frequently all that is required and can be performed with sharp scissors at the inferior-most aspect of the dissection of the medial borders. If complete transection is indicated, the lateral aspect of the platysma can be excised through the lateral neck face-lift flap.^{25,28,72,73}

FIGURE 66-9 Platysmal plication accomplished.

Flap Development Flap development is initiated by undermining 1 cm along the entire length of the face-lift incision. This is accomplished in a subdermal plane with a blade or sharp scissors, using skin hooks for retraction (Figure 66-10). On the underside of the flap, maintain approximately 3 to 4 mm of subcutaneous fat to preserve the subdermal vasculature.

In the temporal region, the depth of the flap should be carried through the temporoparietal fascia (subgaleal) down to the loose areolar tissue overlying the deep temporal fascia. Dissection in this plane creates a thicker flap, providing increased protection from any ischemic injury that would damage hair follicles and create subsequent alopecia. The temporal dissection is extended in this plane using a combination of blunt and sharp dissection.

Blunt-tipped scissors should be used in a push-cutting motion into the residual tunnels that were developed secondary to the previous blunt cannula dissection (Figure 66-11). Rees T-clamps are used for countertraction and aid in the dissection. Undermining in this plane can be safely carried superiorly to the level of the lateral canthus.

At this point the dissection is carried inferiorly and medially across the cheek in the subcutaneous plane. This zone of transition from the sub-SMAS (deep to the temporoparietal fascia) to the subcutaneous plane of dissection corresponds to

FIGURE 66-10 Flap development initiated by 1 cm undermining via a blade or sharp dissection scissors.

the mesotemporalis that contains the superficial temporal artery and the frontal branch of the facial nerve.⁷⁴⁻⁷⁶ The facial nerve is located anterior and inferior to the frontal branch of the superficial temporal artery, so preservation of this vessel during dissection helps to protect this important nerve.

The extent of undermining necessary depends on the patient. Younger patients without excessive laxity of the skin require only 4 to 5 cm of undermining, but older patients with redundant tissue and severe jowling may require undermining to within 1 cm of the oral commissure. When platysma banding is present, the cervical dissection is carried inferiorly to the level of the thyroid cartilage and should communicate with the dissection from the contralateral side.

In the postauricular region, the flap should be developed in the subcutaneous plane below the ear lobe to protect the great auricular nerve. This nerve is the one most commonly injured during rhytidectomy procedures (Figure 66-12).⁷⁷⁻⁷⁹ The great auricular nerve runs just deep to the superficial fascia overlying the sternocleidomastoid muscle and supplies sensation below and behind the ear. With the head turned 45° toward the contralateral side, the great auricular nerve consistently crosses the middle of the sternocleidomastoid muscle at a level 6.5 cm below the caudal edge of the bony external auditory canal (Erb's point).⁷⁹ Maintaining subcutaneous dissection below the ear lobe helps protect the great auricular nerve, but above the level of the ear lobe, the greater auricular is not at risk and dissection may be carried deeper.⁸⁰ Meticulous hemostasis is then accomplished with bipolar cautery. Overzealous use of electrocautery should be avoided on the skin-flap side to reduce the risk of ischemic injury and flap necrosis.

Next, the underlying SMAS in the cheek region is manipulated. Many of the age-related changes in the facial region are due to ptosis of the underlying fat. Correc-

FIGURE 66-11 Scissors are used in a push-cutting motion with the tips up.

tion of these changes is best obtained by repositioning this tissue along direction lines (vectors) different from those used for the skin flap. Independent bidirectional suspension of the SMAS and the skin flap reposition the ptotic facial tissues, providing longer-lasting results and reducing an unnatural appearance.

SMAS manipulation can be by plication, imbrication, or a combination of these techniques; there are proponents of each method. *Plication* is a technique whereby the SMAS is folded upon itself to obtain the desired repositioning, and *imbrication* is a technique in which the SMAS is incised or excised so that the distal portion is repositioned to overlap the proximal tissue (Figure 66-13).

SMAS plication is accomplished with a 2-0 slow-resorbing suture on a tapered

FIGURE 66-12 Great auricular nerve demonstrated.

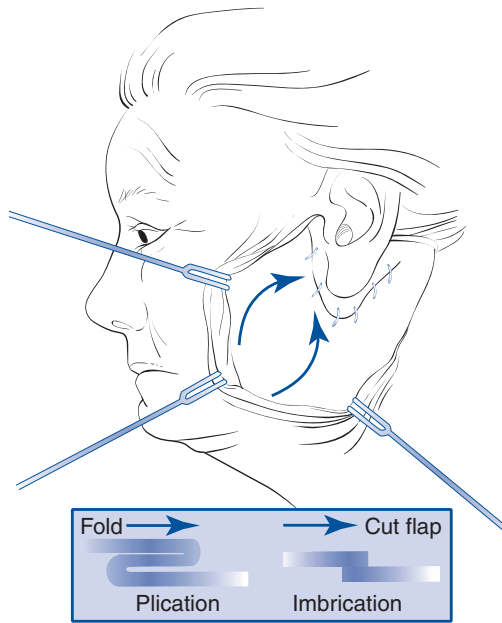

FIGURE 66-13 Illustration of plication versus imbrication.

needle (Figure 66-14). All knots are buried to prevent irritation to the skin flap or palpability. Two key sutures are placed initially, with the first extending from the fascia overlying the angle of the mandible to the fascia immediately inferior to the tragus. The second suture is placed from the fascia lateral to the oral commissure to the fascia immediately superior to the tragus. Several additional sutures may be placed, if needed, in the preauricular and postauricular areas. This suture placement provides a posterosuperior repositioning of the ptotic tissues.

Imbrication requires elevation of a sub-SMAS flap. An incision is made horizontal-

ly just inferior to the zygomatic arch and vertically posterior to the angle of the mandible. Landmarks for the incision include the zygomatic arch, tragus, platysma muscle, and the mandible (Figure 66-15). The horizontal incision is made approximately 1 cm below and parallel to the zygomatic arch to prevent damage to the frontal branch of the facial nerve. The middle portion of the tragus may be used as a reference for staying below the zygomatic arch.

The incision is carried forward 2 to 3 cm. The vertical incision descends inferiorly along the posterior border of the platysma several centimeters below the angle of the mandible. It is important to keep the incision posterior to the angle of the mandible to prevent damage to the marginal mandibular branch of the facial nerve. The SMAS is then elevated for 2 to 3 cm in a sub-SMAS plane (Figure 66-16). The flap is redraped posterosuperiorly and sutured using the technique previously described for plication.

Redraping of the skin flap is performed with the patient's head in a neutral position. Extension or flexion of the neck influences the amount of skin excised and may adversely affect the outcome. Key suspension staples or sutures are placed prior to trimming the skin flap. In general, the skin flap is redraped in a posterosuperior direction with an emphasis on the posterior direction. The majority of the needed superior suspension is accomplished by SMAS

FIGURE 66-16 Following superficial musculo-aponeurotic system flap elevation, 2-0 resorbable suture on a tapered needle is used for buried knots to secure the imbrication.

manipulation. Care should be taken to prevent a misdirection of facial rhytids and a distortion of the temporal hairline. Careful assessment of appearance should be made prior to suturing the flap in place.⁸¹

The first key skin-suspension suture (or staple) is placed in the temporal region just above the ear. The flap is then grasped, and the appropriate vector is determined and held in place while the flap is trimmed and the staple placed. The second staple is placed in the postauricular region at the most posterior and superior aspect of the flap. Careful attention should be given to proper inset of the ear. In a nonoperated ear, the long axis of the ear lobe hangs 10 to 15° posterior to the long axis of the ear proper. This relationship must be maintained to prevent obvious deformities of the ear.

FIGURE 66-14 The area of plication is assessed.

FIGURE 66-15 The area of proposed resection in preparation for imbrication is marked.

Skin Closure Trimming of excess skin is performed with a blade or Iris scissors (Figure 66-17). It is important to be aware of the amount of skin to be excised in the temporal region to prevent distortion of the hairline. The distance from the lateral canthus to the anterior margin of the temporal hairline should be recorded preoperatively to serve as a reference for skin excision. Skin closure in the hair-bearing scalp (ie, temporal and mastoid regions) is performed with subdermal 3-0 resorbable sutures. Staples may be

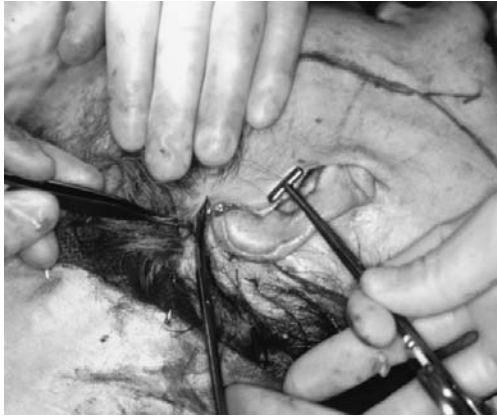

FIGURE 66-17 Following the placement of key staples, flap trimming is accomplished with a blade or Iris scissors.

used to approximate skin margins of the temporal and mastoid scalp. Our preference is to provide a layered closure to minimize tension on the most superficial aspect of the skin.⁸¹ The immediate postauricular region is closed with a 4-0 plain gut suture, without the need for deep sutures. In the preauricular region, a 4-0 resorbable suture is placed followed by approximation of the skin edges with a 6-0 or 7-0 nylon running suture. The deep layers of the submental incision are closed with 4-0 resorbable suture, and 6-0 nylon is used for the skin edges.

The decision of whether to place drains must be made on an individual basis, depending on how much oozing or edema is present. In our experience drains are rarely needed. Antibacterial ointment and gauze dressings should be placed along the incision lines. Gauze is also placed preauricularly and postauricularly as well as in the submental region. The entire face should then be wrapped, taking care to prevent excessive tightness of the dressing as it can lead to ischemia of the flaps (Figure 66-18). Additionally, the appropriate positioning of the ears under the dressing should be noted. Dressings should not be manipulated for evaluation until the first postoperative day. Most complications in rhytidectomy occur early in the postoperative period (ie, 24–36 h); close follow-up is therefore essential.^{82–85} Some surgeons prefer to use

no dressings postoperatively.⁸⁶ The degree of edema and ecchymosis postoperatively is frequently underestimated and can be quite shocking to the patient, despite the surgeon's best attempts to educate him or her. The patient's hair should be gently cleansed and rinsed for additional comfort. Incision lines should be cleansed daily with a 1:1 solution of hydrogen peroxide and water. Antibacterial ointment should be used until all sutures are removed.

The preauricular sutures are removed after 4 to 5 days, as are the staples in the temporal and mastoid regions after 10 days. Patients should be instructed not to wash their hair until all sutures have been removed and then to wash only gently with baby shampoo. Written suggestions for the avoidance of ultraviolet light and high heat from hair dryers and for the use of sunblock and incision massage should be given to the patient and repeated orally in the early postoperative visits. The effects of the procedure are still striking for years after surgery (Figures 66-19 and 66-20).

Deep-Plane Rhytidectomy

After the induction of general anesthesia and intubation, 3 cc of sterile methylene blue is introduced through each parotid duct to stain the parotid glands. This allows for confident and safe dissection and is an excellent teaching aid.

The circle of knowledge and caution (CKC) is then drawn on both cheeks (Figure 66-21). This is a circle of required precise knowledge of facial anatomy needed by both experienced and inexperienced surgeons performing face-lifts. Point A, representing the origin of the zygomatic major muscle, is measured along a line from the lateral canthus to the tragon, 2 cm posterior and 2.5 cm inferior to the lateral canthus. Point B, representing the perforating branch of the transverse facial artery, is measured 3 cm posterior and 3.5 cm inferior to the lateral canthus. A circle is drawn with point A as the center

FIGURE 66-18 Typical face-lift dressing immediately postoperatively.

and the radius being the distance between points A and B. Obviously, these measurements are not exact in every patient.

The CKC represents the most complex area of anatomy and the most dangerous area in terms of risk in a deeper-plane face-lift procedure. The perforating branch of the transverse facial artery that is accompanied by a small sensory branch of the zygomaticofacial nerve is the "caution sign." If the artery is severed during the sub-SMAS dissection, it gives a bloody warning to the surgeon that the CKC is near; with careful dissection in the known area of this artery, preservation can be accomplished but is not mandatory in nonsmokers. Safe entrance into the CKC is from superior to this perforating branch over the origin of the zygomatic major muscle through the zygomatic osteocutaneous ligament. If this is followed, the surgeon will never encounter the zygomatic branch of the facial nerve and only occasionally will encounter the branch of the zygomatic branch that enters the deep aspect of the superior third of the zygomatic major muscle.

FIGURE 66-19 Typical result achieved with a superficial-plane rhytidectomy including superficial musculoaponeurotic system imbrication: A and B, preoperative photographs; C and D, photographs taken 2 years postoperatively.

The contents of the CKC are the perforating branch of the transverse facial artery, the zygomatic osteocutaneous ligaments, the infraorbital osteocutaneous ligaments, the superior portion of the masseteric fascicutaneous ligaments, the origins of the zygomaticus muscles, the inferolateral portion of the orbicularis oculi muscle, the zygomatic branch of the facial nerve and its branch to the deep aspect of the superior third of the zygomaticus major muscle, the occasionally present inferior palpebral branch of the facial nerve to the orbicularis oculi muscle, and possibly the parotid duct.

Xylocaine 2% with epinephrine 1:50,000 is instilled only in the area of the planned incision, not under the skin flap or the SMAS flap. Since an endoscopic brow lift is usually performed simultaneously with this deep-plane technique, an incision, as drawn in Figure 66-22, is usually preferred in both females and males. We prefer the pretragal incision unless a female patient specifically requests a retrotragal incision. Incisions in the sideburn and in the posterior hair edge are significantly beveled to allow hair growth through the resultant scar.

Preauricular subcutaneous dissection is performed to a level superficial to the lateral part of the orbital portion of the orbicularis oculi, which interrupts the fibrous septa in the superficial fat layer that cause crow's-feet rhytids and also interrupts the fibrous septa of the zygomatic osteocutaneous ligaments and masseteric fascicutaneous ligaments. The subcutaneous dissection proceeds 2 cm posterior to the oral commissure and extends just inferior to the lower border of the mandible, where the previously performed cervical subcutaneous dissection is encountered. This subcutaneous dissection is not taken to the melonasolabial groove to allow the SMAS-malar fat pad-skin complex to remain intact. Postauricular subcutaneous dissection is performed superficial to the sternocleidomastoid-investing fascia to the level of the cricoid cartilage and anterior in the neck to the previously performed cervicoplasty subcutaneous dissection superficial to the investing superficial fascia of the platysma muscle. The posterior border of this dissection is the anterior border of the trapezius muscle (Figure 66-23). The subcutaneous dissection is significantly

reduced in smokers and patients with other microvascular disease, and this may compromise the natural postoperative result. In smokers the perforating branch of the transverse facial artery is not interrupted in either the subcutaneous or sub-SMAS planes and is maintained for perfusion of the skin flap border.

The SMAS incision is marked posterior to anterior along the inferior border of the zygomatic arch until the origin of the posterior border of the superficial head of the masseter muscle is palpated (the zygomatic arch descends to meet zygomatic buttress). The marking is then directed toward the pupil extending over the orbital portion of the orbicularis oculi muscle and fascia to the level of the inferior orbital rim. The preauricular SMAS marking is 1 cm anterior and parallel to the skin incision (Figure 66-24). At the lobule of the ear, the SMAS marking turns posteriorly 10° and extends to the level of the cricoid cartilage (extent of neck dissection) parallel and anterior to the posterior border of the platysma muscle.

The SMAS incision is made through the vascular orbicularis oculi muscle with cautery; then a scalpel is used to

FIGURE 66-20 Rhytidectomy procedures often complement various skeletal or orthognathic procedures. This patient had a superficial rhytidectomy, rhinoplasty, and augmentation genioplasty. A–C, Preoperative views; D–F, 2½ years postoperatively.

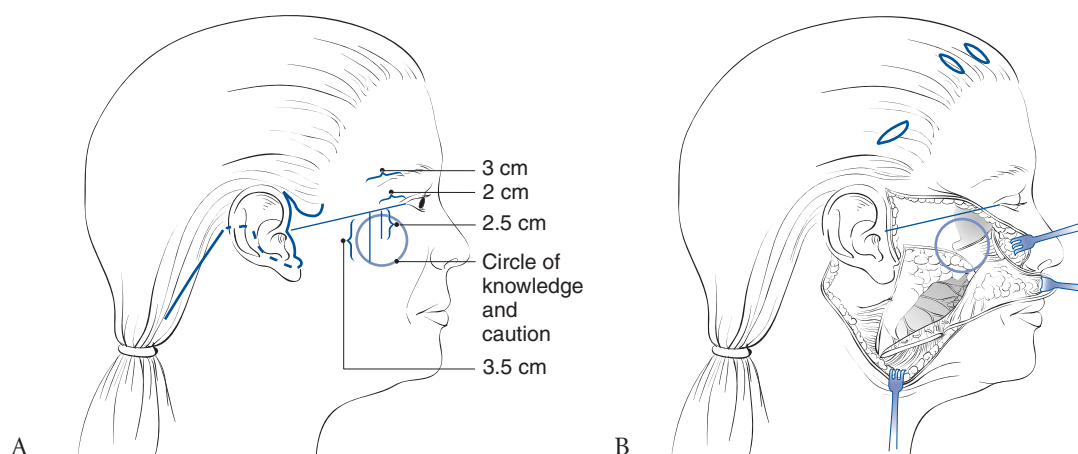

FIGURE 66-21 A, The circle of knowledge and caution (CKC) is constructed by measuring 2 cm and 3 cm from the lateral canthus along a line from the lateral canthus to the tragus. From these respective points, 2.5 cm and 3.5 cm inferior is the origin of the zygomaticus major muscle and the perforating branch of the transverse facial artery. The circle is drawn with the origin of the zygomaticus major as the center, and the radius is the distance from this point to the perforating branch of the transverse facial artery. B, CKC transposed over the extended multiplanar multivector face-lift dissection.

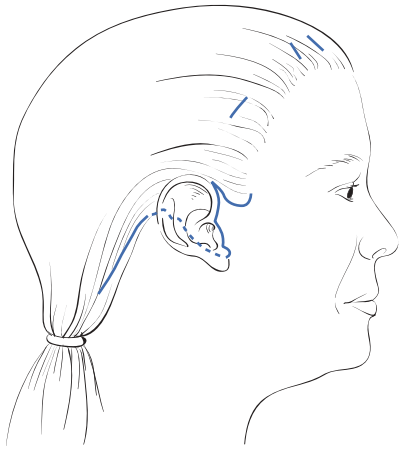

FIGURE 66-22 Face-lift skin incision (pretragal).

FIGURE 66-23 Subcutaneous dissection (sideburn and postauricular hair clipped, not shaved).

continue the incision to approximately 2 cm below the ear lobe. Scissor dissection to protect the great auricular nerve and the external jugular vein completes the SMAS incision in the neck to the level of the cricoid cartilage.

SMAS flap elevation is started with a scalpel at the posterosuperior edge, and sharp dissection exposes the sub-SMAS fat at the superior pole of the parotid gland that protects the frontal branch of the facial nerve. Continued inferior sharp dissection exposes the parotid fascia seen easily because of the blue-stained parotid gland. The CKC area is dissected last, after the rest of the entire SMAS flap is mobilized (Figure 66-25).

As previously described, there is strict adherence between the SMAS aponeurosis and the parotid fascia, and sharp dissection is required to separate the SMAS from the parotid fascia. This same adherence from scarring after SMAS repositioning is what helps give this deeper-plane technique long-term stability. A SMAS incision anterior to the parotid fascia does not give this benefit, and more dependence is placed on the sutures.

Once the anterior edge of the blue-stained parotid gland is seen or the dissection becomes much easier because of fatty/areolar tissue, sharp dissection is stopped. The remainder of the sub-SMAS flap dissection, except for the CKC area, can be achieved with blunt scissor dissection, remaining just deep to the facial SMAS and the neck platysma fascia. The deep fat layer is areolar and more fatty, allowing blunt dissection over the masseteric fascia to or through the masseteric fasciocutaneous ligaments and deep to the platysma fascia in the neck to join the previously performed cervicoplasty dissection. The area over the posterior portion of the submandibular gland is gently bluntly dissected. The only exception to this is in the area of the platysma cutaneous ligaments, where sharp dissection is required. Care is taken around the angle of the mandible to remain just deep to the neck platysma fascia to remain clear of the marginal mandibular branch of the facial nerve, which is rarely seen. Multiple cervical branches of the facial nerve perforating the deep fasciae that penetrate the deep surface of the platysma muscle are visualized in the neck, and vertical blunt scissor dissection preserves them.

The CKC area is next addressed. The caution sign is the perforating branch of the transverse facial artery (Figure 66-26). Once this is encountered, sharp sub-SMAS dissection with scissors is directed superior to this vessel, through the zygomatic ligaments until the origin of the zygomatic major muscle is visualized (Figure 66-

27). Dissection is continued over and parallel to the zygomaticus muscles deep to the superficial leaf of investing superficial facial fascia (SMAS) of the zygomaticus muscles and deep to the anterior portion of the divided orbicularis oculi muscle and its investing fascia (SMAS) for about half the length of the zygomaticus muscles (Figure 66-28). This dissection is safe if it remains superficial to the zygomaticus muscles and deep to the cut anterior edge

FIGURE 66-24 Marking for right-sided superficial musculoaponeurotic system incision. The anterosuperior portion of the mark is directed toward the right pupil, not the lateral canthus.

FIGURE 66-25 The initial sharp dissection of the right-sided superficial musculoaponeurotic system (SMAS) flap, separating the SMAS from sub-SMAS fat superior to the superior pole of the methylene blue-stained parotid gland, and the SMAS from the parotid fascia over the methylene blue-stained parotid gland. The appearance of sub-SMAS fat and the outline of the anterior border of the parotid gland determine the end of sharp dissection and the start of blunt dissection between the SMAS and masseteric fascia.

FIGURE 66-26 Right-sided sub-SMAS (*superficial musculoaponeurotic system*) dissection with the instrument pointing to the perforating branch of the transverse facial artery—the start of the circle of knowledge and caution.

FIGURE 66-27 Right-sided sub-SMAS (*superficial musculoaponeurotic system*) dissection with a clamp grasping portions of the zygomatic osteocutaneous ligaments, which will be interrupted to uncover and visualize the origin of the zygomaticus major muscle.

of the orbicularis oculi muscle. Dissection is continued through the zygomatic osteocutaneous ligaments and the infraorbital osteocutaneous ligaments (often to the nose) (Figure 66-29) and carefully through the superior masseteric fasci-cutaneous ligaments until the SMAS flap, which includes the ptotic malar fat pad, is freely mobilized (Figure 66-30). If more mobilization is required (rarely occurs), blunt dissection is accomplished cautiously through the masseteric fasci-cutaneous ligaments to the anteroinferior insertion of the masseter muscle exposing the buccal fat pad, the peripheral branches of the zygomatic and buccal branches of the facial nerve, and the facial vessels.

Moderate superoposterior traction is placed on the passively mobile SMAS flap, a back cut is made at the superoposterior point, and a key 2-0 slow-resorbing suture is used to fix the SMAS flap to the immobile superoposterior SMAS. The appropriate amount of superior SMAS flap is then excised along with a pie-shaped section of SMAS/orbital portion of the orbicularis oculi muscle. This section is then re-approximated with 2-0 slow-resorbing suture in a superoposterior vector elevating the midface, relocating any prolapsed infraorbital fat, and improving the lower eyelid/cheek junction (along with the pre-

vious interruption of the infraorbital osteocutaneous ligaments). The superior SMAS flap is then sutured with a 2-0 slow-resorbing suture in a vertical vector to elevate the lower face and jawl.

Moderate posterosuperior traction is then placed on the SMAS flap in a direction parallel and slightly superior to the inferior border of the mandible, a back cut is made, and another key 2-0 slow-resorbing suture is placed to fix this SMAS flap to the stout parotid cutaneous ligaments to define the inferior border of the mandible. Mild posterior traction is placed on the neck SMAS (platysma), the excess is excised, and the mobile neck SMAS flap is sutured to the

posterior immobile neck SMAS. Moderate posterior traction is placed on the preauricular SMAS flap, the excess is excised, and the mobile SMAS flap is sutured to the posterior immobile SMAS (Figure 66-31). The SMAS is reapproximated to maintain the integrity of the SMAS/mimetic muscles complex to allow natural animation. Stability is obtained by having the resultant scarring of the SMAS complex in close relationship with the natural facial fascial tissue adherence areas. The vectors of traction are opposite the vectors of aging, with excess SMAS being removed that should be approximately equal to the amount of tissue ptosis present before surgery (Figure 66-32).

Excessive traction on the anterosuperior portion of the SMAS flap will flatten the melonasolabial groove completely giving an unnatural result. Sufficient repositioning of the malar fat pad to rejuvenate, not obliterate, the melonasolabial groove is desired. Rarely, dissection deep to the malar fat pad but superficial to the facial mimetic muscles is required to mobilize the malar fat pad sufficiently, and the malar fat pad is elevated and independently sutured to the SMAS.⁸⁷⁻⁹⁰ The skin is then redraped along a slightly superoposterior vector, and a cut is made to free the ear lobe. The skin flap is then elevated, and any bleeders are coagulated. The area of surgery is irrigated well

FIGURE 66-28 Right-sided subsuperficial fascia dissection superficial to the zygomaticus major muscle for approximately half the length of the muscle.

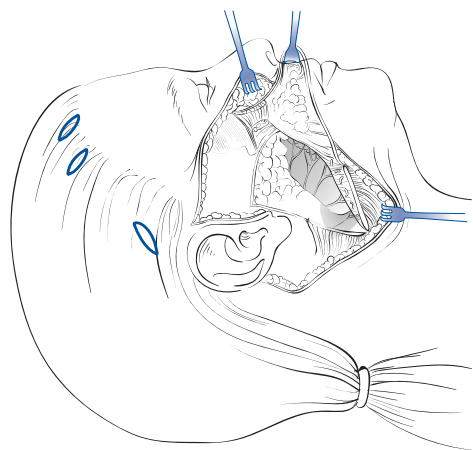

FIGURE 66-29 Right-sided suborbicularis oculi muscle/SMAS (*superficial musculoaponeurotic system*) dissection in the suborbicularis oculi fat to interrupt the infraorbital osteocutaneous ligaments, often as far medial as the nose.

A

B

FIGURE 66-30 A, Right-sided complete mobilization of superficial musculoaponeurotic system flap. The instrument is pointing to the zygomaticus minor muscle. The cut edge of the orbicularis oculi muscle invested by superficial fascia and fat can be seen. B, Illustration of the anatomy in Figure A.

with saline, and both the SMAS and the undersurface of the skin flap are dried with sponges. Fibrin glue is sprayed in all areas, and the skin flap is appropriately positioned. Compression without movement is applied for 5 minutes.

Excess skin is carefully excised and closure is performed with 5-0 polyglactin 910 sutures in the subcutaneous layer, dermal adhesive on the preauricular skin incision, and 5-0 fast-absorbing gut suture in the postauricular skin incisions. No drains are used. Cotton is placed over the areas of surgery, and moderate pressure is applied for 8 to 12 hours with facial and occipital pressure bands. The dressing is intended to prevent abnormal facial and neck movement during the first 8 to 12 hours of the postoperative period.

Summary

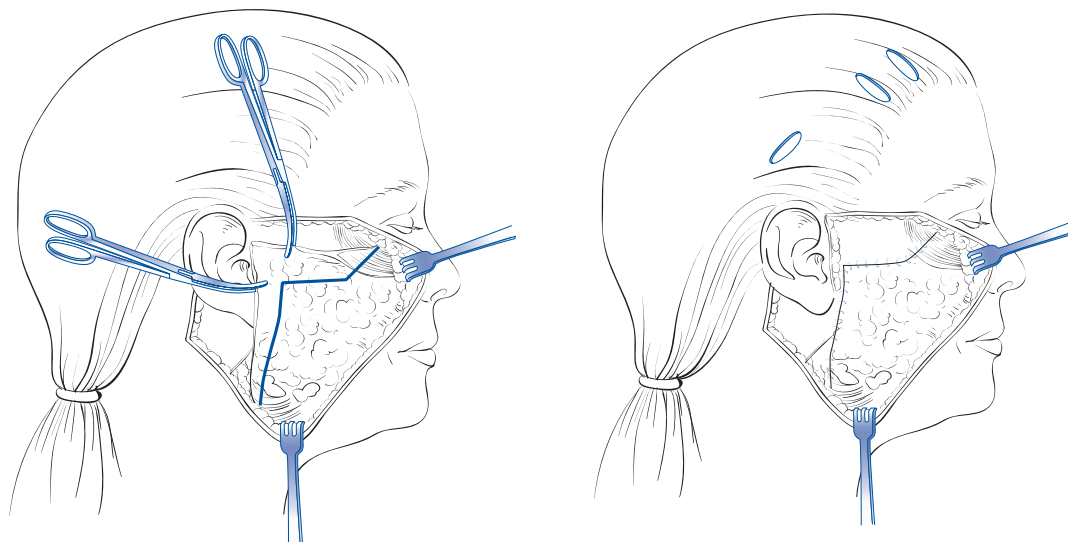

Over the past two decades, numerous rhytidectomy techniques have been described to improve the results of facial rejuvenation. When contemplating facial rejuvenation surgery, the treatment requirements of the surgeon must be balanced with the desires of the patient. These requirements are critical in defining the advantages of one technique of face-lifting over the other. As we prepare our patients for esthetic

FIGURE 66-32 The amount of facial and neck superficial musculoaponeurotic system (SMAS; including the central neck SMAS from cervicoplasty) removed in a typical extended multiplanar multivector face-lift. Notice the passive redraping of the skin.

surgery, we must consider all the variables discussed and individualize each treatment plan. Not all patients should undergo a deep-plane face-lift; however, many will benefit from release of the retaining ligaments and a repositioning of tissues in multiple vectors.

In the realm of oral and maxillofacial surgery, the rhytidectomy procedure finds great application as an adjunct to traditional skeletal surgery. It seeks to reverse the effects of gravity and relaxation of the facial skin and fascia by resuspending the facial units and eliminating excess skin and subcutaneous tissue. Although a wide variety of

A

B

FIGURE 66-31 A and B, Moderate traction is placed on the superficial musculoaponeurotic system (SMAS) flap, the excess SMAS is excised after the superoposterior key suture is placed, and the SMAS flap is sutured in the appropriate vectors to the fixed SMAS.

techniques are reported for face-lifting, we have attempted to provide a broad overview of the superficial-plane rhytidectomy and deep multiplanar techniques. These techniques are both efficacious and safe. By tailoring the approach to the specific needs of each patient, based on a thorough knowledge of surgical anatomy, the maxillofacial surgeon should achieve consistently good results with minimum morbidity.

APPENDIX Postoperative Rhytidectomy Instructions

Immediately upon Arriving Home

- Head elevation: Lie down with your head and back elevated on two pillows. You must sleep in this position for 1 week.
- Dressings: Do not remove bandages. These will be removed at the office on your first postsurgery visit.
- Ice packs: Place ice packs (ice in freezer bags or packages of frozen peas) over the cheek areas on and off over a period of 24 hours. *Do not* put ice on after 24 hours unless you are told to do so.
- Swelling: Ice packs will keep swelling and bruising to a minimum.
- Bruising: Bruising often lasts 7 to 14 days.
- Medication: Take pain medication *only if needed* and with food or crackers.
- Diet: Upon arriving home from surgery, begin with clear liquids until fully awake; then begin regular food intake with soft foods.
- Suture care: Keep all sutures clean with a peroxide-water solution. Keep sutures covered with antibiotic ointment at all times. Clean three to five times per day.

One Day or More after Surgery

- Moist heat: Ice packs are to be discontinued 24 hours after surgery. *Wait 12 hours*; then you may begin moist heat. Use a moist washcloth between an electric heating pad and your face. Do not use heat continuously; for example, use for 30 minutes and then off for 30 minutes. *Do not* set the heating pad higher than *medium* at any time, regardless of how cool it feels to you.
- Activity: Stay up as much as possible. Avoid bending over or lifting heavy objects for 1 week. Strenuous activities should be limited for 2 to 3 weeks.
- Work: Most people plan to return to work in 2 weeks. This depends on how you feel about being seen with bruising. Most of the bruising can be masked with makeup if you prefer to return earlier.
- Makeup: Cosmetics may be applied on the sixth day. Ask about special coverup products for bruising. Mint green coverstick followed by a flesh-tone foundation will cover most bruises.
- Bathing: You may bathe or shower, but keep the bandages dry. When bandages are removed, gently wash the facial areas.
- Hair care: You may wash your hair on the fifth day after surgery. *Do not bend over* to wash your hair; this may cause bleeding or swelling to occur. Use medium heat on your hair dryer. High heat or hot rollers should not be used for 7 to 10 days. You may use color on your hair in 3 weeks.
- Diet: Eat regular but soft meals. You will need to take vitamins and minerals to help with the healing. We will be glad to give you vitamin and mineral information.
- Sun: Protect your facial skin from excessive sun exposure for 1 month after surgery.

Please report any of the following to our office:

- Excessive pain or bleeding
- Itching or rash around stitches
- Oral temperature > 100°F (37.8°C)
- Excessive swelling/bruising, fatigue, or depression

Forehead and Brow Procedures

Angelo Cuzalina, MD, DDS

Upper facial cosmetic surgery has enjoyed an unprecedented increase in popularity over the past decade. The yearning of baby boomers to look and feel rejuvenated has led to new endoscopic techniques aimed at creating a more youthful and natural appearance with shorter recovery periods than existed in past decades.¹⁻³ The ultimate goal of improving a person's appearance remains unchanged. Society shapes our views of what looks attractive, and no mathematic formula can ever be used to determine an ideal eyebrow position (Figure 67-1). Each individual has his or her own unique perception of facial beauty. For most people the upper face and eyes impart more emotion than does any other part of the human body; it is clear that rejuvenation of this vital area can provide an esthetically pleasing result.

Esthetic concerns of the forehead and brow regions of the face affect a wide range of age groups. Unlike the standard lower face and neck rhytidectomy, which more commonly affects patients after the age of 45 years, cosmetic concerns in the upper third of the face may be evident for patients in their twenties and thirties owing to genetic predisposition. The forehead and brow area must be entirely evaluated for a wide range of interlacing diagnoses. Matching the problem(s) to the ideal rejuvenation technique(s) is essential for maximum esthetic benefits. Thinning skin and laxity owing to age and gravity

encompass only a portion of the forehead and brow dilemmas that must be addressed when planning rejuvenation procedures (Figure 67-2).

The aging process typically leads to forehead and brow ptosis on almost every patient; however, it is important to distinguish whether the ptosis in the forehead and brow region is owing to problems with brow position, upper eyelid laxity, or a combination of the two (Figure 67-3). Other problems such as dynamic lines caused by muscle activity in the glabellar

region, variable hairline patterns, bony abnormalities, and asymmetries, as well as skin texture itself, also must be assessed in relation to each other. Achieving the patient's desired expectation depends not only on sound surgical skill and judgment, it also depends critically on communication between the surgeon and patient. Truthful disclosure of what can reasonably be attained is prudent and helps to prevent patient dissatisfaction.

Rejuvenation of the upper third of the face is one of the most rewarding and

FIGURE 67-1 Three different types of esthetically pleasing foreheads and eyebrow position. The tail of the eyebrow is located along the alar-canthal line. The greatest brow arch is seen in the lateral third between the lateral limbus and canthus of the eye. The outer half of the brow is “ideally” located 5 to 10 mm above the orbital rim in females.

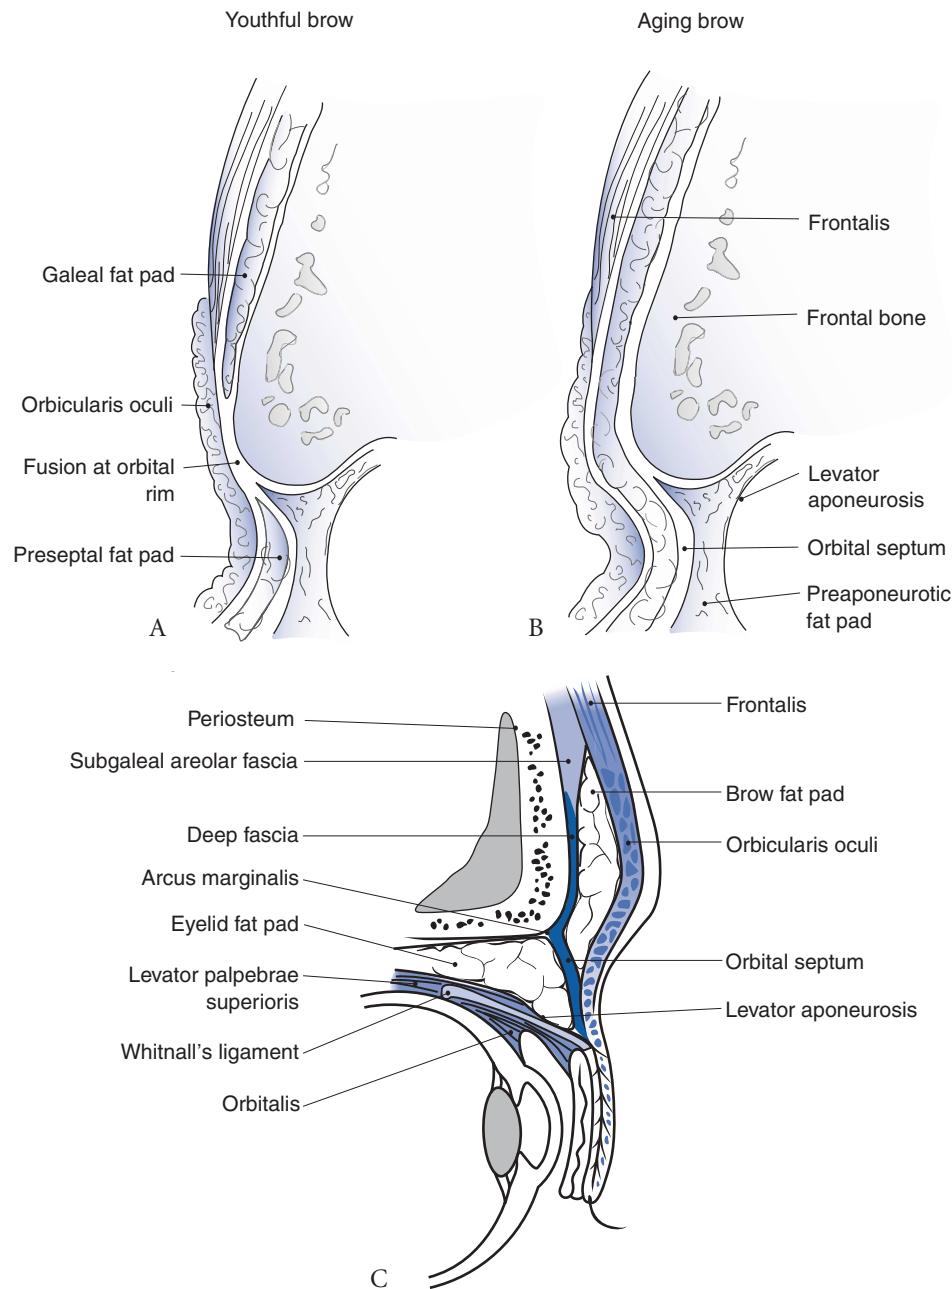

FIGURE 67-2 A, The youthful brow is elevated proportionately and has densely adherent periorbital fascia and muscle. B, Brow descent owing to aging and the associated loss of fascial integrity, along with orbital fat prolapse. C, Cross-section of the brow near the mid-pupillary position.

fulfilling procedures a surgeon can offer to select patients. Specific elevation and correction of lateral hooding can be appear natural and still impart a tremendous improvement in the patient's overall beauty and youthful appearance (Figure 67-4). The goal of this chapter is to review the upper third of facial anatomy specific to forehead and brow rejuvenation techniques and to discuss a variety of the most

common techniques for rejuvenating the forehead and brow region.

Anatomic and Esthetic Considerations

It is generally accepted that a youthful forehead is roughly one-third of the overall facial height.⁴⁻⁹ Essentially, the distance from the hairline to the glabella is equal to the distance from the glabella to the point

at the base of the columella or subnasale (Figure 67-5). A youthful-appearing eyebrow is different for men and women. The female eyebrow should be arched with the highest point of the brow on a sagittal line from the lateral canthus.^{10,11} The entire brow itself should be above the orbital rim. In general the medial brow of the female is located ideally 1 to 3 mm above the orbital rim and the lateral third of the brow 5 to 10 mm above the rim.¹² This is in contrast to a typical male eyebrow that should lie at or only slightly above the orbital rim in a more horizontal or uniform arch fashion (Figure 67-6). Elevating the lateral third of the male eyebrow disproportionately more than the remaining brow will create a feminine appearance.

The detailed anatomy of individual areas has been well described in the literature and often relates to the specific procedure being performed.¹³⁻²⁵ Therefore, the following anatomic discussion is simplified by separating the specific regions into bony landmarks, muscle and fascial anatomy, vessel and nerve anatomy, and specific endoscopic anatomy, and each anatomic region is addressed individually as it relates to specific surgical procedures.

Bony Landmarks

Bony landmarks of the forehead and brow region can be focused all around the frontal bone, which makes up the highest percentage of the upper third of the face. The connections (suture lines such as the nasofrontal, zygomaticofrontal, and coronal) are important landmarks because they can be clinically relevant for limits of dissection and can help surgeons determine their location during dissection. For instance, the zygomaticofrontal suture line is an ideal location to end most basic brow lift dissections (Figure 67-7). Additional dissection can be performed if midface lifting is also planned or if the patient desires more elevation at the lateral canthal region. Overaggressive dissection here in many patients can create an unnatural

FIGURE 67-3 A, Rejuvenation of the upper third of the face must address whether the problem is limited to brow ptosis, eyelid ptosis, or a combination of both, as seen in the patient on the left. Skin texture must also be evaluated. B, This photograph was taken 1 month after a coronal brow lift, upper blepharoplasties, and full-face laser resurfacing.

cat's-eye appearance, particularly if too much tissue is elevated medially along the suture line and lateral canthus. Likewise, the nasofrontal suture line is a nice landmark to note during dissection for a few reasons. First, dissection usually needs to proceed only a few millimeters below this suture level onto the nasal bones for adequate release. Second, the paired procerus muscles can be identified here and transection performed if required. Third, depending on the level of horizontal transection in this area, the nasofrontal angle point of takeoff can be altered slightly if desired. Last, nasal tip rotation can be achieved if wanted, especially with significant dissection below the nasofrontal suture line.

Another general bony landmark is the orbital rim, which limits inferior dissection but must be well visualized and free of periosteal attachments to lift the brow and brow fat pads for long-term results. Important muscle and fascial attachments are also located at the level of the orbital rim medially and laterally. The tenacious temporal fusion line (zone of fixation) that exists along the temporal ridge must be identified during dissection.^{26,27} It is also important to know its location preoperatively so that proper incision placement can be made to facilitate a clean dissection endoscopically (Figure 67-8).

Bony thickness varies in different areas of the skull. In addition, venous lakes present on the inside surface of the skull tend to be more centralized around the sagittal suture line. If bone tunnels or screws are planned for fixation purposes, the midline should be avoided, if possible, because of the sagittal sinus as well as higher-density venous lakes in this area (Figure 67-9). Thickness does increase

posteriorly near the occiput, but screw or bone tunnel fixation here is more challenging and is not required. Caution must be taken also to avoid lateral placement because of thinness of the lateral skull and the middle meningeal arteries. Knowledge of average thickness for a given location and internal anatomy indicates that the safest location for bone tunnels or screws is located along a parasagittal line approximately at the midpupil or lateral limbus line and just anterior to the coronal suture (see Figure 67-9).

Muscle and Fascial Anatomy

Paired muscles of the forehead and brow region are often thought of as elevators and depressors. Although several depressor muscles can pull the brow down or obliquely, the only true elevator of the forehead, the frontalis, moves upward to raise the brow. This movement, along with some static tone, maintains brow position but also can lead to horizontal creases over time. The frontalis originates from the deep galeal plane (galea aponeurotica that

FIGURE 67-4 A, Preoperative view of patient with classic lateral hooding brow ptosis and only "pseudo" upper eyelid laxity or ptosis. B, One week following endoscopic forehead and brow lift only. (Slight overcorrection is noted in this early period.) C, Correction of lateral hooding with isolated brow lift after 1 month.

FIGURE 67-5 A, Example of ideal facial proportions based on vertical facial thirds and horizontal proportions approximately the width of the eye or one-fifth of the facial width. B, Preoperative. C, Six weeks following endoscopic forehead and brow lift along with laser skin resurfacing.

connects to the occipitalis posteriorly). It inserts into the orbital portion of the orbicularis oculi, which inserts into the dermis immediately below the eyebrow. Its lateral extension fuses into the dense collection of fascia almost 1 cm wide, called the zone of adherence, which extends along the superior temporal line and ends inferiorly just above the zygomaticofrontal suture.

The fascial attachments, known as the orbital ligament (see Figure 67-7), are the inferior termination point of the zone of adherence near the orbital rim where connective tissue fibers of the temporoparietal fascia are fixated to the bone at the superolateral orbital rim (Figure 67-10). Lateral and posterior along a near horizontal line from the orbital ligament is the orbicularis-temporal ligament, which is the transverse fusion zone of fibers from the lateral orbicularis, the temporoparietal fascia, and the tempo-

ralis fascia. These are important clinical anatomic areas because freeing the zones of adherence is necessary to achieve long-term results with lift procedures. However, care is required in this region to avoid overzealous stretching and injury to the facial nerve.

The acronym *SCALP* applies for the standard layers in the forehead: skin, subcutaneous tissue, *a*poneurosis (the thick galeal fascia), loose areolar (subgaleal) plane, and *p*eriosteum²⁸⁻³⁰; however, the galeal fascia fuses into the frontalis muscle and its midline fascial attachments at this level. This allows a sliding movement over the scalp with contraction of the muscle. The frontalis and galea together can also be thought of as an extension of the temporoparietal fascia in the temporal region as well as the superficial musculoaponeurotic system (SMAS) below the level of the zygomatic arch.³¹⁻³³ The temporoparietal fascia appears somewhat loose or spongy clinically and houses the temporal nerve within its undersurface.

Many other paired forehead and brow muscles thought of as depressors are present along the brow to facilitate facial expression.³⁴⁻⁴¹ The two most well known are the procerus and the corrugator supercillii, which are present in the glabella (Figure 67-11). The procerus muscles are paired superiorly but fuse inferiorly into one muscle belly that originates from the nasal bones and cartilage. Superiorly procerus fibers insert into medial frontalis and the overlying dermis. The procerus is responsible for depression and frowning in the midline, which often creates a horizontal crease (“bunny lines”) across

FIGURE 67-6 A, Female brow shown with a nicely accentuated arch in the lateral third well above the orbital rim. B, The average male brow position is level with the orbital rim with a symmetric arch form.

FIGURE 67-7 Periosteal elevator shown at a more aggressive level of dissection to elevate the lateral canthus slightly, if desired. Fascial and muscle attachments are labeled. Elevation at this level detaches only the superficial layer of the lateral canthal tendon. (The deep portion of the lateral canthus is 5 mm within the orbital rim attached to Whitnall's tubercle.)

the upper portion of the nose. The corrugator supercilii are depressors that act obliquely across the glabella and produce the classic vertical lines seen when squinting (Figure 67-12). The corrugator originates from the frontal bone just above the nasal bones and inserts in the dermis of the medial brow. The corrugator has two heads, the oblique and the transverse, which act to pull the medial brow in respective locations. Together the paired procerus muscles and corrugator are the main depressors of the medial brow and are the most common muscles treated with botulinum toxin type A to help alleviate frown lines in the glabella. These same two muscles are also most often transected during a brow or forehead lift to achieve a smoother and longer-lasting result (Figure 67-13).

Another depressor muscle of importance is the depressor supercilii, which originates on the frontal process of the

maxilla just below the corrugator supercilii and inserts in the medial frontalis fibers and dermis just above the medial brow. Because it lies superficial to the corrugator, it can be easily paralyzed inadvertently by botulinum toxin. It is also

important to note because it lies behind the corrugator and can be transected by aggressive dissection through the corrugator during a brow lift. Although patients with a very low medial brow position may occasionally benefit from this

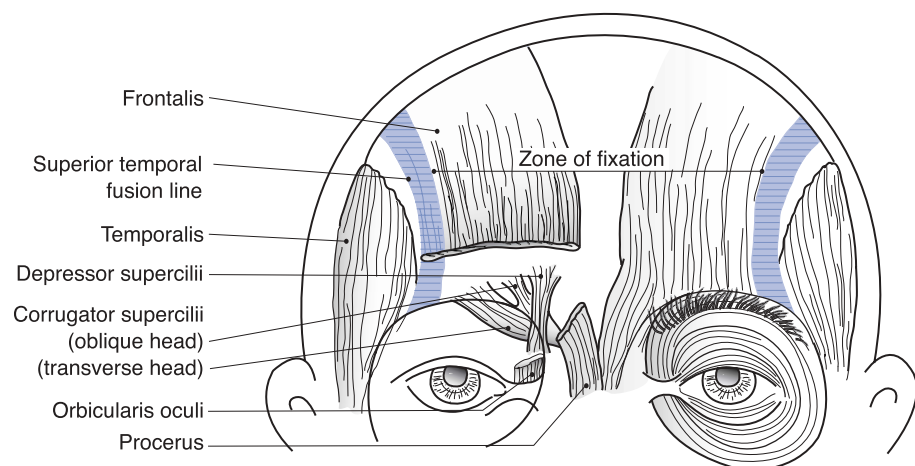

FIGURE 67-8 Cutaway portions of the frontalis muscles, procerus, and orbicularis oculi on one side demonstrate the relationship to the deeper depressors of the brow (corrugator supercilii and depressor supercilii). The zone of fixation (in blue) runs medial to the superior temporal fusion line.

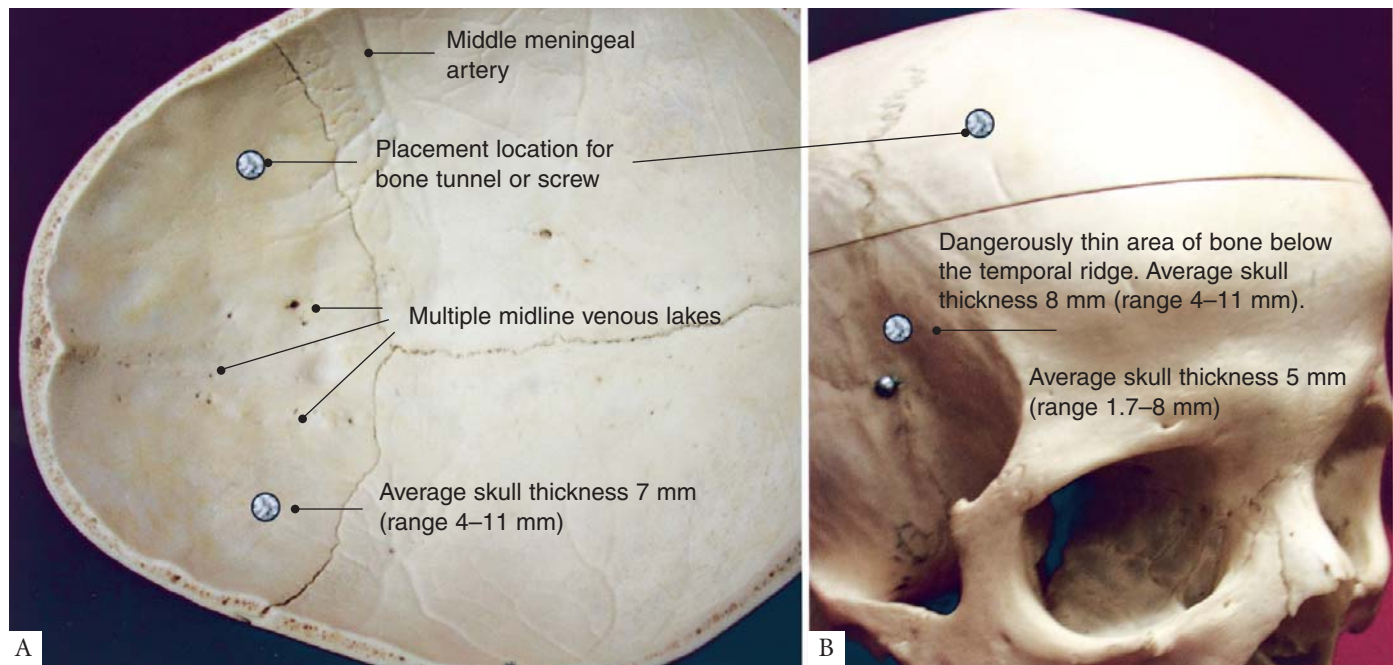

FIGURE 67-9 A, Inside view of the calvarium of the skull demonstrating the high density of venous lakes near the midline and associated structures. B, Illustration of the ideal location placement for bone screws or tunnels based on ideal vector of lift and anatomic limitations.

maneuver, it often gives rise to over-elevation of the medial brow following surgery, which causes the patient to look somewhat surprised (Figure 67-14). Superficial to the depressor supercillii is the orbital portion of the orbicularis oculi that inserts into portions of the adjacent depressors, the superficial sur-

face of the inferior frontalis, as well as the dermis below the brow.^{42,43} The orbital portion of the orbicularis muscle originates in part from the medial canthal tendon and adjacent bone. Deep to all the depressors is the galeal fat pad, which lies immediately below the transverse head of the corrugator and helps in identification

of muscular landmarks.⁴⁴ The galeal fat is usually exposed clinically instantly after transection through the periosteum along the orbital rim (Figure 67-15).

Finally, paired temporalis muscles are located in each temporal fossa, where they originate and then insert on the coronoid process of the mandible. The importance of these muscles during upper facial rejuvenation chiefly pertains to their overlying fascia, which can be used to delineate surgical planes and aid in fixation. The spongy temporoparietal fascia is superficial to the dense and shiny white temporalis fascia. The temporalis fascia adheres to the temporalis muscles below and splits into a superficial and deep layer in the lower half of the fossa. For consistency, the superficial layer of deep temporalis fascia (which really describes only that portion of deep temporalis fascia at the level of the split and below) is subsequently referred to simply as temporalis fascia. In essence, this term will be used to describe any of this deep thick fascial layer that is seen clinically from the temporal crest down to the zygomatic arch (Figure 67-16).

FIGURE 67-10 Layers of fascia are seen on each side of the zone of fixation (in blue). The layers must be elevated and connected to a uniform sliding plane surgically to achieve pleasing and long-lasting brow lift results, while not damaging the associated motor and sensory nerves.

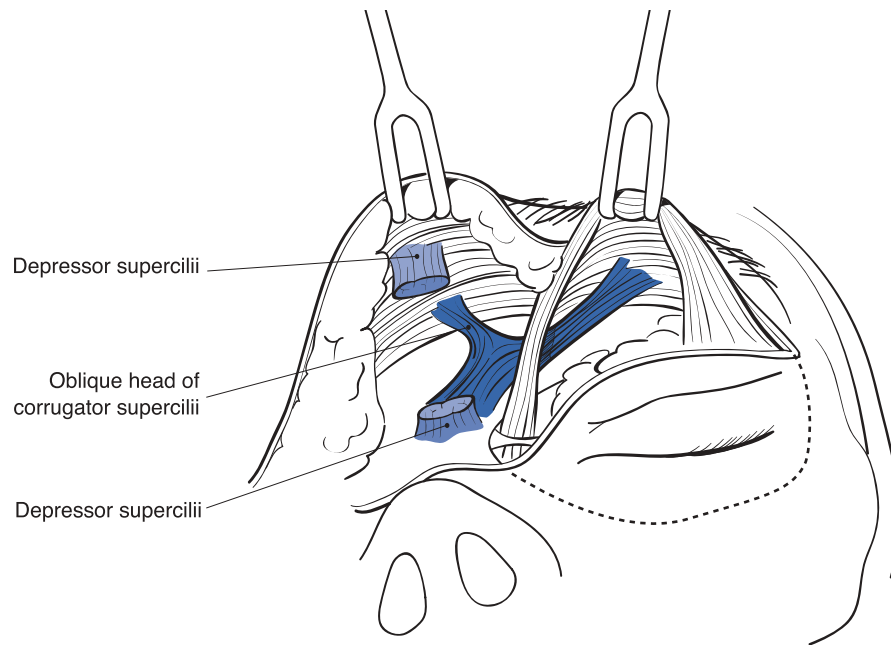

FIGURE 67-11 The oblique and transverse heads of the corrugator supercilii are seen behind the stump of the depressor supercilii. Both heads of the corrugator muscles and the orbicularis oculi insert into the dermis below the brow.

One method of fixation during brow lifting is the use of suture to fixate the temporoparietal fascia from below a skin incision to the dense and adherent temporalis fascia above the incision to elevate the lateral brow. Some surgeons advocate removing a window of temporalis fascia and exposing the underlying temporalis muscle in hopes of creating

scarification in this region and improving fixation longevity.¹²

Vessel and Nerve Anatomy

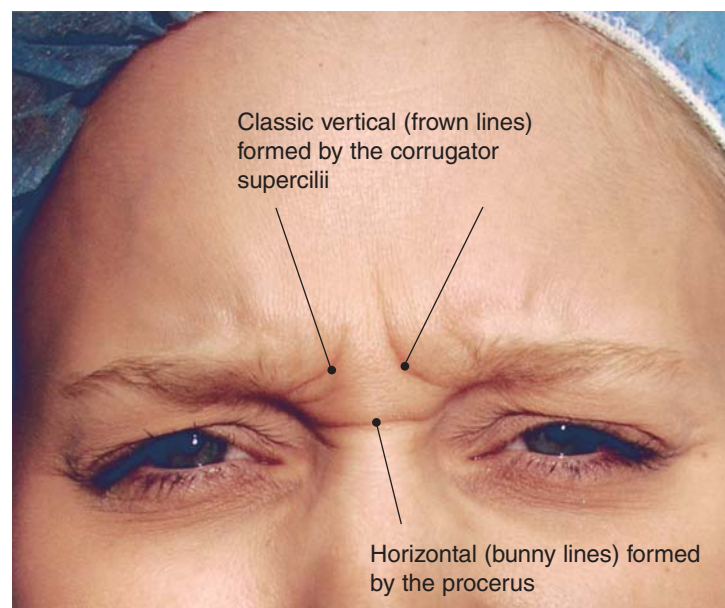

Blood supply to the upper face and scalp is plentiful and comes from multiple sources. Several major vessels of the upper face originate from the external carotid artery including the superficial temporal

artery and the facial artery. These give rise to the blood supply in the medial canthal region via the angular artery and in the lateral canthal region by way of the frontal or anterior branch of the superficial temporal artery. The internal carotid artery gives way to the middle meningeal artery and the ophthalmic artery. The ophthalmic artery then gives rise to the supraorbital and supratrochlear arteries, which exit their respective foramina and supply the majority of the forehead and midscalp with blood. The terminal arterial branches of the upper face have major anastomoses with adjacent vessels.

Venous drainage of the upper face follows the respective arterial supply but can be somewhat more variable. However, one particular vein, known as the sentinel vein (medial zygomaticotemporal vein), runs perpendicular through the temporalis fascia connecting the superficial and middle temporal veins (Figure 67-17).⁴⁵ The sentinel vein can most often be found approximately 1 cm lateral or posterior to the zygomaticofrontal suture line. It is clinically significant during endoscopic procedures because, if injured, it can result in impaired field visualization and significant bruising.

Nerve supply parallels arterial supply to some degree. The supratrochlear and supraorbital nerves, which are responsible for the majority of sensation in the forehead, exit via the same foramina or general location as do the supraorbital and supratrochlear blood vessels. The sensory nerves originate from the first division of the trigeminal nerve. The supraorbital nerve has two divisions after exiting its foramen: the deep (or lateral) division supplies the more lateral and posterior portion of the forehead and scalp, and the superficial (or medial) division pierces the frontalis and runs superficially to the muscle, supplying sensation to the forehead along the midpupil line (Figure 67-18). The location of the supraorbital nerve's exit is relatively consistent. The supraor-

FIGURE 67-12 Frown lines of the glabella are produced by the actions of the corrugator supercilii to produce the classic vertical wrinkles, whereas the actions of the more vertically arranged fibers of the procerus muscle produce the horizontal wrinkles seen across the bridge of the nose.

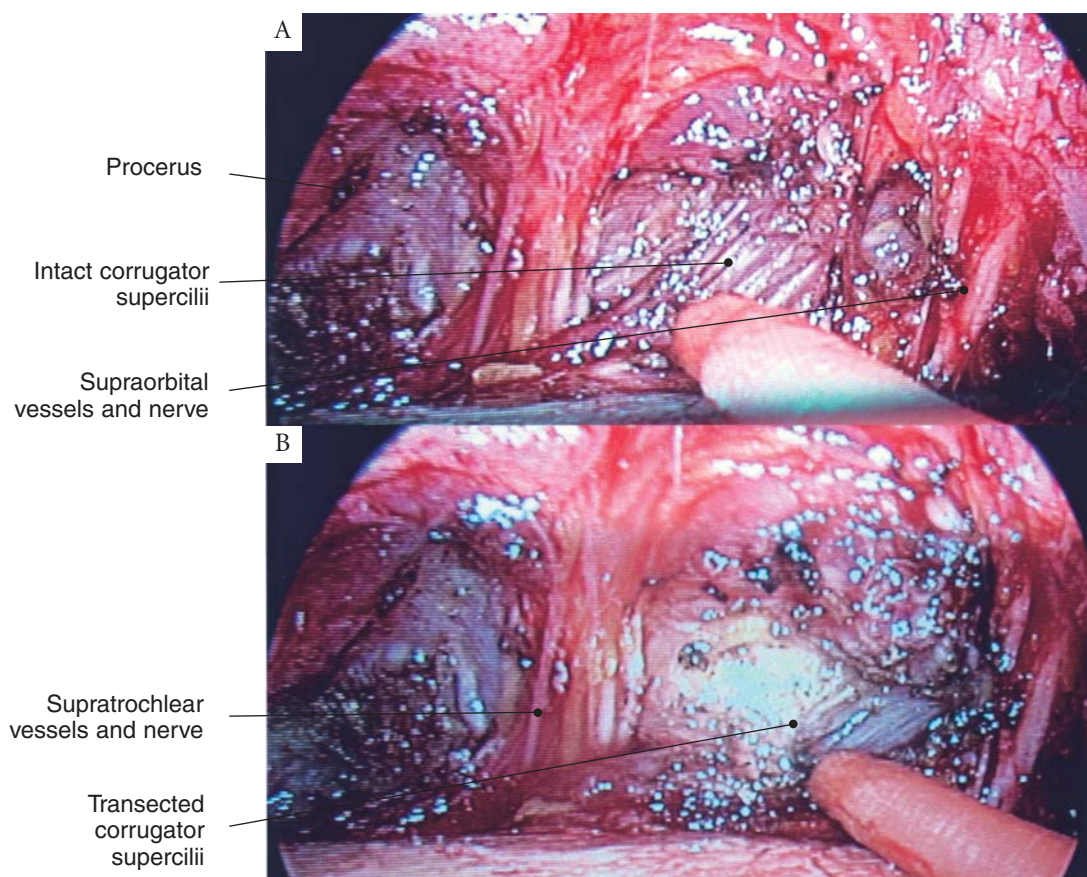

FIGURE 67-13 Endoscopic views of the right side of the forehead. Location of the corrugator supercilii relative to the supraorbital nerve (A) immediately before it is transected with a needle-tip cautery (B). Following transection through the belly of the corrugator supercilii.

FIGURE 67-14 Before (A) and after (B) photos following endoscopic forehead and brow lifting demonstrating good elevation of the lateral hooding but over-resection of the medial depressors in the area indicated (arrow). This can result in a surprised look, especially when the patient elevates the brow, as shown.

bital foramen or notch is typically found within 1 mm of a line drawn in a sagittal plane tangential to the medial limbus (Figure 67-19).⁴⁶ The deep division has been known to exit as often as 10% from another foramen that can be as high as 1.5 cm above the orbital rim.

The supratrochlear nerves exit from around the orbital rim at an average of 9 mm medial to the exit of the supraorbital nerve.⁴⁶ The nerves supply sensation to the midforehead with some overlap from the supraorbital nerves. Infratrochlear nerves, also from division one of the trigeminal nerve, exit just below the supratrochlear nerves around the medial orbital rim to supply sensation to the upper nose and medial orbit. Zygomaticofrontal and zygomaticotemporal nerves are from the second division of the trigeminal nerve. They exit their respective small foramina and supply sensation to the lateral orbit and temporal regions of the face.

The facial nerve supplies motor innervation to the forehead and glabella.⁴⁷⁻⁵¹ The frontal (or temporal) branch of the facial nerve supplies the frontalis muscle, the superior portion of the orbicularis oculi, the superior portion of the procerus, and the transverse head of the corrugator supercilii. The zygomatic branch of the facial nerve supplies the medial head of the orbicularis oculi, the oblique head of the corrugator supercilii, the inferior portion of the procerus, and the depressor supercilii (Figure 67-20).

The auriculotemporal nerve, from the third division of the trigeminal nerve, supplies sensation in front of the ear to the temporal skin above the zygomatic arch and along the course of the superficial artery. It may be confused clinically during a face-lift with the frontal branch of the facial nerve. It can, however, be distinguished from the facial motor nerve because it runs within 1 cm anterior to the tragus of the ear and parallel to the superficial temporal artery. The much more significant frontal branch of the facial nerve

B

runs an average of 2 cm anterior to the tragus when crossing the zygomatic arch. The temporal branch of the facial nerve crosses the arch at an oblique angle at an average of 2 cm posterior to the orbital rim. The depth of the temporal nerve is just below the SMAS at the arch and below the temporoparietal fascia immediately above the arch. The frontal (temporal) branch usually has divided into two rami at the level of the arch and has at least four branches by the time it reaches the level of the eyebrow.

Endoscopic Anatomy

Initial dissection must be performed to gain adequate space for the endoscopic equipment. This early dissection is performed in the posterior forehead and temporal regions; endoscopy-guided dissection is used for the last 2 cm above the orbital rim and zygomatic arch. Elevation of the deep tissues in this "safe zone" is essentially performed blindly through each of the small scalp incisions. Incisions and specific tissue release and fixation

techniques are highly variable among surgeons.⁵²⁻⁵⁹ I prefer to dissect within a completely subperiosteal plane medially to the temporal crest and in the plane immediately above the temporalis fascia below the temporal line on each side. Subperiosteal dissection in the lateral forehead helps to avoid injury to the deep or lateral division of the supraorbital nerve, which runs in the subgaleal plane near the zone of fixation. Some surgeons begin their dissection in a subgaleal plane in the posterior scalp.^{59,60} Regardless, a space is created in the safer posterior areas of the scalp to allow room for placement of an endoscope, which aids dissection in the more risky areas of the forehead.

The first anatomic landmark the surgeon must consider is the zone of fixation along the superior temporal crest. Its inferior edge is found near the superior lateral orbital rim. A convergence of fibers from the periosteum, galea, temporalis, and temporoparietal fascia interlace and fuse to form the zone of adherence, much in the same way the layers of tissue planes come together at the level of the zygomatic arch. The zone of fixation can be elevated bluntly at the hairline level and a couple of centimeters below, but as the surgeon approaches the lateral brow beginning approximately 2 cm above brow level, use of an endoscope aids dissection. At this point the ligament has branches of the temporal nerve within it, and care must be taken to remain against the bone and temporalis fascia below to avoid nerve injury. Another fibrous attachment, the orbicularis-temporal ligament, is also present here and contains motor nerve fibers (see Figure 67-17); it is the decussation of fibers from the temporoparietal fascia and of the temporal fascia that extends laterally from the orbital ligament. The zone of adherence becomes even more tenacious as the orbital ligament (see Figure 67-7) at the orbital rim level is approached. Slow meticulous dissection is required at this point to avoid nerve injury as well as injury to the sentinel

FIGURE 67-16 A and B, Endoscopic dissection must connect the tissue planes on each side of the temporal crest. Various approaches may be used as long as the anatomic planes seen above are sufficiently understood to allow proper tissue release, a clean endoscopic view, and protection of the facial nerve.

vein that is located within the orbicularis-temporal ligament approximately 1 cm laterally to the zygomaticofrontal suture. Careful dissection exposes an intact sentinel vein that can be seen piercing through the temporal fascia at a perpendicular angle and entering the temporoparietal fascia above (see Figure 67-17).

Dissection above the orbital rims in the subperiosteal plane should expose the entire superior orbital rim from each zygomaticofrontal suture. The curvature of the rims should be visualized so that transection through the periosteum can be made at the level of the rims. The nasofrontal suture may not always be seen but can be felt by the periosteal elevator used to lift tissue. When transecting through the

periosteum across the entire orbital rim, subgaleal fat is often encountered initially, except when the transection is directly

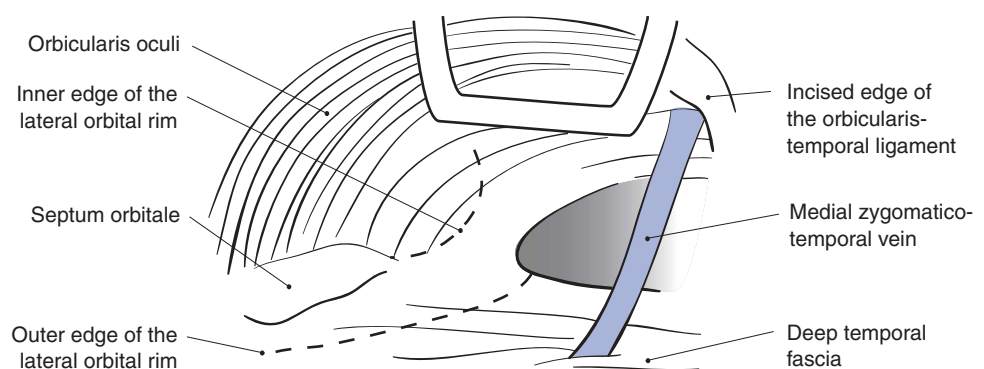

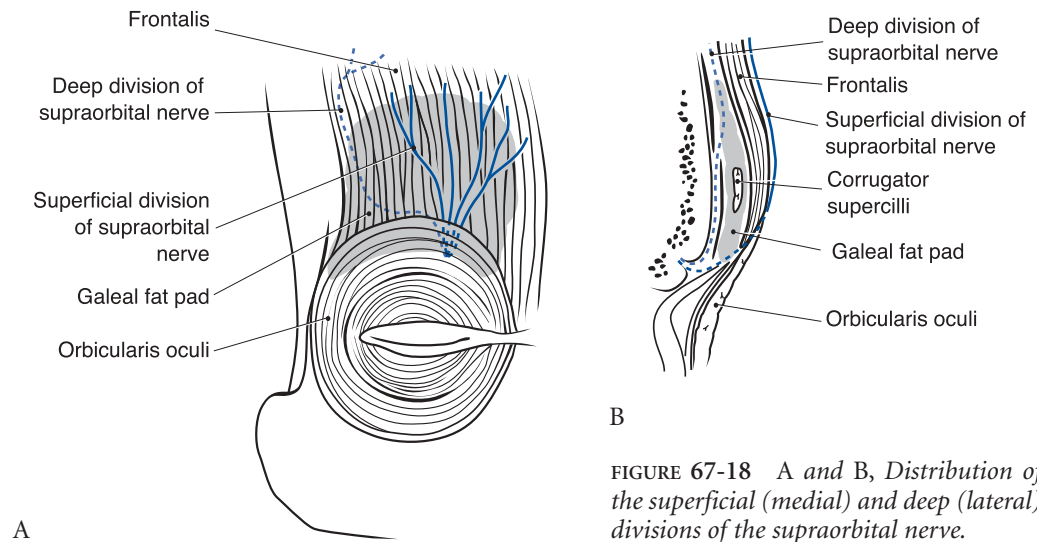

FIGURE 67-17 Dissection below the patient's right temporal crest is shown with release of the orbicularis-temporal ligament. The medial zygomaticotemporal (sentinel) vein seen here pierces the temporalis fascia approximately 1 cm posterior to the zygomaticofrontal suture line.

behind the supraorbital nerve at the rim level where the deep (or lateral) division of the nerve is closely adherent to periosteum (see Figure 67-15). Preoperatively marking a point on the brow at a level tangential to the medial limbus iris helps the surgeon to easily identify the location of the supraorbital vessels and nerves.⁴⁶ Dissection through the periosteum in this region should be performed slowly and superficially to avoid injury to these structures. The transverse head of the corrugator supercilii is seen at the orbital rim level behind the supraorbital vessels and nerves. The corrugator supercilii can be carefully transected or partially excised.⁶¹ Medially, the oblique head of the corrugator is encountered, and by a transection through this portion of muscle, the supratrochlear nerve and depressor supercilii muscle may be seen and protected from injury. Medially, in the glabella, the procerus muscle, which is variable in thickness, is seen. Care should be taken to avoid overaggressive muscle resection in thin patients as this can result in an atrophic defect in the glabella. Deeper dissection toward the skin level under the brow will lead to the orbicularis oculi but is typically not necessary to gain the desired effect (except with regard to the lateral orbicularis, where limited transection may improve lateral brow elevation).^{62,63} Also, one or more incisions through the periosteum at higher levels

under the frontalis muscle in the midline can be performed but is only required if deep horizontal lines are present.⁶⁴ It is more important to gain complete release of the retaining lateral ligaments, transection of those muscles causing glabellar lines, and adequate separation of the periosteum along the orbital rim to get the elevation of brow and forehead tissues for the most pleasing and long-term esthetic result.⁶⁵⁻⁷⁵

Preoperative Evaluation and Surgical Preparation

Determining whether a patient will benefit from a brow or forehead lift and which procedure will work best is critical to avoid disappointing the patient. Commonly the novice surgeon notices only horizontal forehead lines as an indication for a brow lift. Unfortunately, this is much less of a problem for most patients than is a low lateral brow position (hooding) or glabellar crease (see Figure 67-3). As discussed above, the ideal female brow position is above the orbital rim at a level that varies among individuals. An average distance of 5 to 10 mm of brow elevation above the rim in the lateral third generally looks most pleasing. Men require a straight-up elevation of the entire brow to avoid feminizing their appearance by overelevation of the lateral brow. In addition, men may benefit more from a standard upper blepharoplasty and local transpalpebral brow lift if the brow ptosis is minimal. As with any cosmetic surgery, a decision regarding the risks and benefits must be made and must conform to the patient's desires. Patient education is required so that they know the risks as well as what can *realistically* be achieved (Figure 67-21). Even with fairly aggressive muscle resection and forehead elevation, patients often form new dynamic lines in the upper face following surgery. Lateral crow's-feet owing to the action of the orbicularis oculi when smiling may appear improved following a brow lift since the muscle is unfolded. However,

B

FIGURE 67-18 A and B, Distribution of the superficial (medial) and deep (lateral) divisions of the supraorbital nerve.

they are not completely eliminated by brow lifting alone, and the patient must understand that botulinum toxin therapy may be required to treat these particular lines on an ongoing basis.⁷⁶

In addition to lines on the forehead, lines in the glabella, brow ptosis, and the condition of the patient's skin must also be evaluated. Intrinsic skin and collagen damage from the effects of sun, age, and smoking

FIGURE 67-19 A, Preoperative photograph demonstrating the location of the supraorbital vessels by a line drawn vertically from the medial iris. B, One and a half years following an endoscopic forehead and brow lift. No blepharoplasty was ever performed.

FIGURE 67-20 Motor nerve supply to the forehead depressor muscle comes from both the temporal and zygomatic branches of the facial nerve.

FIGURE 67-21 A, Because of both brow ptosis and upper eyelid laxity, the patient shown required upper blepharoplasties as well as endoscopic forehead and brow lifting to achieve the results she desired. B, The patient is shown before and after only blepharoplasty and full-face laser skin resurfacing. She has multiple problems including asymmetry of the brows owing to a blepharospasm on the left side, eyelid asymmetry and severe laxity, pseudoelevation of the brows owing to frontalis compensation for severe eyelid ptosis, and severe actinic skin damage. She is not a good candidate for simultaneous brow lifting since a change in brow position will likely occur following the removal of the eyelid ptosis. She is a good candidate for botulinum toxin therapy on her left side.

are not treated by lifting alone. Topical skin care (eg, retinoic acid, microdermabrasion, pulsed-light therapy, sunblocks) along with possible surgical resurfacing must be considered.⁷⁷⁻⁷⁹ In general the forehead can be treated safely with chemical peels or laser skin resurfacing into the dermal level simultaneously with brow-lifting procedures, provided the lifting is performed with a subgaleal or subperiosteal technique rather than a subcutaneous one. Finally, bony irregularities or hypertrophic bony orbital rims can be evaluated for treatment by means of a cephalometric radiograph or computed tomography (CT) scan as required. Bony contouring can be performed on a limited basis endoscopically, but a major reduction for significant bone hypertrophy such as a frontal boss is best treated with an open (coronal) approach. The amount of bone reduction is limited by the pneumatization of the frontal sinus, which is best evaluated by CT. Although treatment planning for placement of bone tunnels does not require a preoperative CT, a standard cephalometric radiograph may help to reassure the surgeon regarding the thickness of corticocancellous bone available.

As with any surgical procedure, appropriate preoperative laboratory and other indicated tests must be performed. Written instruction are given to the patient regarding pre- and postoperative care, including instructions for shampooing hair with antibacterial soap or other antiseptic shampoo and avoidance of the use of hair spray or other hair products immediately prior to surgery. The patient should be thoroughly instructed on the critical need to avoid all medications that may cause platelet dysfunction 10 days prior to surgery (including aspirin and other non-steroidal anti-inflammatory drugs, vitamin E, and many over-the-counter herbal supplements). Endoscopic techniques require a very dry operating field that necessitates strict avoidance of these medications as well as proper preoperative injection of vasoconstrictive agents.

Prior to anesthesia, photos are taken and the patient is marked while awake and sitting up. Following the introduction of general anesthesia or intravenous sedation, the patient is prepped and carefully injected with local anesthetic with epinephrine. I prefer to use a local anesthetic with 1:100,000 epinephrine along the entire orbital rim, and a tumescent anesthesia solution (250 cc of normal saline mixed with 1 cc of 1:1,000 epinephrine and 20 cc of 2% lidocaine) in the remaining upper forehead, temple, and posterior scalp. Careful injection in the desired tissue planes helps to avoid the formation of a hematoma during the injection and allows for a nearly bloodless procedure. Minor shaving of hair along the marked incision lines is performed if desired immediately prior to the final preparation and draping of the area.

Coronal Forehead and Brow Lift

Still one of the most common approaches for forehead and brow lifting, the classic coronal lift involves an incision across the entire forehead from ear to ear, staying well behind the hairline.⁸⁰⁻⁸⁸ Dissection is typically in the subgaleal or subperiosteal plane and then connects to the subtemporoparietal plane laterally. This gives great exposure of the entire orbital rims for bony osteoplasty, if required, and treatment of muscles that require resection including the depressors (corrugator and procerus) as well as the frontalis. Heavy horizontal forehead creases can be addressed with this technique either by way of midline myotomies or minor midline thinning of the frontalis. Major resection of the frontalis should be avoided to prevent postoperative irregularities and strange facial expressions during frontalis movement. The lateral frontalis should be avoided to prevent nerve damage, ptosis, and other irregularities.

Regrettably, the coronal lift also has the disadvantages of a long incision and a significant elevation of the hairline.

Patients with a high hairline are not good candidates for this technique since a significant amount of scalp excision is required. Many surgeons believe this scalp excision is a reasonable trade-off because they feel that the technique gives a more lasting approach than do newer endoscopic techniques. If performed correctly, the endoscopic technique can be as long lasting and possibly more precise than open brow-lifting techniques. Care must be taken with the coronal lift to avoid elevating the medial brow too much and creating a very high hairline. Roughly, to gain 1 cm of brow elevation, 1.5 to 2 cm of scalp must be excised with this technique. The amount of tissue excised is not a precise determinant of the amount of brow elevation obtained. Scoring of the underlying fascia and muscle resection can cause the tissue to stretch oddly, making prediction of the exact brow elevation difficult.

The benefits of the coronal lift include great exposure and relatively easy dissection. It can also be used to extend the procedure into a deep-plane face-lift by dissection over the zygomatic arches and onto the zygoma and masseter. This much more aggressive lift gives excellent elevation of the midface but greatly increases postoperative edema and the potential for motor nerve damage. The extended technique should only be attempted by an experienced surgeon,⁸⁹⁻⁹³ and careful consideration should be given to alternative treatments. Comparatively, the basic coronal lift is an easier procedure for the novice surgeon. When selecting this tried-and-true method, one should take into account the disadvantages, including the lengthy scar and possible hair loss, significant scalp anesthesia, and a significantly elevated hairline.

Trichophytic or Pretrichial Forehead and Brow Lift

Although trichophytic and pretrichial lifts are sometimes thought to be the same procedure, the *pretrichial* lift actually involves

an incision in front of the hairline. With this procedure, hair does not grow anterior to the incision, leaving a visible scar in front of the hairline. In contrast, in the *trichophytic* lift, although still at the frontal hairline, the incision is placed just behind the hairline. This incision is beveled so that follicles in front of the initial skin incision survive and hair grows anterior to the incision to better camouflage the resulting scar. It should be noted that many surgeons use these terms interchangeably. Even better than the trichophytic lift is the irregular trichophytic hairline, which not only employs a beveled incision but creates a wavy pattern along the hairline for a more natural postoperative appearance compared with a straight-line scar.

Regardless of the specific incision design, the ultimate advantages of the trichophytic forehead and brow lift include great exposure (similar to that with the coronal approach) and the ability to lower a high forehead. Unlike the classic coronal lift, bare forehead skin is excised from the hairline. Also, lateral incisions and dissection are usually limited with this technique unless required. Incision design can even improve hair thinning in the temporoparietal areas by excising the area of hair loss and bringing forward areas of dense hair-bearing scalp. The posterior scalp and hairline can be brought forward to lower a high forehead by almost any amount. The more lowering that is desired, the more posterior is the dissection and release. Limited or no posterior dissection can be performed if the hairline is to remain at the same level.

The forward dissection is the technique that varies the most among surgeons. A totally subperiosteal technique versus a subgaleal technique is an option. A subcutaneous technique has recently become more popular, particularly when the depressors in the lower brow do not require treatment.⁹⁴ Staying superficial to the frontalis breaks the dermal insertions that create deep horizontal rhytids. The subcutaneous lift is occasionally combined

with deep dissection to treat glabellar lines as well as horizontal lines in the forehead.

Overall, the trichophytic technique of forehead and brow lifting is an invaluable tool for any surgeon performing facial cosmetic surgery. When a patient presents with a high forehead and low brow position, the trichophytic approach is the procedure of choice to correct both problems. The main disadvantage is the potential for a visible incision despite best efforts. All prospective patients considering this technique must be informed of the chance that there may be a visible scar at the hairline. Surprisingly, when presented with the potential problems and given the choice, many patients prefer to undergo an endoscopic approach with a slight elevation in hairline rather than risk a visible hairline scar. Still, the patient with an extremely high hairline is often thrilled with the lower hairline obtainable only with the trichophytic approach. Attention to detail and gentle soft tissue management are essential to attaining a natural hairline and hidden scar with this popular technique.

Endoscopic Forehead and Brow Lift

Early attempts at endoscopic surgery began over a century ago with Nietzsche's description of a crude cystoscope. A few decades ago endoscopic surgery progressed through use in upper gastrointestinal

examinations and then intra-abdominal surgery. However, facial endoscopic cosmetic surgery did not blossom until the early 1990s. Over the past decade the endoscopic forehead and brow lift procedure has been considered by many to be the state-of-the-art technique for upper facial rejuvenation.⁹⁵⁻⁹⁷ It is versatile and can be combined with many other procedures. The most noted benefits of the endoscopic technique are the smaller scars hidden in the hairline and selective brow elevation without the need for removal of any hair or skin (Figure 67-22).

The technique involves several incisions placed strategically behind the hairline to gain access for early blunt dissection and insertion of the endoscope and tissue retractor. Other incisions can be used as ports for dissecting tools such as periosteal elevators, electrocautery, lasers, tissue graspers, and suction instruments. Among surgeons a variety of incision (port) designs are used. Fixation points are usually placed at these incision sites; therefore, I prefer five separate 2.5 cm long incisions placed for easy access but mostly for ideal fixation placement. Each of the five incisions begins approximately 1 cm posterior to the hairline. One is placed in the midline in the sagittal plane and two in the parasagittal plane tangential to the lateral third of the brow (where maximum lift is typically desired in females). This same

incision can be moved slightly medially in male patients to give a more even brow elevation. The midline incision plus the two parasagittal incisions are aligned vertically to avoid unnecessary transection of sensory nerves originating from the supra-orbital nerves below. The two parasagittal incisions are placed medial to the temporal crest to gain access to skull bone rather than the more lateral temporalis fascia. Bone is the strongest fixation tissue available and ideally should be used thus.⁹⁸⁻¹⁰⁰

It is important to access the subperiosteal plane easily for a clean future endoscopic view. Accidental placement of the parasagittal incisions too far laterally over the zone of fixation or temporalis muscle makes pocket development difficult and obscures future endoscopic visualization. Moreover, the parasagittal incisions are located in a thick area of the frontal bone where there is a low density of venous lakes. Placing the incision here helps to prevent accidental intracranial injury during bone tunnel creation or placement of bone screws.

Lastly, two temporal incisions are made, one on each side of the head, for direct access to the thick temporal fascia. These incisions are placed perpendicular to the desired elevation vector from the lateral canthal region. Coincidentally, the temporal incision parallels the course of the temporal branch of the facial nerve

FIGURE 67-22 A to F, Sequential appearance following endoscopic forehead and brow lifting (eyelid and skin resurfacing procedures were also performed). Slight overelevation of the brow is noted for 6 days after surgery, as expected. The brow position remains very stable from 2 weeks to 3 years after the surgery.

that is located 2 to 3 cm inferior to this incision. It also parallels the superficial temporal artery and vein. Arranging the three medial incisions on a vertical axis and the two temporal incisions in an oblique position to parallel the nerve and blood supply in each area can reduce interference with sensation and vascular supply to the scalp.

Dissection is performed through the above incisions down through periosteum medial to the temporal crest and down to temporalis fascia lateral to the crest. Some surgeons may elect to use a subgaleal rather than subperiosteal placement of the incision medially. Total subperiosteal dissection medial to the temporal lines rather than subgaleal dissection leads to better fixation and long-term stabilization (see Figure 67-22).

Blunt and blind dissection can be carried out after reaching the subperiosteal and subtemporoparietal planes through the five incisions. Finger dissection and long curved endoscopic periosteal elevators are used to lift the tissue anteriorly to a point 2 cm above the orbital rims and zygomatic arch. Posteriorly blunt dissection should elevate the temporal tissues a few centimeters behind the ear, where the temporal fossa becomes self-limiting. The subperiosteal dissection above needs to elevate the scalp at least 10 cm posteriorly but can extend as far back as the lambdoid suture. Once these areas are freed, a connection can be made from the temporal region to the subperiosteal dissection through the upper portion of the zone of fixation at the temporal crest by finger dissection (Figure 67-23). Blind release of the more inferior portion of the temporal line where the facial nerve crosses should be avoided. Endoscope-guided dissection here helps to prevent nerve injury. Using finger dissection the upper zone of fixation is broken through proceeding from the temporal incision toward the medial scalp, rather than vice versa, to prevent creation of a false tunnel in the spongy or

foamy temporoparietal fascia. False tunnels along the temporal crest create problems when the endoscope is inserted through the parasagittal port to visualize the lateral forehead; the tunnels force the placement of the endoscope in a more superficial plane within the temporoparietal fascia, which greatly increases the chance of nerve injury. Therefore, it is critical to stay firmly against the periosteum and the temporalis fascia when initially elevating the scalp and forehead.

Following blunt elevation of the scalp from each incision for complete flap elevation, the endoscope is normally inserted through one of the three more medial incisions. Poor initial blunt dissection makes the initial endoscopic dissection feel very tight, and care must be taken not to perforate the skin by excessive retraction. Medial dissection over the nasofrontal suture and orbital rims is per-

formed under direct endoscopic vision with a curved and smooth elevator to avoid inadvertent tearing of the periosteum. The periosteum may be thin in some patients, in whom a straighter elevator may be used to transect the periosteum at the level of the rim (arcus marginalis). However, the entire rolled edge of the orbital rim must be visualized before proceeding with periosteal incision (Figure 67-24). Typically the periosteum is more precisely incised with a needle-tip cautery or laser set at low power. The supraorbital nerves and vessels as described earlier are at a level tangential to the medial limbus and are immediately behind (superficial to) the periosteum from the internal endoscopic view.^{46,101} This necessitates meticulous cautery dissection here to avoid injury to these structures (see Figure 67-24). Suction placed by an assistant from another port is required to maintain

FIGURE 67-23 Blind finger dissection is performed initially, avoiding overzealous dissection inferiorly. Dissection proceeds from the subtemporoparietal plane laterally to the already elevated subperiosteal plane medially. The opposite direction of elevation (medial to lateral) may produce false tunnels in the temporoparietal tissue, which impair future endoscopic vision.

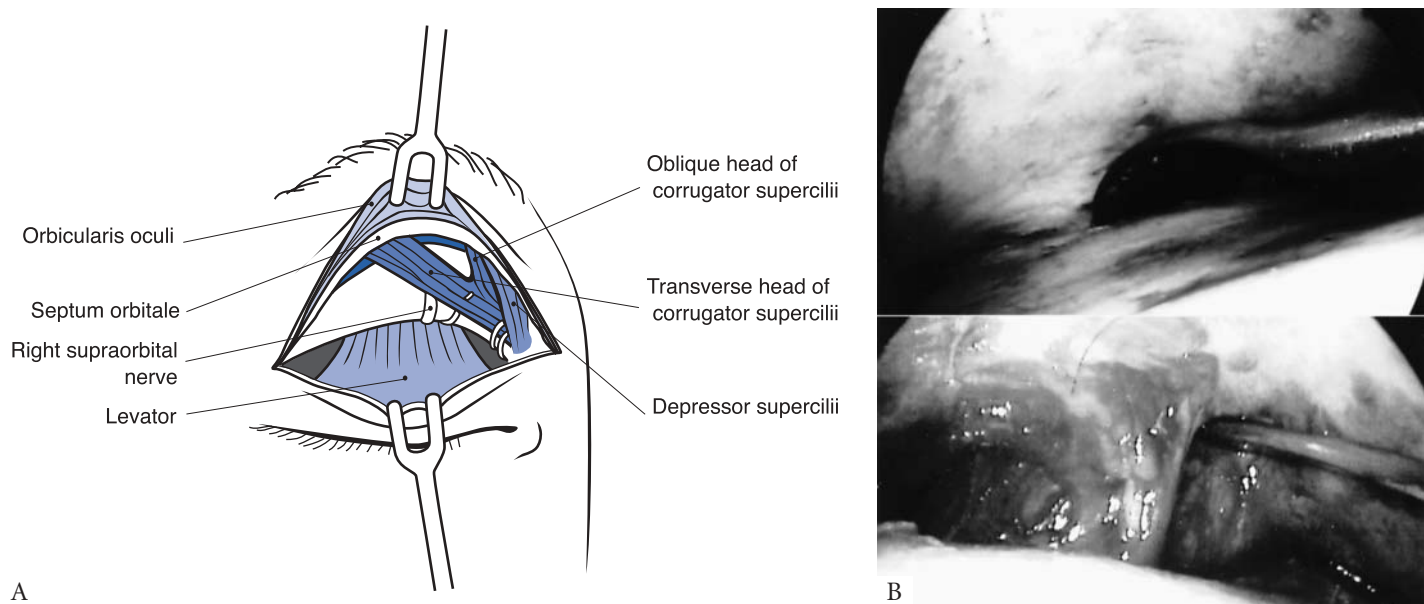

FIGURE 67-24 A, This line drawing demonstrates the orbital rim and local depressor muscle as seen from a transblepharoplasty incision. B, Endoscopic photographs show the rolled border of orbital rim prior to periosteal release in the first view and the supraorbital nerve and vein in the next view after excising through the periosteum.

a clear view when using cautery or laser. Temporal incisions work well for suction ports during dissection over the rims since the endoscope and cautery take up most of the room through any of the middle three incision sites. With clear and near bloodless dissection at this point, transection can be performed through the corrugator supercilii and procerus. If unwanted bleeding is encountered and cannot be controlled easily with pinpoint accurate cautery, then pressure should be applied externally over the rim until improved visualization allows for control of bleeding without nerve damage.

Vertical rhytids in the glabella created by the corrugators can be improved greatly by transection through these muscles. Likewise, horizontal glabellar lines are treated by transection of the procerus muscle that creates these particular facial wrinkles. Some surgeons advocate more aggressive surgical avulsion of these muscles with endoscopic biopsy forceps. Aggressive muscle removal may lead to a more permanent treatment of glabellar lines compared with isolated transection only, but should be avoided in most cases owing to an increased risk of significant postoperative

irregularities and abnormal facial expression. As a rule, patients prefer a more natural appearance with some minor return of frown lines to risking a bizarre facial expression and glabellar depression.

Once the periosteum is completely freed across the orbital rims and appropriate muscles have been treated, the cut periosteal edges are spread apart (periosteal elevators work well for this) by at least 1 cm to aid the release at the arcus marginalis. This allows significant and long-term brow elevation. Next the lateral orbital rim must be exposed in the subperiosteal plane after careful release below the zone of fixation and orbital ligament. Dissection along the anterior and inferior aspects of the temporal crest must be performed cautiously to avoid temporal nerve injury. Overzealous retraction of the dense tissue here that contains the nerve can result in nerve damage. Staying snugly against periosteum and the temporalis fascia helps to prevent nerve damage and produces a much cleaner dissection. Slowly creating a distinct plane of dissection down to the zygomaticofrontal suture line and avoiding excess retraction helps to prevent unwanted bleeding from the sen-

tinel vein (zygomaticotemporal vein), which needs not be sacrificed for a standard endoscopic forehead and brow lift.

Dissection for a standard endoscopic brow lift should not proceed all the way to the zygomatic arch but should stop approximately 1 cm above this level. If an extended midface lift is planned and there is a desire to elevate tissue over the zygomatic arch itself, then dissection must go below the superficial layer of deep temporal fascia just above the arch. Abbreviated midface lifts performed simultaneously with endoscopic brow lifts may simply stay in the subperiosteal plane along the lateral orbital rim and avoid the more risky full-arch release. The beauty of the classic endoscopic brow lift is its versatility and the ease with which additional procedures can be combined simultaneously with this elegant cosmetic surgery. For instance, the temporal incision of an endoscopic forehead lift can easily be extended inferiorly to meet up with the preauricular incision from a standard lower face-lift. Also, midface lifting (with intraoral dissection) can connect the intraoral subperiosteal dissection over the zygoma to the subperiosteal plane from the endoscopic brow lift

through a tunnel near the lateral orbital rim (Figure 67-25).

After all dissection is complete, appropriate elevation and fixation is required (Figure 67-26). Many techniques have been described such as tissue suture only, bone screws and plates, resorbable screws, bone tunnels, local skin excision, temporalis muscle exposure for added scarification, tissue glue, and tight head wraps.¹⁰² Regardless of any specific fixation technique, the key to long-term fixation is adequate lower forehead tissue release during endoscopic dissection. Failure to adequately release internal tissue results in a relapse of brow ptosis, even with heavy fixation and the appearance of a “nice” lift during surgery.

Once complete internal release of the forehead is obtained, the specific lifting vectors must be determined for the most pleasing esthetic effect. The lateral third of the female brow is elevated to the greatest extent, which is up to 1 cm above the orbital rim. The medial brow should be only slightly above the rim level and

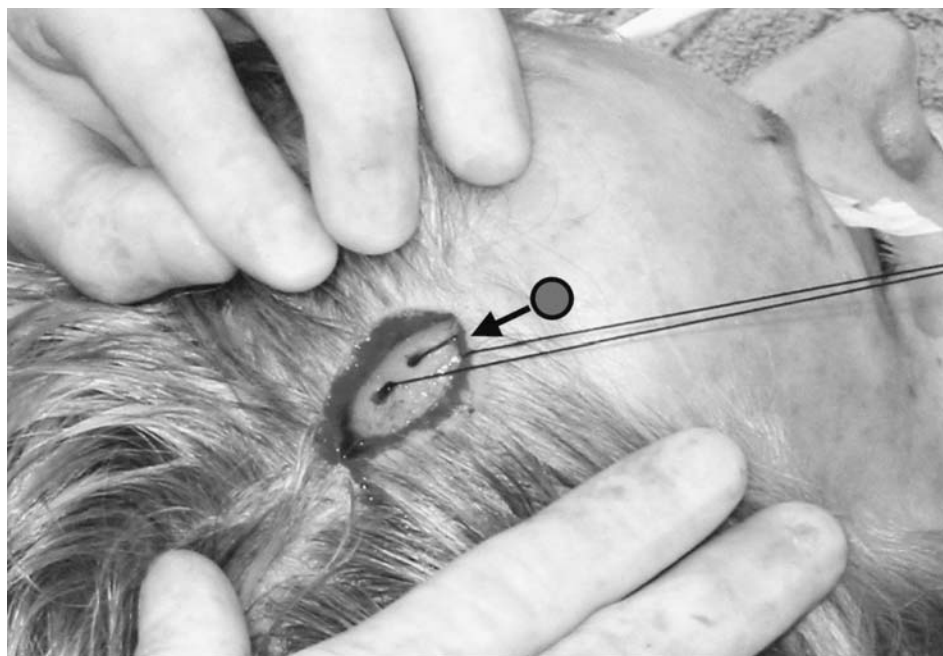

FIGURE 67-26 Example of bone tunnel fixation shown at the site of the right parasagittal incision. The anterior circle represents the position of suture placement through the galea, which elevates the lateral brow toward the bone tunnel.

definitely below the middle and lateral brow levels to avoid a surprised or bewildered expression (see Figure 67-14). Typically the glabellar region is elevated on

its own without the need for midline fixation, which helps to avoid overelevation medially. The lateral third of the brow is lifted straight up and fixated at the level of the hairline. The galeal tissue is typically secured to bone at this point, while the lateral brow is held at the desired height or 1 to 2 mm above the desired level.¹² Very little relapse occurs with proper technique and averages only 1 to 2 mm after 2 weeks. Measurements can also be made with clear circular templates from the pupil to brow to help improve symmetry. The brow position remains very stable following this early recovery period (see Figure 67-22). A question remains as to the time required for complete fixation of the periosteum. Some animal studies suggest a full 12 weeks are required for what is termed *full histologic periosteal refixation*.¹⁰³ However, there is clinical evidence suggesting adequate fixation occurs in as little as 7 days. An example is the common fixation technique used by many surgeons who place a single transcutaneous bone screw at each parasagittal incision, which is removed

FIGURE 67-25 Views before (A) and after (B) an endoscopic forehead, brow, and midface lift. Arrows represent vectors of lift. Fixation is performed at the level of the hairline through the temporal and parasagittal incisions shown.

after only 1 week. The 1-week fixation technique has been used with success for many years. It has been suggested that longer bony fixation may provide longer-term retention and less early relapse that some have considered normal. The key to long-term fixation seems for now to be determined usually by proper tissue dissection and release.

Although there are many fixation techniques, the use of bone tunnels at the parasagittal incisions appears to be one of the best methods for fixing the galea and periosteum near the hairline to a bone tunnel created posteriorly under the incision using a single heavy suture (see Figure 67-26). Fixation of the lateral tail of the brow is performed at each temporal incision, where an isolated heavy suture pliates the temporoparietal fascia in a posterior and superior vector to the thick temporalis fascia. Optional creation of a small window of exposed temporalis muscle in this area may aid in internal scar formation and fixation. The vector of lift at this outer tail of the brow follows a line drawn at an angle from the outer nasal ala that passes just beside the lateral canthus (see Figure 67-25).

Final closure of the hair-bearing scalp incisions can be performed with skin staples only with excellent scar formation since no skin is excised and no pressure exists at the incision sites. Redundant tissue (forehead skin) created by an average of 1 cm of brow elevation is easily distributed evenly over the posterior 15 to 20 cm of elevated scalp, which essentially absorbs or redistributes this excess tissue with few to no signs of bunching. Because of this phenomenon, the endoscopic forehead and brow lift tends to elevate the hairline only a very small amount compared with the open skin excising coronal technique.

Interestingly, in a survey performed in 1998 of American Society of Plastic Surgeons members, of the total 6,951 brow lifts performed by 570 members who

returned the questionnaire, 3,534 involved a coronal technique and incision and 3,417 were performed endoscopically. The most noted difference was the higher risk of hair loss with the coronal technique; however, both techniques enjoyed very low overall complication rates.

Direct Brow Lift

The direct brow lift involves excision of an ellipse of skin adjacent to and just above the eyebrow (Figure 67-27). A beveled incision is used to parallel the hair follicles of the brow or so that some follicles remain at the base of the bevel to grow later above the scar. The dissection remains in the subcutaneous plane to avoid muscle or nerve injury.

Advantages of the direct brow lift are that it is a simple procedure (with an easy two-layer closure), it can be performed under local anesthesia, and it can treat brow position asymmetries. It remains a

good alternative technique that may be an excellent option for an elderly patient who has severe brow ptosis and heavy wrinkles but cannot tolerate more extensive surgery and would benefit from a short procedure under local anesthesia. The main disadvantage is the potentially visible scar immediately above the brow.

Midforehead and Brow Lift

Incisions made in the middle or upper forehead regions have similar advantages and disadvantages to the direct brow lift.¹⁰⁴⁻¹⁰⁷ The incisions are made on each side of the forehead in an elliptic fashion so that the resulting scar follows a horizontal line already present in the forehead. Although this is probably the least used of all the techniques described, it may be a practical alternative for the elderly patient with thin eyebrows and deep horizontal rhytids who requires a short procedure under local anesthesia.

FIGURE 67-27 Representative incisions for typical brow-lifting procedures: (1) direct brow lift, (2) midforehead lift, (3) trichophytic brow lift, (4) coronal brow lift, and (5) endoscopic brow lift.

Transpalpebral and Other Local Brow Procedures

There has been a significant increase in the movement toward minimally invasive techniques to perform cosmetic surgery. New techniques for forehead and brow rejuvenation fill the literature and offer potentially exciting methods to gain esthetic improvement with less risk than with current procedures. A few such procedures include lateral brow lifting with temporal incisions only, denervation techniques through small punctures around the brow, and direct approaches through an upper blepharoplasty incision. It should be noted that although procedures such as making small punctures to destroy medial portions of facial nerve innervating medial depressors may seem minimally invasive, they are certainly not without risk.

Many of the “minimally invasive” procedures take advantage of the proximity of the local depressor muscle. For instance, the transpalpebral or transblepharoplasty approach for forehead rejuvenation gains access to the local depressors through an upper eyelid incision.¹⁰⁸ Dissection through this incision involves a short distance to the corrugator supercilii, the procerus, and depressor supercilii of the glabella, which can each be selectively transected from this incision to reduced unwanted wrinkles and elevate the medial brow (see Figure 67-11). Likewise, the orbicularis can be incised and subperiosteal dissection performed above the orbital rim to elevate the lateral brow through this same local incision. Suture plication of the periosteum above the rim may further elevate the lateral brow.

Another adjunctive technique in the upper third of the face is that of fat grafting in areas of age-related fat atrophy. Fat can essentially be grafted anywhere; however, caution is required in the glabellar region where occasional local necrosis can occur from fat infiltration. This also

occurs occasionally after collagen injections in the same region.¹⁰⁹ There are a great number of alternative techniques, and each must be evaluated for safety, efficacy, and longevity on an individual basis.

Botulinum Toxin–Assisted Brow Lift

Botulinum toxin has been used for nearly two decades to improve the esthetic appearance of the upper third of the face by reducing wrinkles of the forehead (horizontal lines), glabella (frown and bunny lines), and lateral orbital crow’s-feet (laugh lines).¹¹⁰ More recently it has been used specifically to elevate certain regions of the brow to obtain a “chemical brow lift.”¹¹¹ The depressor muscles are paralyzed with botulinum toxin not only to reduce the wrinkles they create but also to allow the frontalis muscle to elevate the brow farther because of the decrease in muscular antagonism. By decreasing the tone and downward pull of the orbicularis immediately below the brow, the lateral third of the eyebrow elevates approximately 2 to 4 mm from the result of botulinum toxin placed in the upper crow’s-feet area. Such treatment of depressor muscles in the glabellar region can help elevate the medial brow. Of course, as with surgical brow lifting, overcorrection in the medial brow may result in an abnormal facial expression.

Dosages used vary with individuals. Botox comes in a 100-unit vial to be mixed with 1 to 10 cc normal saline. The more dilute solutions (6–10 cc/100 units) begin to lose efficacy and can distort the tissue, whereas high concentration mixtures (1–2 cc/100 units) may be wasteful and imprecise. Regardless of dilution, it is the total dosage in units of botulinum toxin and its proper placement that determine the outcome. For most individuals 5 to 10 units is all that is required for each lateral crow’s-foot region. However, the larger muscles of the glabella (procerus and corrugators) require at least 15 units of the toxin and up

to 50 units for maximum results. Appropriate dosage in the glabella is the most variable. Treatment of horizontal forehead lines typically requires between 15 and 25 units. It should be noted that simultaneous treatment of horizontal forehead lines from the frontalis may decrease or eliminate brow elevation that otherwise may have been created by botulinum toxin treatment of the depressor muscles. Moreover, excessive toxin treatment of horizontal lines close to the eyebrows (within 1 cm) should often be avoided owing to the risk of true ptosis of the forehead, brow, and upper eyelids.

Botulinum toxin has also been recommended to aid long-term stability of the surgical forehead and brow lift. The theory involved is that control of the downward pull of the depressors (by temporarily paralyzing them chemically) gives the periosteum time to attach securely in an elevated position. The injection can be done during surgery but there is an increased risk of eyelid ptosis and an unwanted delay since botulinum toxin typically takes 3 to 5 days to take full effect. Therefore, ideally botulinum toxin is injected 1 to 2 weeks prior to surgery. Regardless of any benefit this may give to long-term surgical fixation, the resulting reduction in wrinkles of the forehead and glabella and in crow’s-feet is almost always popular with patients, even though the results last for only 3 to 6 months.

Adjunctive Procedures: Skin Care and Micropigmentation

A variety of procedures can be used for the superficial treatment of poor skin texture and are covered more completely in Chapter 69, “Skin Rejuvenation Procedures.” For complete rejuvenation of the upper third of the face, skin resurfacing techniques may be required to address aging problems, especially those related to sun exposure, that cannot be adequately treated with lifting methods alone.

Prior to any resurfacing procedure such as laser skin resurfacing, chemical

peels, or dermabrasion, the patient should be treated with topical skin medications to decrease the risk of scarring and pigment problems. Retinoic acid–type preparations used for ideally 6 weeks prior to resurfacing and 4% hydroquinone for patients with darker skin tones (Fitzpatrick 3 or higher) are two possibilities (see Chapter 69, “Skin Rejuvenation Procedures”). Simultaneous resurfacing procedures can be accomplished with brow lifting provided the surgical plane of dissection is subperiosteal or subgaleal and not subcutaneous.

Another adjunctive procedure growing in popularity is medical micropigmentation. The use of new skin pigments that do not contain iron oxide has improved the appearance of tattoos placed to enhance a thin eyebrow or as permanently applied eyeliner. The ink is relatively permanent but often requires touch-ups owing to some fading over the first 3 to 5 years. Patients who have poor hand motor skills can greatly benefit from this procedure. A certified technician under a doctor’s supervision usually performs the micropigmentation. However, consultation with a surgeon prior to micropigmentation is important since placement of a permanent brow tattoo in a more elevated position may create problems if the patient desires a surgical brow lift later. Therefore, if a patient is seeking brow lifting in addition to the micropigmentation, it is advisable to perform the surgical brow lift prior to the permanent makeup if feasible.

Postoperative Care

Following surgical forehead and brow lifting, a compression bandage is applied using a material such as Coban or Coflex. The pressure helps to limit edema and hematoma formation while possibly improving fixation. Typically a drain is not required if a very dry field has been maintained. The patient should be instructed to limit activity and to use cold compresses over the eyes and brows. Head elevation is also recommended for the first several

days. Avoidance of antiplatelet drugs preoperatively, a careful surgical technique, and the immediate postoperative use of cold compresses, elevation, and limited strenuous activity significantly decrease postoperative healing time.

The relatively snug postoperative dressing may be removed on postoperative day 1 to visually inspect the surgical site for any problems. A less constrictive Velcro-type head wrap can then be used to allow patient comfort and easy removal for showering. Patients are allowed to gently shampoo their hair after 24 hours but must be cautioned to avoid water pressure directly over any incision sites. Each incision is then cleaned twice a day with a dilute peroxide solution, and a thin layer of antibiotic ointment is applied for the first week. Staples are removed at the end of 1 week. Chemical treatments of hair such as “perms” should be delayed for at least 2 weeks to avoid possible hair loss as a reaction to the harsh chemicals. Hot curling irons or other similar devices must be used with caution since areas of scalp anesthesia may be present for months and can predispose a patient to an accidental self-inflicted burn.

Complications

Fortunately, major complications are rare with properly performed forehead and brow rejuvenation procedures. Good patient selection, diligent preoperative planning, meticulous surgical technique, and thorough postoperative care are all required to help limit the chance for complications.^{112–115} Minor complications can always occur despite a surgeon’s best efforts. No matter how minor the problem, the patient must be treated with concern and compassion. Typically patients who undergo cosmetic surgery are expecting to look better as soon as possible and are not always as tolerant of perioperative problems as are trauma patients. Extensive edema and ecchymoses are not normally considered complications but may war-

rant appropriate reassurance and even simple suggestions to hasten recovery when feasible. Suggestions regarding makeup from a well-trained staff member may greatly improve a postoperative patient’s mood when shown how to better hide persistent erythema or ecchymosis.

True complications include poor scar appearance, wound dehiscence, hematoma, skin sloughs or perforations, asymmetries, sensory disturbances, facial paralysis, eyelid ptosis, corneal abrasions, dry eye syndrome, hair loss (alopecia), infection, relapse, irregular facial expressions, and contour irregularities. Of all these potential problems, permanent facial paralysis and major tissue loss are the most devastating. Fortunately, these particular complications are rare (< 0.3%, which is less than that for a standard lower face-lift). Regardless, it is critical to know the precise anatomy and to avoid improper or excessive retraction, overzealous cautery, and overthinning of the flaps when transecting the depressors. In addition, hematomas must be diagnosed and treated without delay.

Some problems such as corneal abrasions can be very concerning to the patient owing to the severe pain and can be nearly eliminated by proper technique and perioperative attention to detail. For instance, an eye lubricant should always be used. Also, thought should be given to the placement of temporary tape strips, such as Steri-Strips, over the eyelids or a tarsorrhaphy suture to help prevent inadvertent scratching of the cornea by gauze or tubing, for example, during the procedure (see Figure 67-16). All severe pain requires immediate evaluation, and suspected abrasion should be treated by appropriate ophthalmic drops for pain and patching of the affected eye for 12 to 24 hours. Appropriate ophthalmologic consultation is required for persistent or uncontrollable eye pain, persistent dry-eye symptoms, or unusual changes in vision. Minor blurred vision for the first 12 hours is not unusual owing to chemosis and use of ophthalmic ointments.

Alopecia and sensory disturbances can be bothersome to the patient and often are not permanent. The problem is the inability to predict whether the numbness a patient has will partially, fully, or not go away, and just how soon it might be alleviated. With proper technique, an endoscopic forehead and brow lift has a high rate of sensory nerve recovery, but full recovery may take several months and require patient reassurance. Although exact numbers are not known, empiric observation of the last 150 endoscopic brow lifts that I have performed suggests that sensory disturbances are an occasional early concern but an unusual complaint after 6 to 12 months. Alopecia, on the other hand, is a significant concern, especially if it persists longer than 6 to 12 months. Hair may return after an average 4- to 8-month dormancy period of the hair follicle. However, excessive tension on the flaps, rough handling of wound margins, or excessive use of cautery near follicles may lead to permanent hair loss that requires treatment.¹¹⁶

Proper planning, technique, and postoperative care helps to reduce the incidence of complications. Immediate and appropriate treatment along with sincere concern for the patient's well-being should help to reduce the chance of the situation worsening or patient being dissatisfied.

Summary and Conclusions

An explosion in the number of rejuvenation techniques for the upper face in the past decade, led by the use of endoscopes and botulinum toxin, has revolutionized the treatment of aging in this area. Cosmetic surgery treatment of the upper third of the face is frequently an essential component for complete facial rejuvenation. Procedures are highly variable and can offer improvement to both young and old. Matching the problems to the ideal rejuvenation techniques is essential for maximum esthetic benefits. Even the best surgical technique can result in inadequate or even poor results if improper patient

selection or incorrect diagnoses are made; for this reason, the forehead and brow area must be evaluated critically for a wide range of interlacing diagnoses.

Specific skin problems vary with a patient's age and sex, but gravity remains consistent and nonselective; therefore, the only issues regarding the occurrence of brow ptosis are when it will occur and how severe it will be. Wrinkles are also inevitable but may be dynamic or static in nature. Thanks to botulinum toxin, the previously difficult treatment of dynamic upper facial lines can be effected at low risk with a simple injection. The common and consistent finding of brow ptosis, especially in the lateral third of the brow, may now be selectively treated endoscopically to achieve a more youthful appearance. Society's idea of beauty at any one moment in time will ultimately help to guide the patient and surgeon to choose where the brow should be placed as opposed to merely raising it higher. True rejuvenation is likely more complex and involves multiple modalities and even tissue replacement such as fat grafting. Only time and persistence will prove what best restores youth to the upper face.

Facial cosmetic surgery continues to rise in popularity exponentially. The aging population wants to feel and look more youthful but nonetheless demands to remain natural looking. Today's discerning patient is often very knowledgeable on the subject of their cosmetic surgery options and may insist on a specific technique. The advice of a well-trained surgeon and diagnostician may make or break the ultimate result and prevent a cosmetic disaster. It is vital that the surgeon refuse to perform treatment that is not in the best interest of the patient. Cosmetic surgery is a luxury and is an optional procedure, no matter how much of an emergency it seems to the patient. At the end of the day, it is the surgeon's responsibility to provide the patient with the best and safest options available to achieve realistic goals.

Liposculpting Procedures

Milan J. Jugan, DMD

Liposculpting procedures in oral and maxillofacial surgery have been described in the literature since the 1930s; however, since the introduction of blunt cannula liposuction in the late 1970s, the theories, techniques, and indications for fat removal and transfer have evolved tremendously. Excisional techniques of fat removal used for treating most patients with localized submental lipodystrophy yielded variable results, scarring, and high complication rates. In the cervicofacial region the closed liposuction technique has proven to be an excellent technique for the removal of submental fat and, in addition, has provided a simplified technique with relatively few complications. Also, improved techniques for harvesting, preparing, and injecting fat to augment facial defects or create a more youthful appearance have been developed and are demonstrating long-term success. This chapter discusses a wide range of facial liposculpting procedures to include cervicofacial liposuction, autologous fat transfer, and the use of these techniques as adjunctive procedures to facilitate orthognathic, reconstructive, and maxillofacial cosmetic surgery procedures.

Cervicofacial Liposuction

History

Sculpting the body by removing localized fat deposits has been well documented in the literature for almost a century. Early

excisional body-sculpting techniques included direct lipectomy and open instrument curettage.¹ These techniques were also used in an attempt to remove fat and sculpt the regions of the face and neck. Maliniak described submental fat removal and neck contouring with the excision of redundant tissue in the early 1930s.² Two decades later Davis reported using curettes to remove fat through a small submental incision.³ Our modern techniques of cervicofacial liposuction in oral and maxillofacial surgery can be traced to the pioneering work of four surgeons. Schrudde introduced a technique called *lipexeresis* in 1972.⁴ Modifying a uterine cannula, he described a procedure by which he tunneled in the subcutaneous fat and removed fat particles by suction. In the 1980s Illouz defined several principles for the successful treatment of localized lipodystrophy.⁵ His technique of *lipolysis* is accomplished by injecting a mixture of saline and hyaluronidase solution into the surgical site, causing fat cells to rupture. He theorized that this rupturing of fat cells would make their removal by suction cannulas more efficient. Fournier developed the closed syringe technique, using small-diameter cannulas with an attached plastic syringe to generate the necessary negative pressure.⁶ Finally, Klein developed the tumescent technique, a safe and effective procedure used by most surgeons today.⁷ His technique uses large volumes of dilute

epinephrine solution with or without lidocaine. Although the benefit of a large-volume fat removal without creating an electrolyte imbalance is not generally a concern for the oral and maxillofacial surgeon, the reduction in blood loss, decrease in postoperative ecchymosis, and decreased need for compression garment wear all benefit the cervicofacial liposuction patient.

Indications

Cervicofacial suction-assisted lipectomy is mainly used to correct or improve the body-contour irregularities caused by localized fat deposits in the head and neck region. Specifically, those localized fat deposits that tend to be resistant to dieting and exercise tend to respond favorably. In addition to its use as an esthetic procedure, the techniques mastered in cervicofacial liposuction may be used to facilitate flap elevation, defat pedicled flaps, and remove benign lipomas.^{8,9}

In the maxillofacial region liposuction is most effective in contouring the submental, submandibular, and jowl regions of the face. These areas tend to be easily accessible to the liposuction cannulas for removal of the fat deposits and are also amenable to compression garment placement to facilitate recontouring of the regions. Various authors have also suggested the use of liposuction to contour and smooth deep nasolabial folds and to

remove buccal fat pads to recontour full cheeks.^{10,11} In my experience, nasolabial folds are more predictably managed with augmentation procedures (fat injection) than with fat removal. In addition, removal of buccal fat pads may create a hollowing of the buccal region, owing to progressive fat atrophy with aging, and an unnatural noncosmetic-appearing midface.

Patient Evaluation

Successful cervicofacial liposuction requires careful patient selection and a clear diagnosis of the pathologic entity desired to be modified. The patient's skin tone, skeletal configuration, muscular support of the neck, and body habitus should all be evaluated.

The ideal candidate is a woman of average weight and good skin elasticity, who demonstrates localized adipose accumulations that do not correspond to the patient's overall body habitus. If a patient has recently undergone significant weight loss, she should be advised that the ideal time for cervicofacial liposuction procedures is after 6 months of stable weight management. Patients who are generally overweight respond poorly to liposuction procedures and should be treated with caution. If the operating surgeon decides to proceed, these patients should be at the lower end of their usual weight range to obtain maximum benefit from the proposed surgery. In general, women are excellent candidates for cervicofacial liposuction, probably owing to their thinner less sebaceous skin, which tends to contract in a more predictable fashion over the reduced subcutaneous fat.

Skin elasticity should be evaluated in all patients undergoing cervicofacial liposuction. Patients should have sufficient skin elasticity to facilitate smooth and uniform redraping of skin over the recontoured fat and muscle. Those patients with skin excess or extremely lax or inelastic skin may achieve suboptimal results such as postoperative sagging and should be

counseled on the benefit of adjunctive skin-tightening procedures to achieve the desired results.¹²

Finally, those patients with obtuse cervicofacial angles, in addition to fat accumulation, may require deeper plane procedures to achieve an acceptable cosmetic improvement. Patients with platysmal decussation may benefit from platysmal plication in addition to liposuction to achieve a more youthful-appearing cervicofacial region. In those patients with platysmal ptosis and an obtuse cervicofacial angle, liposuction alone leads to less-than-optimal results. These patients are best approached with liposuction in combination with suture suspension to lift the platysma and recreate the cervicofacial angle.¹³

Instrumentation

For the most part, relatively little equipment is required to perform cervicofacial liposuction. Various companies manufacture a host of devices; however, the basic equipment remains a suction device and aspiration cannulas.

Cannula design has changed since the description of the procedure by Illouz.⁵ A variety of lengths, diameters, and tip designs are available to the surgeon, and the cannula should be chosen according to the procedure being performed. The length of the cannula may vary depending on the specific surgical goal. A short cannula may be chosen to access only the submental region, but a longer cannula or second surgical incision may be needed to work at the angle of the mandible. In general, a 25 to 30 cm length is sufficient for most surgeries in the head and neck region.

Cannula diameter affects the volume of fat removed. It is important to remember that the amount of tissue that can be removed with a pass of the cannula depends on the diameter of the cannula lumen and the suction pressure. Therefore, under an equal amount of pressure, a larger-diameter cannula lumen removes

more fat than does a cannula of smaller diameter. If the goal of surgery is to rapidly remove a large amount of excess adipose tissue, then a larger-diameter cannula is chosen. If the goal is to accurately remove a small amount of fat with more control, then a smaller diameter is chosen. A cannula diameter of 2 to 6 mm is generally used in cervicofacial liposuction procedures.

Finally, tip design is evaluated. Most importantly, the cannula should have a smooth tip and aperture opening. Fat is drawn into the cannula lumen through the aperture opening by the vacuum from the suction unit and then avulsed by the back-and-forth movement of the cannula. Neurovascular structures are pushed aside by a blunt smooth tip. Sharp edges will cut and shave, placing surrounding blood vessels and nerves at greater risk for injury. Damage to these structures may result in alterations to sensation, seroma, hematoma, or necrosis of overlying skin. Again, the goals of the surgery are important when choosing a tip design. A narrow cannula with round tips may be used for the precise removal of small fatty deposits. Flat spatula cannulas are more commonly used in open procedures to defat flaps because an effective seal may be maintained with the underlying tissue bed.

In general, cannula design should be selected to facilitate the goal of the surgical procedure, and a variety of designs should be available to provide the patient with an optimum outcome. Figures 68-1 to 68-3 show examples of various cannula designs available for cervicofacial liposculpting procedures.

The suction device provides the vacuum to the aspiration cannula for removal of the fat deposits. This negative pressure may be generated via a hand-held syringe, wall suction, or commercially available suction unit. Hand-held syringe devices are good for use in the head and neck region owing to their low cost, portability, and ease of handling. They provide an efficient technique for precise contouring of

FIGURE 68-1 Various designs of cannula tip available for syringe liposuction systems.

irregularities secondary to cervicofacial adiposity.⁶ The negative pressure is generated by placing 5 cc of tumescent solution into the cannula-syringe unit, placing the cannula working port beneath the flap, and pulling back on the plunger to create the vacuum. When the plunger is pulled back to the fullest extent, it is possible to obtain 1 atm of negative pressure. Various plunger locks are manufactured to hold the plunger in position during the operation. A disadvantage of this system is the loss of vacuum that occurs if tissue contact is lost.

Wall suction and commercially available suction units are useful for closed and open liposuction techniques. They provide continuous vacuum and are most useful for removing large amounts of fat or defating a flap.

A final consideration for choosing a suction device is the ability to vary the amount of negative pressure through the cannula. Whereas 1 atm of negative pressure is ideal for liposuction procedures, 0.5 atm of negative pressure is more appropriate to harvest fat for fat-injection techniques.

Anesthesia

Liposculpting procedures may be performed in various settings from an office or surgicenter to a main operating room.

Although some patients may desire general anesthesia, the vast majority of cervicofacial procedures may be performed with local anesthesia and intravenous sedation.

The tumescent technique of superficial liposuction, published by Jeffery Klein in 1987,⁷ has become the standard against which all other techniques are compared. It is distinct from other liposuction techniques in that the entire procedure can be performed under local anesthesia only if the surgeon so desires. Most importantly for the patient, the tumescent technique provides excellent anesthesia and out-

FIGURE 68-2 Examples of various cannulas available for cervicofacial liposculpting procedures. Note the differences in cannula length, diameter, tip design, and ability for use with a syringe or suction aspiration system.

standing hemostasis. To understand Klein's tumescent technique, one needs to review the wet technique of Illouz.⁵ Illouz injected hypotonic saline, lidocaine, epinephrine, and hyaluronidase into the liposuction site, attempting to cause lysis of fat cells and improve fat extraction. With the wet technique, excessive blood loss remained a significant risk. Large cannulas were used to remove as much fat as possible in the shortest amount of time. Postoperatively, bruising was extensive and patients wore compressive garments for several weeks. Klein's technique for the head and neck advocates the use of a local anesthetic solution containing normal saline, 0.1% lidocaine, epinephrine at a concentration of 1:1,000,000, and bicarbonate. Table 68-1 provides concentration data on several mixtures of tumescent solution that I use. Klein also demonstrated that a large amount of lidocaine could be injected into the superficial fat compartments without a large increase in serum lidocaine levels since aspiration of the infiltrate and fat were being performed.⁷ In general, 50 to 100 cc of Klein's solution are used in the cervicofacial region for liposuction procedures.

In 1997 the American Academy of Cosmetic Surgery published its *Guidelines for Liposuction Surgery* and stated, "The tumescent infiltration (technique) has been shown over the last 9 years to be the safest for liposuction and lipocontouring, with the fastest recovery time and least complications for the patient."¹⁴

FIGURE 68-3 Syringe liposuction system set up for standard syringe liposuction and adaptation to a suction aspiration system. This system is particularly useful for collecting harvested fat in the syringe.

Table 68-1 Tumescent Solution Concentration Data

Component	Solution A*	Solution B†	Solution C‡
Lidocaine (1%)	50 cc (500 mg); 0.05%	100 cc (1,000 mg); 0.1%	150 cc (1,500 mg); 0.15%
Epinephrine (1:1,000)	0.5 cc (0.5 mg); 1:2,000,000	1.0 cc (1.0 mg); 1:1,000,000	1.5 cc (1.5 mg); 1:666,666
Bicarbonate (1 mEq/mL)	10 cc; 10 mEq/L	10 cc; 10 mEq/L	10 cc; 10 mEq/L
Normal saline	1,000 mL	1,000 mL	1,000 mL

*Solution A is used for patients undergoing liposculpting procedures for the first time.
†Solution B is used for revision liposculpting procedures.
‡Solution C is used for liposuction-assisted rhytidectomy procedures and fat harvesting.

Although the tumescent technique will continue to evolve with research and evolution of equipment, it certainly has proven to be a safe and effective therapy for cervicofacial liposuction.

Technique

The goal of cervicofacial liposuction is to create a smooth and regular contour of the head and neck regions by the precise removal of localized fat deposits while minimizing external scarring. To that end, the patient must be educated on the risks and benefits of the procedure. A preoperative consultation should be performed that includes adequate photodocumentation of the patient's preoperative condition. Informed consent for liposuction surgery and sedation must be reviewed and obtained. Appendix A shows a sample consent form for a cervicofacial liposuction procedure. The patient's medical history should be reviewed for any contraindications to surgery and to determine any potentially modifiable factors (eg, use of nonsteroidal anti-inflammatory drugs or herbal medications, and smoking).

On the day of surgery the patient is marked up in the sitting position, and the areas of proposed fat removal are reviewed and verified with the patient. Various other anatomic structures may be marked up depending on the surgeon's preference, but I recommend marking the inferior border of the mandible, sternocleidomastoid muscle, and the top of the thyroid cartilage, as well as the proposed surgical incisions.

All skin incisions should be large enough to accommodate placement of the aspirating cannulas. Incisions that are too large leave an unsightly scar when healed, and incisions that are too small may be damaged by friction from the back-and-forth motion of the cannula. The submental and submandibular areas may be liposuctioned using a single incision in the submental crease. The jowl area may be best approached from an incision in the posterior earlobe crease. A small incision in the nasal vestibule area may allow access to facial adiposity not adequately removed through the previously described incisions.

The patient is placed in a modified semi-Fowler position, monitors are placed, and supplemental oxygen is delivered. Intravenous sedation is then titrated to the level desired by the operating surgeon. Local anesthetic is infiltrated into the incision sites, and an incision is made through the dermis. A small pocket is then created within the superficial fat plane between the dermis and the platysma or superficial musculoaponeurotic system (SMAS). Tumescent liposuction solution is then infiltrated into this space via an infiltrating cannula. Care is taken to remain in the compartment of superficial fat above the platysma muscle. The cannula is advanced in a plane parallel to the skin surface and is easily palpable during the infiltration process. The cannula is advanced in a systematic manner throughout the area to be treated, and the solution is injected as the cannula is being with-

drawn. In the average patient, 100 to 150 cc of solution is deposited in the plane of dissection. The area is then to remain undisturbed by instrumentation for 10 to 15 minutes, allowing for maximum vasoconstriction and providing excellent local anesthesia. Effective placement of the tumescent solution will result in blanching of the overlying skin owing to the vasoconstrictive effects of the solution.

After 10 to 15 minutes, an operating cannula is placed into the incision site, and the process of suction-free pretunneling is begun throughout the surgical site. When the operating cannula is inserted, care must be taken to ensure that the aperture opening is directed away from the skin. If facing the skin, the aperture may cause damage to the subdermal plexus, resulting in an increase in postoperative complications and the potential for postoperative epidermal ridge formation. Pretunneling is performed by systematically passing the cannula back and forth through the fat deposits, with care being taken to remain within the superficial fat compartment. Although not mandatory, pretunneling defines the appropriate surgical plane, breaks up fat cells, and aids in the extraction of fat cell content.

Following pretunneling the cannula is connected to the suction device. Fat is removed from the desired areas by directing the cannula through the pretunneled area in the same systematic manner used initially. Again, care is taken to ensure that the aperture opening is directed away from the skin and that the cannula remains in

the proper plane of dissection. A superficial plane may be maintained by tenting the skin away from the deep tissues with the tip of the cannula and by palpating the cannula through the skin using the nonoperating hand. Fat is extracted from the superficial fat compartment until the desired contour is achieved. Once the main area of adiposity is reduced, the cannula is carried slightly beyond the margins of the original dissection to feather out the edges of the operative site and to reduce the potential for contour irregularities. The site should be inspected frequently to avoid overcorrection. Direct palpation is the most accurate method to assess the amount of fat removed. The skin should be pinched and rolled between the thumb and index finger. The skin should feel loose, with a thin layer of adipose tissue remaining on the undersurface of the dermis. In most cases the surgeon removes between 20 and 100 cc of fat in the cervicofacial region. Additional contouring may be required following the submental approach; in this case posterior earlobe crease incisions may be used to overlap the dissection areas. The same sequence of pretunneling, inspection, and fat removal is used to optimize the final contour enhancement for the patient.

Following completion of the liposuction, residual blood, tumescent fluid, and fat particles are expressed from the space. The incision sites are closed using a 5-0 or 6-0 monofilament suture such as nylon or polypropylene. The wounds are then covered with an antibiotic ointment and dressings. A light pressure dressing is placed to reduce tissue edema and to immobilize and reshape the skin over the recontoured area. Although multiple regimens for compression exist, I instruct patients to wear the compression garment continuously for 7 days and then only at night for an additional 7 days. Appendix B shows an example of postoperative instructions for patients undergoing cervicofacial liposuction.

Complications

Postoperative complications associated with cervicofacial liposuction are rare. Since liposuction of the head and neck region usually involves the removal of < 100 cc of fat from a limited area, the complications associated with whole-body liposuction procedures, such as significant blood loss, rapid fluid shifts, hypotension, shock, and death, are not seen.

Infections following cervicofacial liposuction occur in < 0.2% of cases,¹⁵ and a low rate should be expected with adherence to strict sterile procedure. Since cervicofacial liposuction is a sterile procedure, antibiotics are not required. However, literature suggests that they are commonly used as a prophylactic measure by many surgeons.¹⁶

Hematomas and seromas are rarely seen. Compression garment wear limits the potential for this complication. Small hematomas or seromas are generally managed by needle aspiration and extended wear of a compression garment until completely resolved.

Contour irregularities are probably the most common postoperative complication. They may be treated based on the etiology of formation. Those complications related to excess skin (sagging) should be treated with a skin-tightening procedure. Irregularities of the underlying muscle (platysmal ptosis or platysmal decussation) should be corrected by a procedure designed to correct muscular problems. Both of the above-mentioned complications are the result of poor patient selection and diagnosis. Contour irregularities owing to inadequate fat removal may be corrected with further liposculpting procedures; however, overaggressive removal of fat may be more difficult to correct.

Injuries to the branches of the facial nerve or the greater auricular nerve are rare and may be avoided by adhering to the appropriate technique and ensuring that dissection is in the correct surgical plane. If facial nerve injury does occur,

monitoring and early referral to an appropriate specialist is indicated.

Liposuction as an Adjunctive Procedure

Orthognathic Surgery

Orthognathic surgical procedures have long been recognized as a means to manipulate the esthetics of the face. Hard tissues of the facial skeleton are manipulated by osteoplasty, osteotomy, and skeletal implants to modify a patient's appearance. However, the skin and subcutaneous tissues do play a role in determining a portion of facial esthetics, particularly in the cervicomental region. Those orthognathic procedures that affect the position of the mandible also affect the esthetics of the submental and neck region. For instance, a patient undergoing a mandibular setback procedure may have an esthetic cervicomental angle prior to the procedure but have lax submental tissue following the procedure. This modification of an adjacent esthetic subunit of the head and neck underscores the need for a total facial analysis of our orthognathic patients prior to the initiation of surgical treatment. In the case of liposculpting procedures, a patient's submental, jowl, and neck regions may be treated with cervicofacial liposuction in conjunction with orthognathic surgery to better define the inferior border of the mandible, remove unesthetic submental fat deposits, or assist in tightening lax submental tissues to establish an acceptable cervicomental angle. An important limitation to consider with this type of combined treatment is the etiology of the original craniofacial defect being treated. In those patients with severely hypoplastic mandibles, a deficiency in cervicomental skin and muscle may also exist. In such a case cervicofacial liposuction would not be a benefit in recreating an esthetic cervicomental angle. Figure 68-4 demonstrates reconstruction of the cervicomental region in a patient undergoing combined orthognathic and liposculpting procedures.

FIGURE 68-4 This patient underwent orthognathic surgery consisting of a segmental Le Fort I osteotomy with impaction, bilateral sagittal split ramus osteotomies, advancement genioplasty, and cervicofacial liposuction. A, Preoperative view. B, Postoperative view. Note the esthetic appearance of the cervicomental angle.

Chin Augmentation Cervicofacial liposuction may be performed in conjunction with chin augmentation or advancement genioplasty if the patient exhibits a hypoplastic genial process. The combination of procedures enhances the results that the patient would receive from liposuction alone.¹⁷ The advancement genioplasty or chin augmentation improves the final result by accentuating the depth of the cervicomental angle. In many cases a chin implant may be placed using the same incision through which the liposuction was performed by slightly increasing the size of the incision to accommodate the chin implant. Advancement genioplasty may be performed through an intraoral incision, with closure occurring prior to the start of liposuction; this allows the field to be cleared of all contaminated instruments and provides the surgeons with the opportunity to change their gloves.

Liposuction-Assisted Rhytidectomy

Liposuction may be used to enhance the results of rhytidectomy (face-lift) when

significant submental adiposity exists. Both open and closed liposuction techniques may be used. Three main areas may be addressed with the liposuction technique. First, the technique of pretunneling may assist the surgeon in elevating the facial flap. The blunt-tipped cannula may be passed easily through the subcutaneous fat layer to assist in the dissection and limit the potential for damage to the subdermal plexus. Second, following elevation of the flap, the spatula cannula may be used to defat the SMAS layer and the posterior aspect of the platysma. This maneuver helps to better identify the surgical plane and to limit the potential for postoperative contour irregularities. Any fat that may be associated with excessive jowls may be eliminated from overlying the SMAS at this time. Finally, liposuction may be used in the neck and submental areas to eliminate fatty deposits and potentiate the appropriate redraping of the neck and facial skin. It is important to remember that liposuction provides only an adjunct to rhytidectomy and that SMAS suspension with skin excision must still be per-

formed. Figure 68-5 illustrates a case in which a patient underwent liposuction-assisted rhytidectomy.

Autologous Fat Transfer

History

Autologous fat transfer for soft tissue augmentation or reconstruction continues to be viewed with guarded acceptance by surgeons throughout the world. Many surgeons are able to obtain predictable results, a fact that has spurred continued interest in the concept of fat transfer. In addition, many practitioners now feel that the loss of fat volume in the face may lead to premature aging and a less-than-cosmetic appearance. As a result, there has been a resurgence in the acceptance of fat-injection techniques. The technique itself was first introduced by Neuber in 1893, when he used a free fat graft from the upper extremity to reconstruct a periorbital defect.¹⁸ His data seemed to suggest that smaller grafts were more successful in that they had a greater chance for long-term survival. Building on this knowledge, Verderame in 1909 advocated overcorrection of defects to the significant amount of graft resorption associated with autologous fat transfer.¹⁹ It is important to realize that these studies involved sharply dissected fat grafts with defined clinical margins for vascular ingrowth and not bluntly dissected fat from liposuction harvest procedures. Research continued into sharply dissected autologous fat grafts with several human studies by Peer in the 1950s.^{20,21} He sharply dissected fat from the abdomens of 13 individuals and divided the fat into two equal grafts. One graft was inserted in entirety, whereas the other graft was sharply subdivided into multiple smaller pieces. His studies demonstrated that the greatest damage to the graft occurred at the cut margins and that the grafts that were cut into smaller pieces retained less of their volume. Although this would seem to be contradictory to

FIGURE 68-5 This patient underwent a cervicofacial liposuction-assisted rhytidectomy. A and B, Preoperative frontal and lateral views. C and D, Postoperative frontal and lateral views. Note the excellent definition of the inferior border of the mandible and the esthetic appearance of the cervicomenal angle.

earlier research demonstrating greater graft volume survival in smaller grafts, the contradiction relates to the surgical damage created by the sectioning of a larger graft into smaller portions versus the harvesting of a smaller graft initially.

Blunt lipectomy with autologous fat grafting by injection has recently become popular owing to the relative ease of the procedure. Illouz first wrote about the grafting of liposuctioned fat in 1986,²² and others have published multiple positive reports of the technique based on clinical experience^{23–25}; however, little scientific information on the validity of this technique has become available until recently. Fournier and Otteni studied histologically the damage to lipocytes following their extraction by blunt cannula liposuction and noted no damage to the cells.¹⁶ It is important to note that these studies were carried out using large-diameter cannulas, not the smaller-diameter cannulas used today. More recently Carpaneda demonstrated that the aspirated material retrieved following liposuction consists of adipose cells, collagen fibers, vessels, nerves, ruptured cells, inflammatory proteins, proteases, and lipogenic enzymes.²⁶ Campbell and colleagues studied adipocyte glucose oxidation and lipid synthesis following suction extraction and injection through needles of varying sizes.

Their research showed that the smaller-diameter needles were associated with increasing cell damage.²⁷ More current research focuses on limiting damage to cells on extraction and providing an appropriate environment for cell survival during transfer. Various techniques involve the use of platelet gel, enriched tissue culture medium, and albumin to promote the survival of fat cells and maintain the volume of the grafted tissue.^{28–30}

Autologous Fat Injection

The technique for autologous fat transfer by injection varies with the provider. As demonstrated by the limited literature review previously presented, there are multiple theories and techniques associated with fat transfer. The following technique has been used over a period of years, providing predictable cosmetic results for many patients.

As with cervicofacial liposuction, the appropriate preoperative consultation, medical evaluation, photodocumentation, and informed consent procedures are necessary for all patients. Patients should identify the defect that they desire to be corrected or describe the cosmetic enhancement that they wish to be achieved by autologous fat transfer. Prominent nasolabial or melolabial folds, prominent nasojugal grooving, and atrophic lips are all cosmetic deformi-

ties that lend themselves to correction by autologous fat injection. At the preoperative appointment, a site for fat harvest is chosen. Acceptable sites include the abdomen, lateral thigh, and buttocks.

On the day of surgery, the area to receive fat augmentation is clearly marked and confirmed with the patient. The procedure may be carried out under local anesthesia, but I prefer the use of light conscious sedation and local anesthesia for enhanced patient comfort. The technique previously described for tumescent liposuction is followed for harvesting fat, with one exception. Research indicates that fat cell damage is reduced when lower vacuum pressures are used. In this case 0.5 atm of vacuum pressure is advocated for the harvest of fat to be re-injected. Once the fat is harvested, it is moved to a sterile back table for preparation. The area of harvest is cleaned, excess tumescent solution and debris are expressed, and the wound is closed. The area is then covered with a compressive garment.

At our institution fat to be injected is then processed through a centrifuge at 3400 rpm for 3 minutes to separate viable fat cells from damaged cells and blood products. Following processing, the undesired materials are decanted from the viable fat cells, which are then transferred to an injection syringe.

Fat is transferred into the desired tissue location with a 14-gauge injection cannula and a high-pressure injection device, as demonstrated in Figure 68-6. It is important to remember that the fat should be injected with two to three passes of the cannula in various planes. Theoretically, multiple passes provide an increased surface area for vascular ingrowth leading to increased graft volume survival. Figure 68-7 shows a patient receiving an autologous fat graft to the lips during a rhytidectomy procedure. The grafting cannula is then removed and the area cleaned. There is no need to suture closed the injection sites.

Dermal Fat Grafts

First introduced by Neuber in 1893,¹⁸ dermal fat grafts are used for a variety of reconstructive and cosmetic techniques. In the maxillofacial region a variety of soft tissue deficit reconstructions have been performed using dermal fat grafts, including soft tissue enhancement of hemifacial atrophy patients, reconstruction following radical parotidectomy, repair of gunshot wounds, and various cosmetic augmentation procedures. Peer demonstrated less resorption in dermal fat grafts than with free fat grafting, although he still reported a 50% loss of weight and volume of the grafted fat at 1 year.²⁰ Research by Longacre and by Neumann,^{31,32} who both used pedicled dermal fat grafts for reconstructive procedures, achieved excellent results

FIGURE 68-6 Autologous fat prepared for injection transfer. The high-pressure injection device is loaded with a 10 cc syringe of graft material. Two injection cannulas are available for use.

with retention of fat and postulated that the pedicled blood supply accounted for the reduction in overall fat resorption. Although these grafts do provide a reliable result, they should only be selected for smaller defects of the maxillofacial region. For larger defects microvascular transfer of skin and muscle provides a more predictable and stable cosmetic result.

The technique for obtaining a dermal fat graft is well described. A site for harvesting the graft is selected that has thick but relatively hairless skin. Two techniques for accessing the dermis and fat are generally accepted. The first employs a split-thickness skin graft (0.036 to 0.041 cm), which is lifted to expose the underlying dermis. Sharp excision of the dermal fat graft with a knife is then performed. Care must be taken to ensure that the fat remains attached to the dermis. Figure 68-8 shows a dermal fat graft harvested for soft tissue reconstruction. Once the graft is removed, local hemorrhage is controlled, and the area is closed. The second newer technique involves de-epithelialization of the skin with a CO₂ laser. This technique is extremely helpful in managing a specific area, as in an island or a pedicled flap, and in facilitating an elliptic area of de-epithelialization to allow for straight-line closure. The CO₂ laser is set at 10 W of power with a 1 to 2 mm spot size, and the area to be de-epithelialized is then systematically lasered. When the area has been completed, the area is débrided with a wet sponge. Often, two or three passes with the laser are needed to completely de-epithelialize the area. Care must be taken to limit the thermal damage to the underlying dermis and fat. Once the de-epithelialization is completed, the dermis and fat are harvested with a knife, local hemorrhage is controlled, and the area is closed.

Complications

As with cervicofacial liposuction, the complications associated with the transfer of autologous fat are limited. Primarily, mis-

FIGURE 68-7 Injection of autologous fat grafts into the lip during a rhytidectomy procedure.

placement of the graft, infection, and loss of significant graft volume are worthy of mention. Grafts are generally overcontoured to account for the loss of graft volume during the healing phase. Since the location of graft volume loss is difficult to predict, the potential for graft misplacement exists. Should residual fat remain in an area where it is not desired, the remaining graft may be removed by local suction lipectomy with a syringe and a small cannula. Infection of the graft site is possible if meticulous sterile technique is not followed. I advocate the use of prophylactic antibiotics for all patients undergoing autologous fat transfer. Finally, loss of significant fat volume may occur leading to patient dissatisfaction and irregular or unacceptable contour. Since fat-volume retention seems to be related to a number of variables, patients should be counseled concerning the potential need for multiple

FIGURE 68-8 Example of a dermal fat graft harvested for soft tissue reconstruction.

grafting procedures to achieve the final result. Our experience indicates that most patients achieve their expected results with two or three grafting procedures.

Summary

Liposculpting procedures of the cervicofacial region provide patients with a simple and predictable means for improving their facial esthetics. The procedures have been described in the scientific literature for over 100 years and have been performed safely by many oral and maxillofacial surgeons. Cervicofacial liposculpting techniques can also be used to enhance the results of orthognathic surgery and other more involved maxillofacial cosmetic surgery procedures. With the advent of the tumescent liposuction technique, small-diameter cannulas, and the syringe suction technique, the procedures are easily and safely performed in the modern oral and maxillofacial surgery office environment. Autologous fat-transfer techniques for facial reconstruction and maxillofacial esthetic surgery have also found a place in the contemporary oral and maxillofacial surgery practice.

The views expressed in this chapter are those of the author and do not represent the official policy or position of the Department of the Navy, Department of Defense, or US Government.

Appendix A

INFORMED CONSENT FOR SUCTION-ASSISTED LIPECTOMY (SURGICAL AND SUCTION-ASSISTED FAT REDUCTION)*

I hereby authorize Dr. _____ and staff to perform the following procedure:

and to administer the anesthetic I have chosen, which is () local anesthetic, () intravenous sedation, () or general anesthetic.

Other treatment options: _____

Please initial each paragraph after reading. If you have any questions, please ask your doctor *before* initialing.

Liposuction

I hereby acknowledge that the following has been explained to me and that I have had an opportunity to ask questions.

- _____ 1. Suction-assisted lipectomy is the technique to remove a localized collection of fat beneath the skin.
- _____ 2. I understand the purpose of the surgery is to treat and attempt to correct the appearance of localized areas on my body.
- _____ 3. I have been completely candid and honest with my surgeon regarding my motivation for undergoing a lipectomy, realizing that a new appearance does not guarantee an improved life.
- _____ 4. I understand that if I am an active smoker I must cease smoking at least 2 weeks prior to surgery. Failure to follow this instruction can have dramatic effects on the success of the surgery.
- _____ 5. It has been explained to me that suction-assisted lipectomy is not a substitute for weight reduction that can ordinarily be obtained by dieting and exercise and that it is not a cure for obesity. It is a surgical technique suitable for selected patients.
- _____ 6. I hereby acknowledge that I have attempted to accurately provide Dr. _____ and/or his staff with an accurate medical history, realizing that withholding certain information may adversely affect my diagnosis and the final result of the surgery.
- _____ 7. It has been explained to me that my physical condition may require surgical lipectomy, in which excess skin and fat may be removed instead of or in addition to suction-assisted lipectomy.

Surgical Considerations

- _____ 1. The technique of liposuction has been explained to me. I have been told that suction-assisted lipectomy may be performed under local anesthesia or, in selected cases, with the use of intravenous sedation or a general anesthetic. The procedure begins with small incisions approximately 1 cm long. The doctor will then insert a blunt-ended tubular instrument (catheter) into the area of the incision and then, using suction, extract the deposits of fat. I have been advised that additional incisions may be necessary to gain adequate access to all areas of unwanted fat deposits.

Postoperative Considerations

- _____ 1. The incisions will be closed with small sutures. Generally, the scars are small. However, I have been advised that in some cases scarring may be unpredictable and a second procedure may be required to reduce the scarring.
- _____ 2. Following the surgery I have been told that a snug dressing of elastic gauze may be applied to the entire area to help the skin conform smoothly to the shape of the underlying tissue. This pressure-type bandage is generally worn for about 2 weeks. Some bruising and swelling may persist for several weeks after the operation. Some postoperative pain can be expected, and medication will be prescribed to provide some relief.
- _____ 3. I have been advised and acknowledge that there is no guarantee that the procedure will improve my appearance. Patients react differently depending upon age and health. Some individuals have less skin elasticity and may require additional procedures to remove or tighten excess skin. Further, some people have skin that tends to wrinkle more than do others. To assist in healing, strenuous physical activity such as aerobics or physical labor must be avoided during the first week postoperatively.

Risks and Complications

Dr. _____ has explained to me there are certain inherent and potential risks in any treatment plan or procedure and that, in this specific instance, such operative risks include but are not limited to the following:

- _____ 1. There is a possibility that a second surgery/procedure will need to be performed in the event the doctor encounters an abundance of excess fat.
- _____ 2. Ordinarily, liposuction of the face and neck does not require blood transfusions. However, all patients respond differently. I have been told that there is a possibility that a blood transfusion will be performed, and I have been advised of my rights regarding autologous blood (self and family transfusions).
- _____ 3. The surgery will involve areas of certain cranial or facial nerves. Damage to the nerves can result in numbness, which is usually temporary. However, in rare cases the numbness can be permanent. Additionally, there is a risk of damage to nerves that affect motor function. For example, there may be an inability to purse the lips. The condition is usually temporary; however, in rare conditions it can be permanent.
- _____ 4. It is possible that after fat removal the overlying skin will not be smooth; rather, it may have a “washboard” appearance. A second liposuction procedure or other cosmetic surgery may be necessary to correct this condition.
- _____ 5. In the event that fat is to be removed from the cheek area, I have been advised that a change in facial tone occurs in some cases. The condition is usually temporary; however, on rare occasions this condition can be permanent.

(CONTINUED ON NEXT PAGE)

- ___ 6. Any surgery involves the risk of infection requiring antibiotic treatment. Most cases resolve without complication; however, in rare situations treatment of a serious infection may require hospitalization.
- ___ 7. There is a possibility of localized collections of blood in areas of fat removal. Secondary procedures to remove the blood may be required.

Anesthesia

In the event that I am to receive intravenous or general anesthesia, I understand and agree that I am not to have had and/or have not had anything to eat or drink for 8 hours before my surgery. **FAILURE TO FOLLOW THIS INSTRUCTION MAY BE LIFE THREATENING!**

- ___ 1. I consent to the administration of () local anesthetic, () intravenous sedation, or () general anesthetic, having first had the risks and benefits of each explained to me.
- ___ 2. I have been made aware that certain medications, drugs, anesthetics, and prescriptions that I may be given can cause drowsiness, incoordination, and a lack of awareness, which may be worsened by the use of alcohol and other drugs. I have been advised not to operate any vehicle or hazardous machinery and not to return to work while taking such medications, or until I am fully recovered from the effects of the same. I understand this recovery may take up to 24 hours or more after I have taken the last dose of medications. If I am given sedative medication during my surgery, I agree to have a responsible adult drive me home and accompany me until I am fully recovered from the effects of the sedation.
- ___ 3. I understand that certain anesthetics can cause bodily injury and death.

No Guarantee of Treatment Results

- ___ 1. No guarantee or assurance has been given to me that the proposed treatment will be curative and/or successful to my complete satisfaction. Owing to individual patient differences, there may exist a risk of failure or relapse, my condition may worsen, or selective re-treatment may be required in spite of care provided.
- ___ 2. I have had an opportunity to discuss with Dr. _____ my past medical and health history including any serious problems and/or injuries and have fully informed him of the same.
- ___ 3. I agree to cooperate fully with the recommendations of Dr. _____ while I am under his care, realizing that any lack of such cooperation can result in less-than-optimal results or may be life threatening.
- ___ 4. If any unforeseen condition should arise in the procedure of the operation calling for the doctor's judgment regarding procedures in addition to or different from those now contemplated, I request and authorize the doctor to provide the appropriate service.

Miscellaneous

- ___ 1. I request the disposal by authorities of this medical facility of any tissues or parts that it may be necessary to remove.
- ___ 2. I understand that photographs and movies may be taken of this operation and that they may be viewed by various personnel undergoing training or indoctrination at this or other facilities. I consent to the taking of such pictures and observation of the operation by authorized personnel, subject to the following conditions:
- A. My name and my family's name are not to be used to identify said pictures.
- B. Said pictures are to be used only for purposes of medical/dental study or research.

For Female Patients

I have advised Dr. _____ as to whether I am currently using birth control pills. I have been advised and informed that certain antibiotics and some pain medications may neutralize the therapeutic effect of birth control pills allowing for conception and resulting in pregnancy. I agree to consult with my family physician to initiate additional forms of mechanical birth control during the period of my treatment with Dr. _____ and until I am advised by my physician that I can return to using birth control pills exclusively.

I have had an opportunity to have my questions answered, and I certify that I understand the English language.

Appendix B

POSTOPERATIVE INSTRUCTIONS FOR FACIAL LIPOSUCTION*

Please read your instructions carefully and call us if you have any questions.

Swelling and a large amount of discoloration are normal following liposuction surgery. The following instructions are designed to help you minimize discomfort after surgery.

Position

Elevate your head and back using several pillows or use a recliner chair with the head at a 45° angle. It is important that you do so for *1 to 2 days* after your surgery. Lay on your back, rather than on your side or stomach.

Ice

Ice may be used over the surgical area for the first *24 hours* around the clock, as directed (leaving it off for eating and performing hygiene).

Activity

During your *first day* after surgery, stay up as much as possible. You should sit, stand, or walk around rather than remain in bed. However, you should rest when you become tired. Avoid bending or lifting more than 2.5 kg during the first week. You may do *passive exercises only!* Stay away from any activity that raises the pressure in your face for *2 weeks* as excessive pressure may cause a severe bleed. Avoid excessive talking and extreme facial movements (which may increase bleeding/bruising).

Diet

- Day of surgery, postoperatively: Start with clear cool fluids when these are tolerated, advance to warm (*not hot!*) fluids and very soft foods only, such as soups, dairy products, and applesauce.
- From the second day after surgery until your next office visit: Eat warm soft foods or cool foods—foods that do not require a lot of chewing. Also, make sure you are drinking lots of fluids during your postoperative recovery, at least eight 250 mL glasses a day for about 3 weeks. *This is very important!*
- One week after surgery: Resume your regular diet.

Medication

Pain medication: Take one dose when you arrive at home, then as needed every *4 to 6 hours* for discomfort or pain.

Caution: Do not drive or operate dangerous machinery while taking narcotic pain medication. Do not drink alcohol while taking pain medication or antibiotics.

Heat

Begin using moist heat on the second postoperative day. A moist towel should be placed between the skin and the heat source. Do not use heat continuously, only for *20 minutes four times per day* for a *2-week period*.

Sun Exposure

Protect the facial skin from excessive sun exposure for 1 month after surgery. Use a sunblock that is SPF 15 or higher. Wear a hat.

Sports

Do not participate in swimming, gym activities, or strenuous activities for *1 week*. Do not dive or ski for *2 months*. Passive exercise such as walking is permitted.

Acetylsalicylic Acid

The use of acetylsalicylic acid (Aspirin or medications containing ASA) should be avoided for *10 days* prior to surgery. Take acetaminophen (Tylenol) for headaches and minor pain.

Smoking

Smoking should be stopped at least *2 weeks* prior to surgery. Smoking impairs circulation, and good circulation is needed for proper healing. An adequate blood supply leads to a good surgical result for you.

Bruising/Swelling

Bruising and swelling are to be expected. Bruising is usually gone in 7 to 10 days. The swelling takes a while longer to subside.

Bleeding

If the dressing or elastic support is quite bloodstained, this should be reported to the doctor *immediately!*

Dressings

A compression dressing must be worn continuously for 1 week; it may be removed for short periods of time and then reapplied. Leave this on *24 hours a day for the first week*, and then mainly wear the support dressing at night.

Bathing

You may bathe in the tub or shower, and shampoo your hair during the *first day* after surgery. Use mild soaps and shampoos to avoid irritation.

Shaving

Resume shaving when swelling subsides and the area is not too tender.

Care of Your Incisions

Supplies needed: bacitracin ointment, 1/2 oz; cotton-tip applicators (eg, Q-Tips)

1. Use cotton-tip applicators and warm water to clean all blood and material from the cuts. *Do not* leave any crusts or blood on the stitched areas. Repeat a minimum of four to five times per day.
2. Cover *all* cuts and abrasions with ointment—do not allow *any* areas to dry out or scab over.
3. Do not apply any bandages or other materials to the surgical area unless otherwise instructed.

Follow-Up Appointments

Please check off postoperative appointments as they are kept:

1 to 2 days _____ 5 days _____ 2 weeks _____
2 months _____ 6 months _____

Final Note

Faithful adherence to the preoperative and postoperative instructions will not only help to minimize swelling, pain, and discomfort, but will also aid in achieving an excellent surgical result. If you do have problems, don't hesitate to contact our office for assistance.

Please report any of the following to our office:

- Excessive bleeding
- Sudden swelling
- Any itching, rash, or reaction to any of the medications
- Temperature above 101°F (38.3°C) (taken orally)

*Adapted from a form by the Oral and Maxillofacial Surgery Clinic, Naval Medical Center, San Diego, CA.

Skin Rejuvenation Procedures

Gary D. Monheit, MD

The pursuit of youth and beauty has become a hallmark of the baby-boomer generation, which has now advanced to midlife and beyond. The distinct increase in an older population due to newer medical and technological advancements and career development has brought a larger healthy population interested in cosmetic procedures. This mid-age population has remained active in the workforce and now demands “no downtime” procedures for skin rejuvenation that will maintain their appearance for work and pleasure. This has encouraged the development of new lasers, new fillers, botulinum toxin, cosmeceuticals, and many other innovations that have reduced the downtime and increased the safety of our cosmetic facial rejuvenation procedures. Anyone interested in providing facial cosmetic procedures and surgery needs to become familiar with all the procedures now available.

Aging of the skin is the combined result of both intrinsic factors and extrinsic external influences from the environment. Intrinsic aging is the roles that genetics plays in relation to chronologic age. These include alteration of skeletal mass and proportion, atrophy and redistribution of subcutaneous fat, increased laxity of underlying fascia and musculature, and skin changes characterized by thinning and atrophy. Most intrinsic factors cannot be prevented, but rejuvenative changes can be made with cosmeceutical agents and resurfacing procedures.

Extrinsic factors are preventable environmental influences leading to premature aging of the skin, including ultraviolet (UV) exposure, smoking, chemicals, and gravity. UV exposure is the primary environmental factor, preferentially affecting those with a lighter skin color. The mechanism includes the production of UV-inducing oxygenated fine radiants that have been shown to invite a cascade of molecular events leading to the production of collagen-degrading enzymes. This creates the characteristic features of photoaging, including rough texture, atrophy, fine and coarse wrinkles, and sallow and leathery appearance with dyschromia.¹

In the evaluation of the patient with photoaging, equal emphasis must be placed on prevention as well as treatment. Agents available range from cosmeceutical topical agents to filling agents that include resurfacing devices such as chemical peels, ablative resurfacing lasers, and dermabrasion. An initial consultation is performed to determine which of these tools is best for the patient based on severity and diversity of the condition.

Methods to evaluate photoaging include the Glogau classification of wrinkles. It classifies patients into one of four groups based on degree of severity (Table 69-1). Category I patients are young, with “no wrinkles” and minimal photoaging and are best managed with cosmeceutical agents and superficial resurfacing proce-

dures such as light chemical peels and microdermabrasion. Category II patients are in their thirties, with early to moderate signs of photoaging and characterized by wrinkles in motion. Category III patients have moderate to advanced photoaging with static wrinkles requiring more significant ablative resurfacing techniques. Category IV patients are the oldest, with more severe photoaging changes and wrinkles

Table 69-1 Glogau’s Classification of Photoaging

Group I: Mild (typically age 28–35 years)
A. Little wrinkling or scarring
B. No keratoses
C. Requires little or no makeup
Group II: Moderate (age 35–50 years)
A. Early wrinkling; mild scarring
B. Sallow color with early actinic keratoses
C. Little makeup
Group III: Advanced (age 50–65 years)
A. Persistent wrinkling or moderate acne scarring
B. Discoloration with telangiectasias and actinic keratoses
C. Wears makeup always
Group IV: Severe (age 60–75 years)
A. Wrinkling: photoaging, gravitational, and dynamic
B. Actinic keratoses with or without skin cancer or severe acne scars
C. Wears makeup with poor coverage

significant enough to justify deep resurfacing and other surgical techniques.²

Ablative resurfacing injures the skin in a controlled fashion to a specific depth, encouraging the growth of new and improved skin. These methods include chemical peeling, dermabrasion, and laser resurfacing. Skin resurfacing techniques are divided into superficial, medium depth, and deep, relating to the level of injury (Figure 69-1). The deeper procedures are restricted to the face since other body areas do not have the healing capacity to rejuvenate new skin after such an injury. Care must also be taken with the neck, which may scar with medium-depth or deep injury.³

Table 69-2 presents a useful classification system for categorizing skin resurfacing methods. It is based on the objective data collected by Stegman, who correlated strengths of trichloroacetic acid (TCA) by biopsy of depth of tissue destruction and then new collagen rejuvenation.⁴ Thus superficial, medium depth, and deep resurfacing correlates modalities of peeling, dermabrasion, and laser to common denominators; namely, inflammation and injury.⁴

A useful method of assessing skin-related photoaging is the Monheit-Fulton

index (Table 69-3). This system categorizes the visual changes in photoaging skin and quantitates the amount to guide the physician with appropriate therapy. The system combines age-related textural and lesional changes into a numeric system that will predict how aggressive a physician should be in using superficial, medium-depth, and deep resurfacing procedures.⁵

Medical Care of Photoaging Skin

The basis of all rejuvenative therapy involves using sunscreen protection and cosmoceutical preparations that will help reverse photoaging changes. These products include sunscreens, retinoids, hydroxy acids, antioxidants, and bleaching agents as needed.

Ultraviolet damage is caused by both UVB (290 to 320 nm) and UVA (320 to 400 nm). Both the burning rays of UVB and the more deeply penetrant UVA cause problems of photocarcinogenesis and photoaging of the dermis. Most sunscreens provide adequate protection against the burning effects of UVB but deliver only partial protection against UVA. Sunscreens are divided into chemical and physical blockers. The chemical

screens include oxybenzone, para-aminobenzoic acid, and octyl methoxycinnamate. The physical blockers nowadays are transparent micronized formulations of titanium dioxide and afford more complete UVA and UVB protection.⁶

Topical retinoids have a direct effect on epidermal cell proliferation and dermal collagen growth. They have demonstrated significant effects on photoaging skin including dyschromias, epidermal growths, and fine wrinkle lines. The Federal Drug Administration has approved topical retinoids for the treatment of aging and photodamaged skin in the form of tretinoin cream (0.05% or 0.02%) and most recently tazarotene cream 0.1%. Use of a retinoid with a sunscreen is basic in skin care for photoaging skin problems. It is also used prior to resurfacing procedures to enhance the epidermal and dermal regenerative effect after resurfacing injury.⁷

Hydroxy acids have become a part of skin care programs for their effect on thinning the stratum corneum and decreasing epidermal cell cohesion. This has a regenerative effect on epidermal cell kinetics, giving the skin texture a plumper rejuvenative appearance. There is little definitive evidence that topical alpha-hydroxy acids have an effect on dermal collagen per se.⁸

Topical antioxidants have shown an effect in retarding the reactive oxygen species created by ultraviolet damage. Vitamin C (ascorbic acid) has been shown to be a potent scavenger of free oxygen radicals. Topical products have shown activity in the experimental mode but clinical efficacy as of yet is anecdotal. Vitamin E is a lipid-soluble antioxidant that has become popular in topical form, but little true objective data are present to document its effect on photoaging skin.⁹

Chemical Peeling

Chemical peeling remains one of the most popular choices for both patient and physician. In comparison to some of the newer options available, chemical peels have a

long-standing safety and efficacy record, are performed with ease, are low in cost, and have a relatively quick recovery time. Various acidic and basic compounds are used to produce a controlled skin injury and are classified as superficial, medium-depth, and deep peeling agents according to their level of penetration, destruction, and inflammation (see Table 69-2). In general superficial peels cause epidermal injury and occasionally extend into the papillary dermis, medium-depth peels cause injury through the papillary dermis to the upper reticular dermis, and deep peels cause injury to the midreticular dermis.⁴

Prior to the application of peeling solutions the surgeon must vigorously cleanse the skin surface to remove residual oils, debris, and excess stratum corneum. The face is initially scrubbed with 4" × 4" gauze pads containing 0.25% Irgasan (Septisol solution; Calgon Vestal Laboratories, St. Louis, MO, USA), then rinsed with water and dried. Because of the defatting and degreasing properties of acetone, gauze pads moistened in an acetone preparation are then used to cleanse the skin even further. The importance of cleansing in the peeling procedure cannot be overemphasized. A thorough and evenly distributed cleansing and degreasing of the face assures uniform penetration of the peeling solution and leads to an even result without skip areas (Figure 69-2).¹⁰

The effect of a chemical peel is dependent upon the agent used, its concentration, and the techniques employed before and during its application. Each wounding agent used in peels has unique chemical properties and causes a specific pattern of injury to the skin.³ It is important for the physician using these solutions to be familiar with their cutaneous effects and proper methods of application to ensure correct depth of injury. The marketplace has been flooded with numerous proprietary formulations of these peeling agents, with each product claiming

unique advantages. These products are often expensive and have not been unequivocally shown to be safer or more effective than the conventional solutions. The following sections will therefore focus on the specific chemical agents that are actively responsible for producing the various patterns of injury.

Superficial Chemical Peeling

Superficial chemical peels are indicated in the management of acne and its postinflammatory erythema, mild photoaging (Glogau I and II), epidermal growths such as lentigines and keratoses, as well as melasma and other pigmentary dyschromias. Multiple peels on a repeated basis are usually necessary to obtain optimal results. The frequency of peels and degree of exposure to the peeling agent may be increased gradually as necessary. Results are enhanced by medical or cosmeceutical therapy.¹¹ All superficial chemical peels share the advantages of only mild stinging and burning during application as well as minimal time needed for recovery. They are a part of office-based procedures.¹²

Superficial chemical peels are divided into two varieties; very light and light (see Table 69-2). With very light peels the injury is usually limited to the stratum corneum and only creates exfoliation, but the injury may extend into the stratum granulosum. The agents used for these peels include low potency formulations of glycolic acid, 10 to 20% TCA, Jessner's solution (Table 69-4), tretinoin, and salicylic acid. Light peels injure the entire epidermis down to the basal layer, stimulating the regeneration of a fresh new epithelium. Agents used for light peels include 70% glycolic acid, 25 to 35% TCA, Jessner's solution, and solid carbon dioxide (CO₂) slush.¹³ During the application of superficial peeling agents, there may be mild stinging followed by a level I frosting, defined as the appearance of erythema and streaky whitening on the surface (Figure 69-3).

FIGURE 69-2 A, Irregular surface. B, Clean regular surface.

Alpha-hydroxy acid (AHA) peeling agents have been used widely in skin rejuvenation programs since the early 1990s. The depth of injury is determined by the specific AHA used, its pH, the concentration of free acid, the volume applied to the skin, and the duration of contact or time that the agent is left on the skin before neutralization.⁸ In low concentrations (20 to 30%), AHAs have been shown to decrease the cohesion of corneocytes at the junction of the stratum corneum and the stratum granulosum, whereas higher concentrations (up to 70%) are associated with complete epidermolysis. Weekly or biweekly applications of 40 to 70% unbuffered glycolic acid with cotton swabs, a sable brush, or 2" × 2" gauze pads have been used most often for acne, mild photoaging, and melasma.⁸ The time of application is critical for glycolic acid, as it must be rinsed off with water or neutralized with 5% sodium bicarbonate after 2 to 4 minutes.

Application of 10 to 20% TCA with either a saturated 2" × 2" gauze pad or

q.s.a.d. = quantum satis ad ("up to sufficient quantity").

FIGURE 69-3 A, Level I frosting as found with light chemical peeling; erythema with streaky frosting. B, Level II—erythema with diffuse white frosting. C, Level III—solid white enamel frosting.

sable brush produces erythema and a very light frost within 15 to 45 seconds. The depth of penetration of the peeling solution is related to the number of coats applied; thus, deeper penetration and injury can occur with overcoating. Ideally, a level I frosting is obtained with superficial TCA peels. Protein precipitation results and leads to exfoliation without vesiculation. Concentrations of TCA up to 35% can also be used alone as a superficial peeling agent but may create an injury that extends partially into the upper dermis.¹³

Jessner's solution is a combination of keratolytic ingredients that have been used for over 100 years in the treatment of inflammatory and comedonal acne as well as hyperkeratotic skin disorders (see Table 69-4). Jessner's solution has intense keratolytic activity, initially causing loss of corneocyte cohesion within the stratum corneum and subsequently creating intercellular and intracellular edema within the upper epidermis if application is continued.¹⁴ The mode of application for the Jessner's peel is similar to that of the 10 to 20% TCA peel. The clinical end point of treatment is erythema and blotchy frosting. It is a good repetitive peel for photoaging skin because of its inflammatory effects. The peel can be repeated every 2 weeks.

Salicylic acid, a beta-hydroxy acid that is one of the ingredients in Jessner's solution, can also be used alone in superficial chemical peeling.¹⁵ It is a preferred therapy for comedonal acne as it is lipophilic and concentrates in the pilosebaceous apparatus. It is quite effective as an adjunctive therapy for open and closed comedones and resolving post-acne erythema (Figure 69-4). It is also a peel of choice for melasma and pigmentary dyschromia because it has minimal inflammatory action. Used repeatedly it has the least risk of postinflammatory hyperpigmentation. Superficial peeling for abnormal pigmentation is combined with skin care and topical retinoids, a bleaching product (hydroquinone, including 4 to 8%), and an adequate sunscreen.¹⁶

Prior to the initial treatment with a superficial peel, both patient and physician must understand the limitations, especially on photoaging, to avoid future disappointment. The effect of repetitive superficial chemical peels never approaches the beneficial effect obtained with a single medium-depth or deep peel, in that the improvements in photoaged skin following superficial peels are usually subtle because there is little to no effect on the

FIGURE 69-4 Salicylic acid peels are effective for the treatment of acne and comedones. Repetitive treatment over 6 weeks with acne treatment will hasten resolution of the condition. A, Pretreatment, active acne. B, Perifollicular frosting seen with salicylic acid, a lipophilic chemical. C, Post-treatment result 6 weeks later.

dermis. Nevertheless their ease of use and minimal downtime makes these “lunchtime” peels rewarding for patients with realistic expectations and are a favorite among the busy baby boomers.

Medium-Depth Chemical Peeling

Medium-depth chemical peels consist of controlled damage through the epidermis and papillary dermis, with variable extension to the upper reticular dermis. During the 3 months postoperatively, there is increased collagen production with expansion of the papillary dermis and the development of a mid-dermal band of thick elastic-staining fibers.⁴ These changes correlate with continued clinical improvement during this time.

For many years 40 to 50% TCA was the prototypical medium-depth peeling agent because of its ability to ameliorate fine wrinkles, actinic changes, and preneoplasia. TCA as a single agent for medium-depth peeling has fallen out of favor because of the high risk of complications, especially scarring and pigmentary alterations, when used in strengths approaching 50% and higher.¹⁷ Today most medium-depth chemical peels are performed using 35% TCA in combination with either Jessner's solution, 70% glycolic acid, or solid CO₂ as a "priming" agent (Table 69-5). These combination peels have been found to be as effective as 50% TCA alone but with fewer risks. The level of penetration is better controlled with these combination peels, thereby avoiding scarring seen with higher concentrations of TCA.

Brody developed the use of solid CO₂ to freeze the skin prior to the application of 35% TCA.¹⁸ This causes complete epidermal necrosis and significant dermal edema, thereby allowing deeper penetration of the

TCA in selected areas.¹⁰ Monheit then described a combination medium-depth peel in which Jessner's solution is applied, followed by 35% TCA.¹⁴ Similarly, Coleman and Futrell have demonstrated the use of 70% glycolic acid prior to the application of 35% TCA for medium-depth peeling.¹⁹ Jessner's solution and glycolic acid both appear to effectively weaken the epidermal barrier and allow deeper, more uniform, and more controlled penetration of the 35% TCA.

Current indications for medium-depth chemical peeling include Glogau level II or moderate photoaging, epidermal lesions such as actinic keratoses, pigmentary dyschromias, and mild acne scarring, as well as blending of the effects of deeper resurfacing procedures. The most popular of the medium-depth peels for facial rejuvenation is the Jessner's–35% TCA peel, with other combination peels being used less frequently. This peel has been widely accepted because of its broad range of uses, the large number of people in whom it is indicated, its ease of modification according to the situation, and its excellent safety profile. It is not a "lunchtime" treatment, however, and should be considered a surgical procedure requiring preoperative consideration and preparation, operative sedation, and after-care for 1 week or more.

The Jessner's–35% TCA peel is particularly useful for the improvement of mild to moderate photoaging. (Figure 69-5). It freshens sallow atrophic skin and softens fine rhytids with minimal risk of textural

or pigmentary complications (see Figure 69-5). Collagen remodeling occurs for as long as 3 to 4 months postoperatively, during which there is continued improvement in texture and rhytids. When used in conjunction with a retinoid, bleaching agent, and sunscreens, a single Jessner's–35% TCA peel lessens pigmentary dyschromias and lentiginos more effectively than do repetitive superficial peels (Figure 69-6). Epidermal growths such as actinic keratoses also respond well to this peel. In fact the Jessner's–35% TCA peel has been found to be as effective as topical 5-fluorouracil chemotherapy in removing both grossly visible and clinically undetectable actinic keratoses but has the added advantages of lower morbidity and greater improvement in associated photoaging (Figure 69-7).²⁰

This peel is also useful to blend the effects of other resurfacing procedures with the surrounding skin. Patients who undergo laser resurfacing, deep chemical peeling, or dermabrasion to a localized area such as the periorbital or perioral region often develop a sharp line of demarcation between the treated and untreated skin. This is because the surrounding photoaging skin has significant dyschromia and textural aging. The treated skin may appear hypopigmented (also known as pseudohypopigmentation) in comparison to the untreated skin. A Jessner's–35% TCA peel performed on the adjacent untreated skin helps to blend the treated area into its surroundings. For example, a patient with advanced photoaging in the periorbital region and moderate photoaging on the remaining face may desire CO₂ laser resurfacing only around the eyes. In this patient, medium-depth chemical peeling of the areas not treated with the laser would improve the photoaging in these regions and avoid a line of demarcation.²¹ It is important to note that when used in combination with other resurfacing procedures such as laser irradiation or dermabrasion, the peel should be performed first, in order to

Table 69-5 Agents Used for Medium-Depth Chemical Peeling

Agent	Comment
40–50% TCA	Not recommended
Combination 35% TCA–solid CO ₂ (Brody)	The most potent combination
Combination 35% TCA–Jessner's (Monheit)	The most popular combination
Combination 35% TCA–70% glycolic acid (Coleman)	An effective combination
88% phenol	Rarely used

CO₂ = carbon dioxide; TCA = trichloroacetic acid.

B, Application of 35% trichloroacetic acid directly after Jessner's solution. C, White enamel frosting (level III) from 35% trichloroacetic acid. D, Desquamation and inflammation 4 days after peel. E, Final results 6 months later.

FIGURE 69-6 Postinflammatory hyperpigmentation unresponsive to topical agents (hydroquinone and tretinoin) and superficial chemical peeling. Full response to medium-depth chemical peel and topical agents. A, Preoperative. B, Six weeks postoperative.

avoid accidental application of the peeling agent onto previously abraded areas of skin (Figure 69-8).

Using either cotton-tipped applicators or 2" × 2" gauze pads, a single even coat of Jessner's solution is applied first to the forehead, followed by the cheeks, nose, and chin, and lastly, the eyelids. Proper application of Jessner's solution causes minimal discomfort and creates a faint frost within a background of mild erythema (level I). After a 1- to 2-minute wait for the Jessner's solution to completely dry, 35% TCA is then applied evenly with one to four cotton-tipped applicators (Figure 69-9). The effectiveness of this peel is directly dependent on the depth of penetration of the peeling solutions, and this depth is a function of the adequacy of degreasing and the amount of both solutions applied. The use of cotton swabs, particularly for the application of TCA, is advantageous because it allows the surgeon to easily vary the amount of solution applied according to the patient's specific needs. The amount of TCA delivered to the skin surface is determined by the number of applicators used, their degree of saturation, the amount of pressure applied to the skin surface, and the duration of their contact with the skin. Four moist cotton-tipped applicators are applied in broad strokes over the forehead and on the medial cheeks. Two mildly soaked cotton-tipped applicators can be used across the lips and chin, and one damp cotton-tipped applicator on the eyelids. The depth of penetration and completion of the peel reaction can be monitored by the level of frosting. A full combination Jessner's–35% TCA peel should obtain a level II to III frosting. One should never overcoat TCA on a level III frosting, as the injury may be pushed to a level that can cause complications (ie, pigmentation or scarring).

Anatomic areas of the face are peeled with TCA sequentially from the forehead to temple to cheeks and finally to the lips

FIGURE 69-7 Medium-depth chemical peel for treatment of diffuse actinic keratoses and photoaging. The Jessner's–35% TCA peel was used as a single treatment, with healing in 8 days. A, Preoperative. B, Frosting after trichloroacetic acid. C, One month postoperative.

and eyelids. Careful feathering of the solution into the hairline and around the rim of the jaw and brow conceals the demarcation line between peeled and nonpeeled skin. Areas of wrinkled skin are stretched taut with the help of an assistant to allow even application of the solution into the folds and troughs. This technique is particularly helpful on the skin of the upper and lower lips. For perioral rhytids, TCA is applied with the wood portion of a cotton-tipped applicator and extended onto the vermilion border (see Figure 69-9D).

Eyelid skin must be treated delicately and carefully to avoid overapplication and to prevent exposure of the eyes to TCA solution.²² The patient should be positioned with the head elevated at 30 degrees, and excess peel solution on the cotton tip should be squeezed out so that the applicator is semidry. With the eyes closed a single applicator is rolled gently from the periorbital skin onto the upper eyelid skin without going beyond the moveable lid. Another semidry applicator is then rolled onto the lower eyelid skin within 2 to 3 mm of the lid margin while the patient is looking superiorly. Excess peel solution should never be left on the lids because it can roll into the eyes, and tears should be immediately dried with a cotton-tipped applicator

because they may pull the solution into the eye by capillary action.

The white frost from the TCA application appears on the treated area within 30 seconds to 2 minutes (see Figure 69-5C). This response is representative of keratocoagulation and indicates that the TCA's physiologic reaction is complete. TCA

takes longer to frost than phenol preparations but a shorter period of time than the superficial peeling agents. The desired endpoint in medium-depth peeling is level II to level III frosting (Table 69-6). Level II frosting is defined as a white-coated frosting with a background of erythema (see Figure 69-3B).

FIGURE 69-8 Combination procedure using perioral–periorbital carbon dioxide laser resurfacing with Jessner's–35% TCA peel over the remaining face. The peel will blend color and texture of the laser-treated areas. A, Preoperative: the eyelids and lips need deeper resurfacing than cheeks, which require only medium-depth injury. B, Four days postoperative: note the difference in rate of healing between laser- and peel-treated areas. C, One year postoperative.

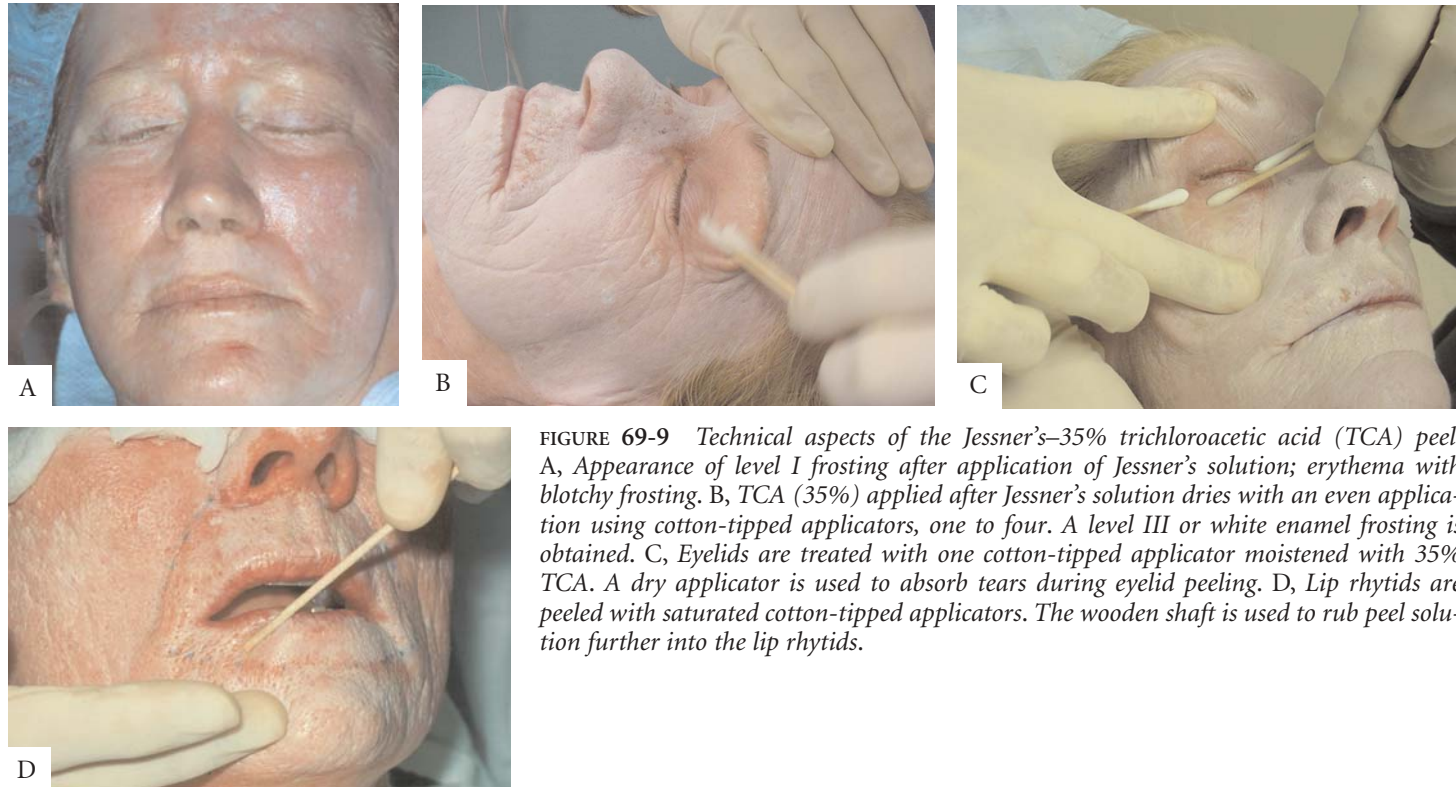

FIGURE 69-9 Technical aspects of the Jessner's-35% trichloroacetic acid (TCA) peel. A, Appearance of level I frosting after application of Jessner's solution; erythema with blotchy frosting. B, TCA (35%) applied after Jessner's solution dries with an even application using cotton-tipped applicators, one to four. A level III or white enamel frosting is obtained. C, Eyelids are treated with one cotton-tipped applicator moistened with 35% TCA. A dry applicator is used to absorb tears during eyelid peeling. D, Lip rhytids are peeled with saturated cotton-tipped applicators. The wooden shaft is used to rub peel solution further into the lip rhytids.

Level III frosting, which is associated with penetration to the reticular dermis, is a solid white enamel frosting with no background of erythema (see Figure 69-5C). A deeper level III frosting should be restricted only to areas of thick skin and heavy actinic damage. Most medium-depth chemical peels achieve a level II frosting, and this is especially important over the eyelids and areas of sensitive skin. Areas with a greater tendency to form scars, such as the zygomatic arch, the bony prominences of the jawline, and chin, should receive no greater than level II frosting.

Before re-treating an area with inadequate frosting, the surgeon should wait at least 3 to 4 minutes after the application of TCA to ensure that frosting has reached its peak. Each cosmetic unit is then assessed, and areas of incomplete or uneven frosting are carefully re-treated with a thin application of TCA. Additional applications of TCA increase the depth of penetration as well as the risk of complications, so one

should apply more solution only to the underfrosted areas.

Although there is an immediate burning sensation as the peel solution is applied, the discomfort begins to subside as frosting occurs and resolves fully by the time of discharge. This peel can be performed with light sedation such as

- Diazepam 10 mg orally
- Meperidine 50 mg intramuscularly
- Hydroxyzine 25 mg intramuscularly

After the skin is cooled with saline the patient will remain comfortable throughout the postoperative period. Cool saline compresses offer symptomatic relief at the conclusion of the peel. Unlike the compresses in glycolic acid peels, the saline following a TCA peel simply provides relief and does not “neutralize” the acid.

Deep Chemical Peeling

Patients with more extreme photoaging skin may require deep chemical peeling, motorized dermabrasion, or laser resurfac-

ing to improve their greater degree of skin damage. As discussed with medium-depth peels, deep chemical peeling leads to production of new collagen and ground substance, down to a level in proportion with the depth of the peel. The peeling agent of choice is the Baker-Gordon phenol peel.

The Baker-Gordon peel uses phenol in a formulation that permits deep penetration into the dermis, deeper than full-strength phenol.²³ The Baker-Gordon formula consists of Septisol solution, croton oil, and tap water added to a solution of phenol, reducing its concentration to 50% or 55% (Table 69-7). The mixture of

Table 69-6 Grades of Frosting with Trichloroacetic Acid Peels

Grade	Visual Finding
I	Erythema with streaky frosting
II	White frosting with visible erythema
III	White enamel frosting, no erythema

Table 69-7 The Baker-Gordon Formula

88% liquid phenol (USP), 3 mL
Tap water, 2 mL
Septisol liquid soap, 8 drops
Croton oil, 3 drops

USP = United States Pharmacopeia.

ingredients is freshly prepared and must be stirred vigorously prior to application due to its poor miscibility. The liquid soap, Septisol, is a surfactant that reduces skin tension, allowing a more even penetration. Croton oil is a vesicant epidermolytic agent that enhances phenol absorption. Recent investigations into the effects of this peel using varying concentrations of both phenol and croton oil have suggested that the procedure's efficacy is more related to the amount of croton oil than phenol.^{24,25}

There are two main variations in deep chemical peeling with the Baker-Gordon phenol formula: occluded and unoccluded. Occlusion of the peeling solution with tape is thought to increase its penetration and extend the injury into the midreticular dermis. This technique is particularly helpful for deeply lined "weather-beaten" faces but should be used only by experienced surgeons because of the higher risk of complications.²⁶ The unoccluded technique as modified by McCollough and Langsdon involves a more vigorous cleansing of the skin and the application of more peel solution.²⁷ This may enhance the efficacy of the solution but without penetration as deeply as in an occluded peel. In the hands of a skilled and knowledgeable surgeon both methods are safe and reliable in rejuvenating advanced to severe photoaged skin. Deep chemical peeling can significantly improve or even eliminate deep furrows as well as other textural and pigmentary irregularities associated with severe photoaging (Figure 69-10). A remarkable degree of improvement is the expected result of deep chemical peeling when performed properly on carefully selected patients.

FIGURE 69-10 Advanced photoaging of perioral rhytids treated with Baker-Gordon phenol peel. A, Preoperative photograph, demonstrating perioral rhytides, textural and pigmentary changes with epidermal growths. B, Postoperative photograph, 2 years later. Note the phenol peel maintains correction for many years.

The patient undergoing deep chemical peeling must understand and be willing to accept the significant risk of complications and the increased degree of morbidity. The most notable complications include scarring, textural changes such as "alabaster skin" or "plastic skin," and pigmentary disturbances. It is not uncommon for patients to experience postoperative erythema that can take many months to resolve and that may be followed by variable hypopigmentation (Figure 69-11). Male patients and patients with darker complexions are less favorable candidates for deep chemical peeling since the hypopigmentation is less easily camouflaged. Since phenol is cardiotoxic, preoperative evaluation includes a complete blood count, liver function tests, serum urea nitrogen and creatinine and electrolyte determinations, and a baseline electrocardiogram. Any patient who has a history of cardiac arrhythmias or who is taking a medication known to precipitate

arrhythmias should not undergo a full-face Baker-Gordon phenol peel. Patients with a history of hepatic or renal disease are also poor candidates.

Compared with medium-depth and superficial peeling, the Baker-Gordon phenol peel is a time-consuming procedure and must be performed only in a properly equipped facility. The required waiting period after the treatment of each cosmetic unit limits the rate of cutaneous absorption, thereby preventing the serum levels of phenol from reaching a dangerous peak during the procedure. Intravenous hydration with 1 L of lactated Ringer's solution before the procedure and another liter during the peel also promotes phenol excretion and prevents toxicity. Continuous electrocardiography, pulse oximetry, and blood pressure monitoring are mandatory during the entire perioperative period. Any abnormalities, such as a premature ventricular contraction or premature atrial contraction, necessitate abrupt stoppage of the procedure and careful evaluation for toxicity.²⁸ Oxygen is supplemented throughout the procedure as some physicians feel that it has a protective effect against cardiac arrhythmias.

After thorough cleansing and degreasing of the skin, the chemical agent is applied sequentially to six esthetic units: forehead, perioral region, right cheek, left cheek, nose, and periorbital region. There is a 15-minute time interval between the

FIGURE 69-11 Complications from Baker-Gordon phenol peel with prolonged nonhealing, resulting in hypopigmentation and marbled scarring.

treatment of each cosmetic area, allowing 60 to 90 minutes for the entire procedure. Cotton-tipped applicators are used with a similar technique as discussed with the medium-depth Jessner's–35% TCA peel, though less solution is used because frosting occurs very rapidly (Figure 69-12). Occlusion of the peel can be accomplished with strips of waterproof zinc oxide tape (eg, 0.5 inch Curity tape) to each cosmetic unit just after the phenol is applied. Care is exercised to extend the peel slightly beyond the mandibular rim to conceal the demarcation between treated and untreated skin. The last esthetic unit, the periorbital skin, is treated cautiously and conservatively to avoid overpenetration which can lead to ectropion or scarring. It is important to remember that diluting a phenol compound with water may increase its penetration, so mineral oil rather than water should be used to flush the eyes if contact occurs.

Application of the peeling agent creates an immediate burning sensation, which lasts for 15 to 20 seconds, subsides for 20 minutes, and then returns for the next 6 to 8 hours. Ice packs may be applied as necessary for patient comfort. Narcotics are usually prescribed on discharge for adequate pain control. Systemic steroids are also administered by some surgeons to lessen the inflammatory response. For untaped peels, petrolatum is applied and a biosynthetic dressing can be used for the first 24 hours.

FIGURE 69-12 Rapid frosting from small amounts of Baker-Gordon phenol solution applied with cotton-tipped applicators.

Mechanical Resurfacing Procedures

During the past five decades, dermabrasion using a rotating abrasive surface attached to a power-driven hand engine has been considered a premier skin resurfacing procedure for facial scars. It has generally been regarded as a deep resurfacing modality based on its depth of injury and its prolonged healing time. The original descriptions of modern dermabrasion involved the use of a wire brush, which remains in use today.^{29,30} In 1957 the diamond fraise was introduced and became the preferred instrument for dermabrasion by some surgeons because it is less aggressive and more forgiving than the wire brush.³¹ Recently there has been a resurgence of interest in manual dermasanding which allows for more deliberate and controlled skin planing and microdermabrasion.^{32,33}

Microdermabrasion

Microdermabrasion is considered superficial because it removes the stratum corneum and outer epidermis. Its classification as light or very light in comparison to the other superficial resurfacing procedures depends on the techniques and aggressiveness of the operator. The microdermabrasion unit's handpiece is a closed system, which propels aluminum oxide crystals at the skin at high speeds and simultaneously removes them with suction. These units were developed commercially in the mid-1990s and are currently in widespread use in both physicians' offices and nonmedical esthetic spas. Microdermabrasion may be indicated for acneiform conditions, pigmentary dyschromias, and as a "lunchtime" procedure for facial rejuvenation in all skin types.^{34,35} Both the patient and physician must understand that the degree of objective improvement with microdermabrasion may be limited. This is a repetitive procedure performed every 2 weeks along with appropriate cosmeceutical agents.

Ideal candidates for microdermabrasion typically are young patients who desire limited facial rejuvenation without "downtime" and thus must have realistic expectations of the limited anticipated results. Patients often report that their skin has a smoother texture and that cosmetics are easier to apply and blend in with their skin more easily (Figure 69-13). Although the role of microdermabrasion in facial rejuvenation has grown dramatically since these units were developed, the scientific data to justify their use has been lacking.

Manual Dermasanding

Manual dermasanding involves abrading the skin by hand using silicon carbide sandpaper or wallscreen commercially available at any hardware store. Its classification as a wounding agent is entirely dependent on the type of paper used, the force applied by the surgeon, and the duration of contact with the skin. Although it can be used to produce a wound as deep as with wire brush dermabrasion or several passes with a pulsed CO₂ laser, manual dermasanding is probably most commonly used as a medium-depth or "minimally deep" resurfacing modality (Table 69-8).

Manual dermasanding is most often used for resurfacing localized regions to minimize the appearance of a scar or to

FIGURE 69-13 Microdermabrasion: aluminum oxide crystals are propelled at high speeds within a closed system and removed with suction.

Table 69-8 Advantages of Manual Dermasanding over Motorized Dermabrasion

Greater control over depth of injury, particularly on the lips and orbital rims
Blending of abraded areas into adjacent unabraded areas accomplished more easily and with better results
Lower cost and greater simplicity of instrumentation and set-up
No risk of aerosolizing infectious particles
Possibly lower incidence of postinflammatory hypopigmentation ^{37,38}

blend or enhance the effects of a medium-depth chemical peel or a combination procedure.³⁶ It can be used following CO₂ laser resurfacing to feather the transition into hair-bearing areas that are inaccessible to the laser. Manual dermasanding of the eyebrows and hairline and gentle abrasion of the upper neck at the inferior aspect of the laser-irradiated zone are all effective at minimizing lines of demarcation between treated and untreated skin (Figure 69-14). It can also be useful immediately after laser resurfacing for stubborn rhytids, particularly in the perioral region. Manual dermasanding can improve the outcome by producing a slightly greater depth of injury in a controlled fashion where further thermal injury would be risky. It will also remove adherent necrotic debris and thermal damage, thus speeding up the healing process. Similarly a medium-depth chemical peel can be immediately followed by manual dermasanding on the more troublesome areas to enhance the results and also along the borders of the peeled skin to blend the effects. Our clinical

FIGURE 69-14 Manual dermasanding using 320-grit silicone carbide sandpaper to blend carbon dioxide laser resurfacing into the eyebrow area.

experience suggests that dermasanding after a Jessners–35% TCA peel may yield impressive postoperative results that approach those seen with either motorized dermabrasion or CO₂ laser resurfacing in patients with photoaging skin. (Figure 69-15). This combination is particularly helpful in patients who may not tolerate the greater degree of sedation often necessary with CO₂ laser resurfacing.

The necessary materials for manual dermasanding include silicon carbide sandpaper or wallscreen. Both may be purchased in a variety of grades: fine grade (no. 400), medium grade (nos. 220–320), and coarse grade (no. 180). The sandpaper is easy to use because of its flexibility and is easily cut into smaller pieces, which can be steam autoclaved. A 1.5" × 3" piece of sterilized sandpaper is wrapped around either the barrel of a 3 mL syringe or a rolled-up 2" × 2" gauze pad and moistened with saline or a soap-free cleanser for lubrication. A 1% solution of lidocaine with epinephrine may be used instead if additional anesthesia is necessary. Both back-and-forth and circular motions are used to gradually abrade the skin layer-by-layer until the hills and valleys are softened or adjacent areas are blended to the desired degree. Coarse grades may be used initially for “debulking,” followed by finer grades later in the procedure. The fine grade is used to blend delicate areas of skin, such as around the eyelids. At the completion of the procedure the dark-colored silicon carbide particles remaining on the skin surface should be rinsed off because there is a theoretical risk of their becoming implanted.

Motorized Dermabrasion

Some of the units most commonly used today are the Bell hand engine (Bell International, Burlingame, CA), the AEV-12 hand engine (Ellis International, Madison, NJ), and the Osada surgical hand-piece (Osada, Inc., Los Angeles, CA). A topical refrigerant spray (Frigiderm, Frigiderm Corp., Costa Mesa, CA) is used to produce anesthesia and to harden the skin as it is abraded. The spray immobilizes the topographic features so that there is no distortion by the pressure of the abrasive instrument.

The two abrasive instruments most often employed with these units are the wire brush and the diamond fraise. The wire brush has numerous small-caliber stainless steel wires that project circumferentially from the curved side of a cylindrical hub. A diamond fraise consists of a stainless steel cylinder to which industrial-grade diamonds are bonded to create the abrasive surface. As compared with wire brush instruments, diamond fraises are manufactured with a greater variety in shape, width of abrasive surface, wheel diameter, and coarseness of grit. The wire brush is more aggressive and cuts more quickly and more deeply into the skin with each stroke, thereby posing a greater risk of injury and requiring more skill to operate. Although the diamond fraise is generally safer and more forgiving, it may not yield the degree of improvement possible with the wire brush, especially for more stubborn conditions such as deep acne scarring (Figure 69-16).

Because dermabrasion with either instrument is highly technique-dependent and its learning curve is steep, there may be considerable variability in the clinical results obtained by different operators. It is very important for beginning dermabraders to attain thorough hands-on instruction from an experienced operator in order to be adequately trained. The proper techniques for motorized

D, One-month postoperative photograph revealing improvement in all areas.

dermabrasion have also been the subject of comprehensive reviews in the literature.^{37–39} Careful evaluation of the depth of injury throughout the procedure is critical to ensure sufficient depth for optimal results without penetrating beyond the desired level and risking scarring. Because of the potential for aerosolization of infectious particles during dermabrasion, appropriate precautions are mandatory to protect the operating room staff.

Moderate to severe acne scarring is the most notable indication for dermabrasion, as laser resurfacing has yielded variable results and chemical peeling is generally disappointing (Table 69-9). Dermabrasion selectively planes off the “hilltops” that surround the atrophic “valleys,” whereas chemical peeling and lasers produce an injury of equivalent depth in both areas (Figure 69-17).

FIGURE 69-16 Mechanical dermabrasion is performed with a diamond fraise over rigid skin cooled with a topical refrigerant spray.

The use of CO₂ lasers has revolutionized resurfacing techniques for photoaging skin. Because of the varying properties of lasers, the physician must be thoroughly familiar with the physics, technology, and operating geometry of the laser. Whether or not the laser is pulsed, continuous, or computer scanned impacts the physiologic response. The level of destruction is different for each laser; thus, the physician should be familiar with the laser of choice. For reliable vaporization of skin layers, a pulsed laser with a computer-generated scanner (CPG) makes the procedure safer. Each pass destroys 75 to 100 μ m of tissue with a zone of thermal damage below. Thus, two to three passes with an ultra-pulse CO₂ laser is maximal for rejuvenation of photodamaged skin—a deep resurfacing technique. The zone of thermal damage causes collagen shrinkage or contraction, which is a unique characteristic for CO₂

laser resurfacing. This gives an added benefit to wrinkle treatment that is not found with either dermabrasion or chemical peeling. This is especially true with perioral and periorbital wrinkled skin.

CO₂ laser resurfacing requires anesthesia: either general operative anesthesia or tumescent local anesthesia for the entire face. Laser safety precautions are needed to prevent laser fire or laser injury to the employees, the unprotected skin, the teeth, or even the endotracheal tube for general anesthesia. These must be protected with appropriate laser-resistant materials: eye shields, teeth guards, and appropriate laser-resistant endotracheal tube wrapping. Using the CPG the operator must remember that the pulse overlap for a chosen pattern size and shape is set so that each pattern is made to touch yet not overlap. The density is an important parameter in determining laser beam intensity. One

Table 69-9 Conditions for Which Motorized Dermabrasion May Be the Preferred Resurfacing Modality

Acne scarring
Surgical or traumatic scars
Benign neoplastic processes (multiple trichoepitheliomas, syringomas, adenoma sebaceum)
Malignant and premalignant neoplastic processes (skin cancer treatment and prevention in basal cell nevus syndrome and xeroderma pigmentosum as well as management of extensive carcinoma in situ)
Extensive epidermal lesions such as epidermal nevi
Decorative or traumatic tattoos unresponsive to the pigmented lesion lasers
Rhinophyma

FIGURE 69-17 Full-face dermabrasion performed for acne scars. A, Preoperative: shallow and atrophic scars most amenable to dermabrasion. B, Postoperative dermabrasion prior to biosynthetic dressing. C, Three months postoperative.

should not go above a density of 6 with facial resurfacing. Each pass should cover the face fully, vaporizing the tissue to ash and debris, which is wiped off between each pass. The visual end point is a mauve or slightly yellow discoloration indicating denaturation of dermal collagen. Further passes cause deeper dermal scarring. Special care must be taken over scar-prone areas such as the bony prominences of the chin, jawline, malar ridge, and forehead.

The eyelid is treated more conservatively as collagen can precipitate an ectropion, with or without scar. The lips are treated with two to three passes but not over the vermilion line as this can flatten the lip in an unesthetic manner. Bordered facial creases such as the jawline and neck should be blended with light chemical peeling and minimal dermasanding to soften the demarcations of treated and untreated photoaging neck skin.

Of equal importance to the operative technique is proper postoperative wound care. Partial thickness skin wounds heal fastest when kept at or near 100% humidity or occlusive or semi-occlusive dressings. Nonstick pads and hydrogels are changed daily to remove coagulation debris and necrotic tissue. This is important to prevent secondary wound infection with resultant scarring. My usual postoperative program is 4 to 5 days of biologic hydration, changed daily, followed by 5 days of 0.25% acetic acid soaks (1 teaspoon white vinegar in 1 pint of warm water) four times a day followed by occlusive ointments such as petrolatum ointment or eucerin cream. After 10 days, the patient is usually ready for light cleansers and creams and a mild topical steroid cream for erythematous areas (Table 69-10).

Full makeup can be used with sunscreen after 2 weeks. Sunscreen with strong sun avoidance should be adhered to for 2 to 3 months to prevent postlaser hyperpigmentation.

Herpes simplex infection can occur during the healing period following medium-depth or deep ablative injury. Antiviral prophylaxis should begin during the operative session and continue beyond reepithelialization, 10 to 14 days. If infection occurs, punctate vesicles occur with pain and full treatment therapy should be carried out to prevent scarring.

Delayed wound healing may be a sign of bacterial infection, or resurfacing too deep to heal normally. It should be treated with biologic dressings, appropriate

Table 69-10 Avoiding Complications Postoperatively for Skin Resurfacing

<p>Use proper occlusive wound care, and monitor daily.</p> <p>Watch for pain; it may indicate herpes simplex virus infection.</p> <p>Watch and treat early bacterial and fungal infection.</p> <p>Evaluate closely and follow areas of poor healing.</p> <p>Treat prolonged erythema or early scarring early and vigorously.</p>
--

antibiotics, and cortisones as indicated. The diligent physician must watch his or her patients carefully during the postoperative course to catch these complications early and prescribe appropriate treatment. This will prevent the permanent complications of pigmentation changes and scarring.

Conclusions

The general public has a renewed interest in skin rejuvenation. Although there are many techniques presently available, it is up to the cosmetic physician to match the appropriate tool with the patient's needs, to give proper benefit with the least risk. These tools call for special training and experience, and as one gains further knowledge and skill, these procedures generally occupy a rewarding part of one's practice.

Alloplastic Esthetic Facial Augmentation

Bruce N. Epker, DDS, MSD, PhD

Alloplastic esthetic facial augmentation of the chin, mandibular angles and inferior borders, skeletal nasal base, and cheeks is the standard of care, as opposed to autogenous augmentation. A variety of approved alloplastic facial implants are available to the surgeon. In general, marketed implants are proven nontoxic, noncarcinogenic, and nonantigenic, and they are inert in body fluids.¹⁻³ Moreover, the optimal material is user friendly; it is easily modified, maintains the desired shape, is not mobile, and is cost effective.

No single implant possesses all of these optimal properties, yet some are clearly closer to these ideals than others. The more commonly employed esthetic facial implants, which most closely achieve these ideals, include porous polyethylene, silicone, and polytetrafluoroethylene (PTFE) and high-density polyethylene. It is not the intent of this article to compare and contrast these facial implant materials as they are all approved and acceptable and each is espoused by different surgeons as the preferred material for cosmetic esthetic facial augmentation.

To achieve predictable and successful results with alloplastic esthetic facial augmentation, special attention to the differential diagnoses established via a detailed patient evaluation,⁴⁻¹¹ meticu-

lous surgical technique, proper modification, and placement of the implant are essential. Accordingly, this chapter emphasizes and details these aspects of esthetic facial augmentation.

An additional item discussed herein is still controversial—the use of antibiotics with surgery for alloplastic facial augmentation. A recent survey of surgeons revealed a spectrum of opinions. Approximately 30% of surgeons use no antibiotics or intravenous antibiotics only during surgery. About an additional 30% continue antibiotics for 1 to 3 days postoperatively, and 40% use them for 4 to 7 days postoperatively.¹² Unfortunately, the incidence of infection with the various regimens is not available; however, the overall incidence is very low. I use a single intraoperative dose of intravenous antibiotics at the commencement of surgery; generally, I use cephalosporin regardless of whether an extraoral or intraoral approach is taken.^{13,14}

Finally, alloplastic nasal augmentation is not discussed here as, in general, I prefer autogenous materials for this purpose.

The Chin

Alloplastic chin augmentation is generally reserved for the patient who has lax and/or redundant soft tissues or who is undergoing simultaneous neck surgery, such as

cervicofacial liposuction, platysma plication, or rhytidoplasty. When this approach is used, special care is directed to evaluating for a tapered chin appearance or “marionette grooves,” which frequently exist in the older patient population. Many commercially available alloplastic chin implants *do not* provide adequate lateral augmentation and posterior extension in the parasymphysis regions to correct these problems. Therefore, the modification or selection of a properly sized and shaped alloplastic implant is important.

Preoperative planning consists of a systematic sequential esthetic clinical evaluation and a lateral cephalometric evaluation to determine the specific shape and magnitude of the augmentation.

Chin augmentation has long been an esthetic adjunct to numerous orthognathic, craniofacial, and cosmetic procedures. Various authors have proposed and extolled the advantages of their “modifications” of this basic operation, but, despite its widespread application, its esthetic demands and results are not yet well specified.¹⁵⁻¹⁷

This procedure is planned to achieve specific esthetic objectives:

- Frontally, a well-defined smooth inferior border of the mandible that separates the lower third of the face from

the neck proper is important for good esthetics. A lack of this distinct border detracts from good chin-neck esthetics. A posteriorly well-extended implant and proper inferior placement, at the inferior mandibular border, help to achieve this objective.

- The esthetically attractive chin is balanced in width with the other facial features, especially the bizygomatic and bigonial facial widths. Many individuals with recessed chins also have dolichocephalic facial features, or what has been described as the “pointed chin” or “witch’s chin.” When this condition exists and is not deliberately modified, augmentation of the chin often results in an accentuation of the existing pointed chin. In persons with this facial structure, augmentation of the chin should be accomplished by *enhanced lateral augmentation*. This is accomplished by modifying standard chin implants as described in the surgical technique discussion to follow.
- The esthetically attractive chin has no evidence of parasymphyseal depressions or grooves. These soft tissue marionette grooves may exist independently of or in concert with the pointed chin. This condition is accentuated in most older individuals. When these grooves exist, special attention is given to lateral or parasymphyseal augmentation, similar to that used to improve the pointed chin.
- The esthetics of anteroposterior chin position is determined by evaluating the cephalometric values: NB:Pog, A:Pog, and subnasale perpendicular. The normal relations of these are as follow: NB:Pog line has the lower incisor tip and bony chin prominence on a 2:1 to 1:1 relationship. Line A:Pog has the tip of the lower incisor on or 1 to 2 mm posteriorly positioned. The soft-tissue chin is 4 mm distal to SN perpendicular. These values are used to determine the optimal relationship of the hard

and soft tissues of the chin relative to lower incisor position, lower lip, and upper lip. Two qualifiers regarding esthetic anteroposterior chin augmentation are important in the context of the proposed cephalometric treatment planning. First, *do not* advance the bony chin beyond the anterior position of the lower incisor as determined by the NB:Pog and A:Pog criteria, even when subnasale perpendicular soft tissue values suggest otherwise. Second, in older individuals, often those undergoing cervicofacial liposuction, rhytidoplasty, or both, anteroposterior augmentation of the chin to its “ideal” hard and soft tissue values generally results in an excessive amount of chin projection *in the eyes of the patient*. This is perhaps because the individual has had the deficient condition for so many years that he or she has become accustomed to it.

In sum, before performing esthetic chin augmentation, consider all of these criteria and *do not* rely primarily on achieving the ideal anteroposterior chin position; otherwise, the esthetic results in a significant number of patients will fall short of the desired results.¹⁸

This procedure is most often performed under local anesthesia with sedation, along with other procedures such as blepharoplasty, rhinoplasty, cervicofacial liposuction, and rhytidoplasty.

With a surgical marking pen, the true chin and neck midlines are marked to aid subsequently in precise implant positioning; also, the planned submental incision is marked.¹⁹ When this procedure is being performed under local anesthesia with sedation, bilateral inferior alveolar nerve blocks are given with 2% lidocaine with 1:100,000 epinephrine. Next, the submental area where the incision is to be made and the entire area to be undermined subperiosteally are infiltrated with about 7 to 10 cc of local anesthetic with epinephrine.

Seven to 10 minutes are allowed to pass after infiltration of the local anesthetic.

The implant is to be placed through a submental incision of about 5 cm, made just distal to the normal submental crease. When the incision is made in the naturally occurring submental crease, it can accentuate this crease and cause an unesthetic dimpling in that area. The incision is made through the skin and subcutaneous tissue, and hemostasis is obtained with needle-point diathermy. The incision is then carried directly down to the inferior border of the mandible and through the periosteum with diathermy cutting.

After identification and exposure of the inferior border of the mandible, a subperiosteal dissection is completed along the entire inferior aspect of the mandibular symphysis, *well posterior* on each side to the region of the gonial notch. Following exposure of the inferior border, the subperiosteal dissection is carried superiorly beginning anteriorly. Laterally it is extended superiorly only enough to allow the mental neurovascular bundles to be identified and visualized. No attempt is made to expose them extensively because doing so increases the potential for neurosensory defects to the lower lip and chin.

An extended preformed implant is generally selected, one that is configured in such a way that it extends posteriorly into the molar region.^{8,17,19} In patients with a tapered (pointed) chin or marionette grooves, the selected implant is modified. The selected implant is 2 to 4 mm greater in the anteroposterior dimension than the desired anteroposterior augmentation.¹⁹ This dimension is reduced at surgery and, in essence, accentuates the parasymphysis augmentation to improve the pointed chin or parasymphysis depressions. These alterations are made to provide a more lateral (parasymphysis) augmentation than is available in most preformed alloplastic chin implants (Figure 70-1).

After trial insertion of the implant, the surgeon determines the need for addition-

FIGURE 70-1 Reduction of the anteroposterior thickness effects a rounding of the chin and visibly changes a pointed chin into a more rounded one. Adapted from Epker BN.¹⁹ p. 27.

al adaptations in either the implant or the subperiosteal dissection to ensure that it rests passively on the lateral and inferior borders of the mandible. The mental neurovascular bundles are visualized during the trial insertion to make certain that the implant does not encroach on them. If this does occur, these areas are marked in situ on the implant, and the implant is removed and these areas relieved.

On completion of all adaptations, two holes are drilled through the implant and outer cortex of the underlying bone. The implant midline and marked facial midline are checked, and the implant is then stabilized with titanium screws to prevent inadvertent early postoperative displacement and to avoid mobility of the implant. If the implant is porous, it is vacuum impregnated with an antibiotic solution before it is definitively stabilized into position.

The incision is closed in layers with 4-0 polyglactin 910 platysma muscle sutures, 4-0 chromic gut subcutaneous sutures, and 5-0 braided polyester or monofilament nylon skin sutures. Antibiotic ointment and a perforated film absorbent dressing (Telfa) are placed over the incision, and a multiple-layered 1.25 cm tape dressing is placed to reduce edema and or hematoma formation. The dressing is left in place for

48 hours. When additional neck surgery is done, as is frequently the case with this procedure, a more extensive neck pressure dressing may be placed. Generally, intraoperative antibiotics are used and no postoperative antibiotics given.

Sutures are removed on the fifth postoperative day, and after 7 to 10 days any areas of irregularity caused by edema or hematoma are treated by deep massage and heat. No other special treatment is needed.

Complications that occur with this procedure vary and are generally minimal.¹⁸

The patient seen in Figure 70-2 is shown before and after alloplastic chin augmentation, emphasizing lateral parasymphysis augmentation to reduce the pointed appearance of the chin and the marionette grooves.

Mandibular Angle and Inferior Border

A well-defined mandibular angle and inferior mandibular border are important to an esthetically pleasing face. Indeed, proper definition in this region is the very basis of visually separating the face from the neck, thereby making them distinct from one another. When this area is not well defined, the face and neck become confluent and unattractive. Accordingly, in selected individuals esthetic augmentation of the mandibular angles and inferior mandibular borders is to be considered.¹⁹

The differential diagnosis of poor definition of the angle and inferior mandibular borders is important; one must consider whether it results from abnormal skeletal support, cervicofacial lipomatosis, soft tissue redundancy, or a combination of these conditions

A routine clinical evaluation via multidirectional observation and palpation can readily allow the surgeon to diagnose cervicofacial lipomatosis and/or soft tissue redundancy. A standard lateral cephalometric evaluation of the mandibular plane angle is used to determine the presence and degree of an underlying skeletal sup-

port abnormality. The normal mandibular plane angle (FH:Go-Gn) is 24°. One then draws the normal inferior border line angle. This in essence represents the newly to be constructed inferior mandibular border and allows the surgeon to determine the specifics of vertical and anteroposterior implant design.

The vertical linear distance between the two mandibular planes (the patient's and the constructed normal) in the gonial angle is measured. This distance is the amount of vertical change in the angle that would be indicated to create ideal skeletal support. Generally, the older the patient, the less one augments this area all the way to the ideal. The lateral superior height is measured so that it extends to above the midramus. Anteroposteriorly the mental foramen is generally the limiting extent of the implant. Finally, frontal face esthetics is evaluated to determine the approximate desired lateral width of the implant in the angle-ramus area. In the esthetically pleasing face, the mandibular angle area is medial to the zygomatic area so that the face tapers slightly from the zygomatic area.

When soft tissue conditions coexist with the defined underlying skeletal abnormalities, correction of the skeletal deformity may produce significant improvements in the associated soft tissue conditions. Finally, when identifiable skeletal and major associated soft tissue problems coexist, the skeletal surgery described herein can be done either primarily or simultaneously with liposuction or rhytidoplasty; however, I prefer to perform the face- and neck-lift secondarily.

Once the above data are established, a preformed porous polyethylene implant is selected and appropriately modified at surgery as discussed in the surgical technique section to follow.²⁰⁻²³

Surgery can be performed with general anesthesia or intravenous sedation and local anesthesia.¹⁹ Inferior alveolar nerve blocks are given bilaterally. In addition, a 2% local anesthetic containing 1:200,000

FIGURE 70-2 Preoperative (A and C) and postoperative (B and D) photographs of a patient who underwent chin augmentation to reduce a pointed chin appearance illustrating more lateral augmentations.

epinephrine is infiltrated bilaterally just lateral to the mandible from midramus to the angle and along the entire lateral aspect of the mandibular body to the region of the mental neurovascular bundle. Approximately 10 cc of local anesthetic is infiltrated on each side. The surgical procedure is begun about 7 to 10 minutes after injection of the local anesthetic.

The incision is begun posterolaterally, just anterior to the bulge of the fat pad, midway down to the depth of the sulcus. This incision is made through the mucosa, buccinator, and periosteum, anteriorly to the region of the canine tooth; however, as one proceeds anteriorly into the premolar region, the incision is initially carried only through the mucosa to avoid inadvertently transecting the mental neurovascular bundle.

After the mental neurovascular bundle is exposed, the remainder of the dissection is done entirely in the subperiosteal tissue plane. This begins anteriorly with deliberate mobilization of the tissues around the mental neurovascular bundle, carrying the dissection inferiorly subposteriorly to the inferior border of the mandible. The dissection is next carried posteriorly to the angle of the mandible, while the masseter

muscle is elevated superiorly about half way up the ascending mandibular ramus. No attempt is made to penetrate the periosteum at the inferior and posterior borders of the mandible.

In the region of the mandibular angle and along the posterior border, a J-shaped periosteal elevator is used to complete the subperiosteal dissection (Figure 70-3).

Once the lateral body and ascending ramus of the mandible are exposed in the subperiosteal tissue plane, the periosteum can be opened with finger dissection at the inferior aspect, as necessary for adequate relaxation.

My preferred augmentation material is porous polyethylene, which is available in several preformed sizes and shapes. The approximate size and shape of the implant should be determined previously, as discussed in the previous section. On the basis of the measurements, the preformed implant is modified during the actual surgical procedure. After the initial modifications, before a try-in placement, the implant is vacuum impregnated with an antibiotic solution. This is achieved by placing the implant into a 60 or 90 cc syringe in which the antibiotic solution is present, inserting the plunger of the

syringe and evacuating all air, and repeatedly withdrawing the plunger forcefully while holding a finger over the end of the syringe. This removes the air from the porous implant and replaces it with the concentrated antibiotic solution. The procedure requires considerable effort and pressure, often taking a few minutes. When this process reaches its end point, the implant sinks in the solution.

The initial try-in is then done. Additional modifications are often necessary, such as notching the implant in the region of the mental neurovascular bundle and molding it slightly into a curved

FIGURE 70-3 Use of a J-shaped elevator to remove the tenacious angle muscle attachments. Adapted from Epker BN.¹⁹ p. 84.

configuration to adapt it more precisely to the lateral aspect of the ramus and body of the mandible. To bend the implant, it is placed in sterile hot saline; this removes its original memory and allows it to be readily molded.

The implant is inserted into position. Once inserted and its inferior and posterior aspects “locked” beneath the posterior and inferior borders of the mandible, the implant is inspected for any final adaptations. At this point the implant is removed, placed back into the antibiotic, and the wound packed.

The identical dissection is then completed on the opposite side, and before insertion of the second implant, the same basic modifications are made to a second implant so that the implants are virtual mirror images of one another. This assumes that the patient has a symmetric deformity in this area. When asymmetry exists, it is identified and recorded preoperatively, and the modification of the implants for independent shaping of the right and left sides is done preoperatively.

After completion of the dissection on the second side and the try-in of the second implant, both implants are ready for final insertion. The implants are irrigated free of blood and debris and vacuum impregnated again with the antibiotic solution. One or two monocortical titanium screws are placed to stabilize the implant (Figure 70-4).

The implant is inserted on one side first, and the incision is closed in two layers. The first layer is the periosteal and buccinator muscle, which is closed with 3-0 chromic sutures. Then, with a running 3-0 chromic horizontal mattress suture, the mucosal layer is closed. Interrupted sutures are finally placed as needed to effect a watertight closure of the incision. After completion of closure on one side, the second antibiotic-impregnated implant is placed into the opposite side, and the stabilization and layered closure are completed.

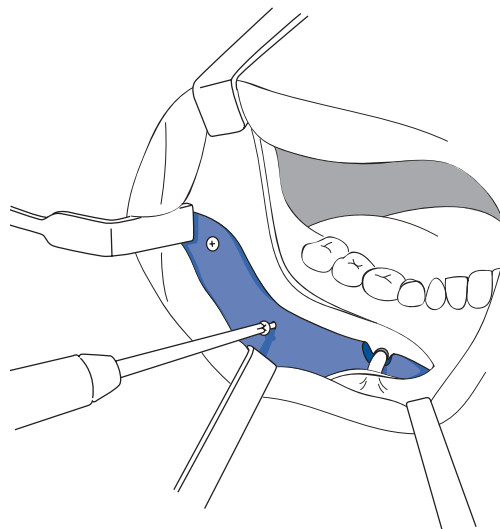

FIGURE 70-4 Stabilization of the implant with monocortical titanium screws. Adapted from Epker BN.¹⁹ p. 89.

A multilayered 1.25 cm tape dressing is placed so that the tape extends from the cheek area well inferiorly into the neck, thereby applying primarily lateral pressure to this area to minimize postoperative edema and hematoma. When this dressing is applied, it is placed so that the pressure is directly applied laterally. This dressing is left in place for 48 hours. On removal of the tape dressing, the patient is instructed to use heat to decrease the swelling.

Postoperatively the patient is placed on a clear liquid diet for the first 24 hours and then advanced to a full liquid diet for 4 to 5 days. After this time, he or she may begin a mechanical soft diet for 10 to 14 days until the intraoral incision lines are completely healed. After approximately 2 weeks, the implants are self-stabilized by fibrous soft tissue ingrowth, and the incisions are completely healed; at this time unlimited physical activity is permitted.

At the 2-week period patients generally have some limitation in the range of mandibular motion because of the surgery and its sequelae. Accordingly, they are placed on a regimen of active jaw exercises, three times a day for approximately 5 minutes each. These exercises consist of maximum interincisal opening, protrusion, and clenching. Generally, within 7 to

14 days asymptomatic full range of mandibular motion is obtained.

This procedure is designed to accentuate and normalize the mandibular angle and inferior mandibular border to set the lower third of the face off clearly from the neck, making each into a discrete esthetic unit. Additionally, this procedure effects some tightening of the overlying soft tissues, affecting a “mini face-lift” in individuals who have slight skin laxity and/or mild jowls (Figure 70-5). The procedure is often done in concert with other orthognathic, reconstructive, and cosmetic facial procedures.

Skeletal Nasal Base

The indication for skeletal nasal base augmentation is based on a clinical esthetic facial evaluation in individuals who are not Class III maxillary deficient. This condition is frequently associated with inherent nasal deformities.^{19–24} The typical clinical esthetic findings are outlined below.

Frontally the alar base width is highly variable but most often is somewhat narrow, and the upper lip vermilion is often deficient or exhibits a “gullwing” appearance. Moreover, the patient has deficiency in the paranasal areas, as opposed to prominent soft tissue nasolabial folds (Figure 70-6A). In profile, flat to concave paranasal anatomy and a groove ratio of nasal tip–subnasale to subnasale–alar is approximately 1:1 instead of the normal 2:1. In addition, the following most often coexist: a relatively prominent nose, poor nasal tip projection, unesthetic nasal tip rotation (droop), and lack of a supratip break (Figure 70-6B).²⁵

Anatomically, the skeletal nasal base is the area that, in part, determines paranasal fullness, alar base position, nasal tip support, *relative* nasal prominence, and internal nasal valve (liminal valve) function. Accordingly, the esthetics of these areas depends on but is not totally determined by the underlying skeletal anatomy.

FIGURE 70-5 Preoperative (A and C) and postoperative (B and D) photographs of a patient who underwent mandibular angle-inferior border augmentation. Note the tightening of soft tissues with a reduction of the laxity, especially in the jowl. Reproduced with permission from Epker BN.¹⁹ p. 94.

FIGURE 70-6 A and B, Patient with a Class I occlusion and classic features of skeletal nasal base deficiency. Reproduced with permission from Epker BN.¹⁹ p. 116.

The cephalometric analysis may or may not exhibit evidence of maxillary deficiency in the presence of a Class I occlusion. This is true because these cephalometric values have traditionally been determined by measures around a point that may not be deficient. However, the piriform rims per se, as well as the immediate adjacent areas of the maxilla, are deficient. Unfortunately, these areas are not amenable to measurement or evaluation with conventional lateral cephalometrics.

Individuals to be considered for skeletal nasal base augmentation are those with *isolated skeletal nasal base deficiency* who possess a functional Class I relationship and are not candidates for orthognathic surgical consideration. In some individuals, in whom a skeletal Class III deformity exists in the mandible and is corrected with an osteotomy to set back the mandible, the skeletal nasal base deficiency can be simultaneously corrected by skeletal nasal base augmentation.²⁴ Finally, this procedure is indicated in certain individuals who present for rhinoplasty and/or septorhinoplasty.²⁵

Two approaches to the surgery are used, depending on the severity of the deficiency as determined by the clinical findings: a limited approach and an extended approach. The limited approach is used when the magnitude of augmentation planned is minimal (2–3 g of hydroxylapatite per side). In such individuals the alar base width is generally normal, and in profile the nasal size, tip projection, and a supratip area are essentially normal. This approach *does not* noticeably affect the upper lip vermilion exposure.

Conversely, the extended approach permits alar base width adjustment and control of upper lip vermilion exposure (increased exposure). Also, since it is used for larger augmentations (4–6 g per side), it effects a relative decrease in nasal size, increasing the tip projection and supratip break.

The procedure can be readily performed under either general or local anes-

thetia with or without sedation. Before injection of the local anesthetic, the alar base width is measured and an esthetic determination is made as to its most desirable postoperative width. About 10 minutes before initiation of the actual surgery, the infraorbital nerves are blocked bilaterally, and 10 cc of 2% lidocaine with 1:200,000 epinephrine is infiltrated from the zygomatic-alveolar crest area on one side to the same area on the opposite side, up into the region of the frontal process of the maxilla. When the limited augmentation is to be done, about 2 to 3 g of hydroxylapatite are used on each side, as opposed to 4 to 6 g for the extended augmentations.

The limited approach is achieved through two vestibular incisions. On each side a diagonal incision is made from the piriform rim area in the depth of the vestibule down to the level of the attached gingiva in the canine region. This incision is carried directly down to bone. The anterior maxilla is then subperiosteally exposed so that the surgeon can visualize the piriform rim of the nose medially and extended superiorly and laterally by the desired amount (Figure 70-7). The augmentation material is perhaps most easily delivered by means of the syringe technique. About

FIGURE 70-7 When less augmentation is necessary, the limited incision approach is used. Adapted from Epker BN.¹⁹ p. 126.

2 to 3 g of nonresorbable hydroxylapatite is mixed with sterile saline and a collagen hemostatic and placed into a 3 cc syringe that has had the delivery end cut off.¹³ Closure is performed with running 3-0 chromic horizontal mattress sutures. No dressings are placed. Gentle external massage is done to ensure symmetry.

For the extended augmentation approach, a standard horizontal incision is made in the depth of the maxillary vestibule from the second premolar area on one side to the same area on the opposite side. This incision is carried directly down to bone, and the entire anterior maxilla is exposed subperiosteally. The exposure extends posteriorly only to the anterior aspect of the zygomatic alveolar crest, then superiorly to expose the infraorbital nerve and medially above the nerve onto the infraorbital rim. The lateral and inferior region of the bony piriform rim is exposed including the anterior nasal spine. The periosteum in this region is carefully mobilized over the piriform rim and into the nasal cavity for about 5 mm. In this phase of the subperiosteal dissection, care is exercised not to tear the periosteum and enter the nasal cavity. When this occurs it is best to suture this communication to avoid possible postoperative infection.

Before augmentation, sutures are placed to control the alar base width. A hole is drilled in the anterior nasal spine. Depending on the predetermined esthetic desires for alar base width changes, these sutures are variably tightened to control the alar base width at its presurgical width, permit it to widen, or allow it to somewhat narrow. This latter objective is seldom indicated in this condition because the alar base width is most often narrow, and the patient generally benefits from some controlled degree of alar base widening. However, when this area is not controlled with alar base retention sutures as described, it widens unpredictably and often excessively. Two separate 2-0 slowly resorbable sutures are placed through a single hole drilled

through the anterior nasal spine region. Next, the upper lip is grasped, and the forefinger is placed facially, precisely over the inferior alar rim while the lip vestibule is retracted with the intraorally placed thumb. With toothed forceps the area in the vestibular incision directly adjacent to the everted alar rim is firmly grasped. This tissue is a combination of the fibroareolar extension of the lower lateral cartilage and the lateral nasalis muscle; occasionally, a small sesamoid accessory of cartilaginous component is noted (Figure 70-8). When the proper tissue is grasped and the lip released from the fingers while maintaining the tissue grasped with forceps, the alar base is readily advanced medially toward the columella; the alar base is then observed and measured facially. Sometimes several attempts at grasping the proper tissue with the forceps must be made to identify the tissue that permits virtually unrestricted medial movement of the alar base. For the alar base cinch procedure to be effective, the proper tissue in this area must be identified bilaterally to effect symmetric control of the alar bases.

Once the proper tissue is identified, while it is maintained in the forceps, a Burnell or figure-of-eight tendon-type suture is placed with a 2-0 polyfilament slowly absorbable suture. A separate suture is passed through each side first and the needle left attached to the suture (Figure 70-9). Then each needle is passed

FIGURE 70-8 Alar cinch with attention to proper tissue selection and suture technique. Adapted from Epker BN.¹⁹ p. 123.

FIGURE 70-9 Independent suturing of each side to anterior nasal spine. Adapted from Epker BN.¹⁹ p. 124.

through the hole placed in the anterior nasal spine. These sutures are later tied after the actual augmentation.

The skeletal nasal base augmentation is performed with a nonabsorbable mixture of particulate hydroxylapatite and a hemostatic collagen preparation, moistened with sterile saline. Only enough collagen hemostatic material is used to form a dough mass that does not flow.

Generally, between 8 and 12 g of hydroxylapatite are used in the extended approach, depending on the relative severity of the skeletal nasal base deficiency. The mixture is separated into two equal portions so that equal augmentation is attained on both sides. After placement, it is molded with a periosteal elevator to conform it to the underlying bone. Most often this material is extended superiorly to the infraorbital nerve and often more medially to the infraorbital rim. Care is taken not to place much of the material into the region of the frontal process of the maxilla because this unesthetically widens the nose. Once the implants are placed bilaterally, equally and symmetrically adapted, and contoured to create facial symmetry, the incision is closed.

First, the alar base sutures are tied. Each suture is independently hand tied while that side's alar base width is observed (measured) facially. As a general principle, the alar base should be narrowed 2 mm more than desired because some widening tends to occur postopera-

tively. Next, the vestibular incision is closed with deliberate attention to control of the upper lip fullness and the amount of exposed vermilion. Often, after the alar base cinch sutures are tied, the labial mucosa is somewhat tethered superiorly and must be undermined in the region of the alar base cinch suture. This is important to avoid reduction of the upper lip's vermilion exposure with the subsequent vestibular closure.

When there is no desire to alter the preexisting upper lip esthetics, the mucosal portion of the incision is closed in the usual V-Y fashion, with the vertical extent of the Y being about 10 to 15 mm. This basically avoids reduction in exposure of the upper lip vermilion (Figure 70-10).

More often, it is desirable to increase the exposure of the upper lip vermilion, especially when the preoperative lip has gullwing characteristics. In these instances an extended closure is done, requiring extensive undermining of the upper lip mucosa. While the lip is retracted with a single skin hook placed precisely in the midline and with a retractor placed laterally, undermining of the lip mucosa is performed with small scissors. The extent of the mucosal undermining is determined by the desired esthetic changes in the upper lip. When maximal increased exposure of the upper lip vermilion is wanted, as is the case with a gullwing upper lip appearance, extensive undermining is achieved anteriorly almost to the wet line of the lip and an equivalent amount posteriorly. When this undermining is completed, it is critical that the surgeon be able to pass the scissors freely from one side to the other, demonstrating a continuous pocket. Next, the horizontal vestibular limbs are closed with interrupted or continuous 45° angled sutures to reduce tension and further advance the mucosa.

When the extensive mucosal undermining is done with a V-Y closure, a dental cotton roll coated with an antibiotic ointment is inserted into the depth of the

labial vestibule in the midline, and tape is placed tightly over the lip to maintain pressure. The tape is extended inferiorly over the lip mucosa. When this is not done, considerable lymphedema occurs in the midline of the upper lip. The cotton roll and tape dressing are left in place for 48 hours and then removed. Similarly, layered tape dressings are applied to the paranasal regions and maintained for 48 hours. Cold is applied to the face during this time.

After surgery and the removal of the dressing, the patient must maintain a liquid to very soft diet for 7 to 10 days until the vestibular incision is well healed. After 3 to 4 days he or she is instructed to begin forceful lip exercises to further reduce edema. At this time, when the edema is resolving, the surgeon gently palpates the paranasal areas to ensure symmetry. The implanted material can be gently molded for about 5 to 7 days before it assumes a solid state without flow properties.

The limited exposure approach is done primarily to reduce mild paranasal depressions (Figure 70-11). The extended procedure produces esthetic changes consistent with improved frontal face esthetics,

FIGURE 70-10 V-Y closure is done to enhance exposure of upper lip vermilion. Adapted from Epker BN.¹⁹ p. 127.

FIGURE 70-11 The limited exposure can be performed without significant effects on the nose or upper lip.

including improved upper lip fullness, increased exposure of the upper lip vermilion, improved balance of the alar base width with the remainder of the facial features, and decreased prominence of the nasolabial folds. In profile the concave-to-flat paranasal region becomes normally convex. Prominence of the nose is decreased, nasal tip projection is improved, often with the creation of a supratip break, and some cephalic rotation of the nasal tip is achieved (Figure 70-12). This extended procedure is frequently

used with other skeletal/soft tissue cosmetic maxillofacial procedures, especially rhinoplasty.

The Cheek

Esthetic cheek augmentation may be indicated as an isolated esthetic maxillofacial surgical procedure or be performed in concert with other skeletal/soft tissue facial esthetic surgeries.²⁶⁻³⁵ As with the other procedures discussed in this chapter, this statement implies that the patient both *possesses* the deformity (albeit to highly

variable degrees) and *desires* enhancement. Moreover, it must be appreciated that three patients with the same degree of anatomic deformity may each desire different degrees of augmentation, much the same as occurs with breast augmentation.

Esthetic cheek augmentation is indicated in individuals who frontally exhibit poor lateral cheek projection (bizygomatic width) in relation to the bigonial and bitemporal widths. Many such patients *appear* to exhibit vertically long faces, even though they do not possess any of the

FIGURE 70-12 Preoperative (A and C) postoperative (B and D) appearances after an extended approach with an alar cinch and a V-Y augmentation of the upper lip. Reproduced with permission from Epker BN.¹⁹ p. 130-1.

objective criteria of the long-face syndrome. This is because of the abnormal facial length-to-width relationships caused by the abnormal narrow bizygomatic width. Similarly, poor cheek projection is noted in the three-quarter oblique view. In profile these same individuals possess variable degrees of inadequate cheek and/or lateral infraorbital rim projection.^{19,25}

A detailed systematic esthetic examination of this area is performed because the evaluation of this area of the face must be multidirectional. Esthetic judgments made exclusively from a single view are incomplete with respect to the specificity of the deficiency.

Frontally the area of maximum cheek prominence is located about 10 mm lateral and 15 mm to 20 mm inferior to the lateral canthus. The cheek prominence is positioned more laterally than the mandibular angle. The bizygomatic width of the esthetically attractive face is the widest dimension of the face, with the bitemporal width and bigonial widths following. Silver has defined a malar prominence triangle, which very closely locates the malar prominence to this same location.²⁶

From the profile perspective, the cheek prominence and infraorbital rim in the esthetically attractive individual are situated so that the infraorbital rim is about equally projected with the anterior-most projection of the globe, and the cheek prominence is located several millimeters anterior to the globe. This relationship results in the cheek area being *clearly convex* in its configuration, as opposed to flat or concave.

Most analyses of the malar prominence that have been described in the literature are from the three-quarters view. These include Hinderer's, Wilkinson's, Powell and colleagues', and Prendergast and Schoenrock's methods.³⁶⁻³⁹ These methods result in highly variable ideal locations for the malar prominence, both vertically and laterally. Specifically, Hinderer's method is too nonspecific, Wilkin-

son's locates the prominence quite inferiorly, and Prendergast and Schoenrock's locates it medially. Powell and colleagues' analysis is comparable with the frontal view values recommended by the author. In the three-quarters oblique esthetic assessment, the esthetically attractive contralateral cheek prominence extends well beyond a line from the lateral commissure of the mouth to the lateral canthus. Its most prominent location is about 15 to 20 mm beneath the lateral canthus.

The basal view simply supplements the findings from the other perspectives and also reveals both the true lateral and, to a lesser degree, anterior projections of the cheeks. This view is important to best determine the symmetry of the cheeks.

The surgeon must not only evaluate the cheek prominence proper but also the buccal area because excessive fullness in the buccal region can lead the surgeon to the erroneous *impression* that cheek deficiency exists. When cheek deficiency and buccal fullness coexist, the surgeon must exercise caution with respect to whether and how much cheek augmentation versus buccal fat pad reduction is to be performed.

A mark is made on the face in the ideal region of the cheek eminence, 10 mm lateral and 15 to 20 mm inferior to the lateral canthus. This mark aids in the proper superoinferior and lateral positioning of the cheek implant. Similarly, it helps in *predetermining* the desired lateral and anteroposterior thickness of the cheek augmentation. It is important to create a gentle convex surface curvature beginning in the infraorbital area and extending inferiorly 15 to 20 mm. In concert with this marking, a tangent from the soft tissue gonial angle to this region is constructed with a ruler to "estimate" the desired lateral projection as determined by the criteria previously discussed.

The procedure can be readily performed under either general anesthesia supplemented with a local anesthetic with 1:200,000 epinephrine, or local

FIGURE 70-13 Extent of undermining for the placement of a cheek implant. Adapted from Epker BN.¹⁹ p. 147.

anesthesia and sedation. About 10 minutes before surgery the infraorbital nerves are blocked bilaterally with a few cubic centimeters of 2% lidocaine with 1:200,000 epinephrine. A few minutes later the entire maxillary vestibule is infiltrated transorally with approximately 10 cc of the same agent, from the zygomatic-alveolar crest area on one side to the same area on the opposite side. In addition, the subperiosteal dissection extends laterally along the zygomatic arch.

FIGURE 70-14 Symmetric and good stabilization of the right and left cheek implants is best achieved with screw fixation. Adapted from Epker BN.¹⁹ p. 152.

A horizontal vestibular incision is made with diathermy in the depth of the vestibule from the canine region distally to that of the molars. This incision is carried tangentially down to bone, and the entire malar area is sequentially exposed subperiosteally. This exposure extends superiorly to the infraorbital nerve and then medially above the nerve to expose the infraorbital rim. Next, the superior and lateral extents of this subperiosteal dissection are completed. Superiorly, lateral to the infraorbital nerve, the lateral infraorbital rim is exposed. The subperiosteal dissection is

then extended along the lateral aspect of the zygomatic arch posteriorly. The dissection must be liberal enough to create an adequate “pocket” into which the implant can be placed *passively* (Figure 70-13).

Once the subperiosteal dissection is completed, the predetermined desired size and shape of the implant is adapted for a try-in. Currently a large number of different-shaped cheek implants exist, constructed from various materials. Moreover, variable techniques and even locations for their placement are espoused. I currently prefer porous polyethylene implants because they

do not have complete memory, are readily modifiable at surgery, are porous (resulting in tissue ingrowth and self-stabilization), and are able to be optimally molded after heating in sterile hot saline. When porous polyethylene is used, it is vacuum impregnated with an antibiotic as described above. Careful adaptation of the preformed implants is necessary to obtain optimal results.

After initial trial the implant is revised with a surgical blade and/or heating to mold it to the underlying bone. The need for any additional adjustments

FIGURE 70-15 Preoperative (A, C, and E) and postoperative (B, D, and F) appearances of a patient who underwent a cheek augmentation. Reproduced with permission from Epker BN.¹⁹ p. 156–7.

is determined at this time while the implant is held in its proper position, visualized through the incision, and facially palpated.

After the final adjustments are completed on the first side, the contralateral implant is modified to be a mirror image so that perfect right-to-left symmetry is achieved, unless the patient possesses some asymmetry. The identical vestibular incision and subperiosteal dissection is then carried out on the opposite side.

The implants are then both rinsed in the antibiotic solution, placed carefully into their proper location, and stabilized with one or two titanium screws. It is essential that the positioning and stabilization of the right and left cheek implants be precisely symmetric and that they exhibit no tendency to rotate or displace. If either of the latter is evident on one or both sides, a second screw is placed to prevent this movement (Figure 70-14).

Any asymmetry or instability of one or both implants at the termination of surgery will become clinically evident after resolution of the edema following surgery; *this is the most frequent cause for postoperative patient concern after this procedure.*

The vestibular incision is closed with a single-layered 3-0 plain horizontal mattress gut suture. A layered tape dressing is applied for 48 hours. After removal of the dressing the patient maintains a liquid to very soft diet for 7 to 10 days until the vestibular incisions are well healed. After complete healing of the vestibular incisions, the patient is instructed to begin vigorous lip exercises to expedite resolution of residual edema and to improve natural lip motion.

This procedure may be performed independently or in concert with other skeletal/soft tissue esthetic maxillofacial procedures as described in the introductory section of this chapter. The results obtained with this procedure can be predictable and esthetically impressive (Figure 70-15).

Summary

Alloplastic facial augmentation has become a standard of care. Careful preoperative detailed systematic esthetic evaluations permit the various areas of the face to be augmented precisely.

Otoplastic Surgery for the Protruding Ear

Todd G. Owsley, DDS, MD

Auricular deformities, in particular prominent or protruding ears, are a common congenital anomaly, affecting nearly 5 % of the Caucasian population.¹ Congenital in nature, children are most likely to suffer the consequences of the deformity in the form of ridicule by their peers. Protruding ears, commonly referred to as *prominauris*, can be predictably treated for children prior to entering grade school, and thus help the children avoid the emotional trauma caused from the ridicule. Otoplastic surgery is primarily performed on children and can be a valuable service for the patient and satisfying for the surgeon.

It is important for the surgeon to understand the history of various surgical techniques to develop a predictable and successful technique to address the problem of protruding ears. Dieffenbach (1845) is credited with the first otoplastic technique to correct a prominent auricle.² Ely, in 1881, authored the first case report describing correction of prominent ears in a 12-year-old boy who was being teased at school.³ Since that report, over 180 surgical techniques have been described in the literature for the correction of protruding ears.

When clinically evaluating the facial complex, the ears are often overlooked. If protruding ears are present, reduction otoplasty as an adjunctive or isolated procedure can be performed predictably

and often with satisfying results. A thorough understanding of the embryology and development of the human auricle along with the resultant external anatomy of the ear are of paramount importance in developing a predictable and stable technique to deal with the common auricular deformities.

Embryology of the Auricle

Malformations of the auricle are common, occurring in 1 out of 12,500 births.⁴ They can occur alone or in combination with a syndrome affecting the head and neck structures. The embryogenesis of the auricle exemplifies in miniature the precise and logical progression so characteristic of the developing human form. The external ear development during the third to twelfth weeks of embryonic life is complex. The precursors to the auricle present in days 36 to 38 of intrauterine life, developing first from the first branchial groove where the first (mandibular) and second (hyoid) branchial arches are present (Figure 71-1). Both arches give rise to the auricular hillocks often referred to as the auricular tubercles of His.⁴ Numbers 1, 2, and 3 arise from the caudal border of the mandibular arch, while numbers 4, 5, and 6 are formed from the cephalic border of the hyoid arch. The auricular hillocks present in their most prominent and characteristic form by

intrauterine day 41. During this same stage, the groove between the mandibular and hyoid arches (hyomandibular groove) widens and deepens by the increased growth of the hillocks. This groove eventually forms the external auditory canal and concha. By day 43 to 45, the hillocks have migrated and coalesced to form the auricle.⁴ During this union, the mesenchyme of the hyoid arch increases substantially relative to the mandibular arch to contribute 85% of the external adult ear. Hillocks 2 and 3 from the mandibular arch lose their individuality and fuse to form the helical crus. Later, hillocks 4 and 5 from the hyoid arch merge and alter their configuration as they give rise to the helix and antihelical fold. Hillock 1 remains prominent and becomes the tragus, and hillock 6 becomes the antitragus.⁴

Surgical Anatomy

The majority of the growth of the pinna is completed by an early age. The average child has 85% ear development by 3 years of age. The ear is nearly fully grown by the age of 7 to 8 years. The ear height continues to grow into adulthood, but the width and distance of the ear from the scalp changes little after 10 years of age. It is important to note that each individual's ears often vary in size and shape.⁵ The average adult ear is approximately 6.5 cm

FIGURE 71-1 Development of the auricle from the first and second branchial arches. The numbers in the left diagram correspond with the structures in the right diagram. Adapted from Owsley T. *Otoplastic surgery for the protruding ear*. In: Fonseca RJ, editor. *Oral and maxillofacial surgery*. Vol. 6. Philadelphia (PA): W.B. Saunders; 2000. p. 408-18.

in length and 3.5 cm in width. In the normal ear, the auricle lies between horizontal lines drawn from the upper rim of the orbit and the nasal spine. The normal posterior wall of the conchal bowl is set at an angle of approximately 90° to the mastoid.⁶ A second 90° angle is formed as the antihelical fold and is called the scaphoconchal angle. These two angles in combination with the curvature of the helix set the auricle adjacent to the scalp at approximately 25 to 35° and is called the auriculocephalic angle (Figure 71-2).⁷ In otoplastic surgery, when correcting prominent ears, there are three important anatomical pearls that can be used intraoperatively to assess the final result. The helical rim should be seen just lateral to the most lateral presence of the antihelix from the frontal view. The distance measured between the helical rim and the mastoid area is slightly less than 2 cm. Finally, the distance between the skull and the uppermost aspect of the helix is approximately 1 cm (Figure 71-3A and B).

The auricular cartilage is a unique and delicate structure that is intricately shaped with multiple elevations and depressions providing both skeletal support and form to the adult ear. The cartilage of the auri-

cle is a single piece of yellow (elastic) fibrocartilage with a complicated relief on the anterior, concave side and a smooth, posterior convex side. Cartilage thickness is fairly uniform throughout. The cartilage is covered on both surfaces by a thin, firm, adherent layer of perichondrium. The anterior lateral surface of the cartilage is covered with a fine, thin skin, closely adherent to the cartilaginous framework. Subcutaneous fat is practically nonexistent, but a diffuse subdermal vascular plane exists which supports flap viability.⁸ The posterior surface of the cartilage framework is draped with a less adherent skin that contains two layers of fat and a larger subdermal plexus of arteries, veins, and nerves.

A helical border terminates anteriorly in a crus, commonly called the radix, which lies almost horizontally above the external auditory meatus. The antihelix crowning the posterior conchal wall separates and diverges into both a superior and anterior crus enclosing the triangular fossa. Between the helix and the antihelix lies a long, deep furrow called the scaphoid fossa. The conchal cavity, composed of the cymba (superior) and cavum (inferior) concha, arises from the floor, which is

approximately 8 mm deeper than the overlying tragus and antitragus. The inferior tip of the helical cartilage is referred to as the cauda or tail. Extending from this inferiorly is the lobule, hanging devoid of skeleton (Figure 71-4A and B).

Blood Supply

The arterial blood supply to the ear is derived principally from two main branches of the external carotid artery: superficial temporal artery and posterior auricular artery. The superficial temporal artery emerges from the parotid capsule, 1 cm in front of the ear deep to the veins and below the anterior auricular muscle. It gives off the superior, medial, and inferior branches supplying the anterior and anterolateral surface of the auricle (Figure 71-5A). The posterior surface is dominantly supplied by the posterior auricular artery which travels parallel to the postauricular crease upwards crossing below the great auricular nerve and under the posterior auricular muscle. Awareness of this relationship is important to avoid damage to the artery or nerve during surgery. The posterior auricular artery gives off three

branches: superior, medial, and inferior, providing a greater volume of blood to the postauricular ear than its anterior counterparts. These same vessels perforate the auricular cartilage over a large surface of the anterior ear and anastomose with the branches of the superficial temporal artery. The external ears have a tremendous blood supply, allowing multiple surgical approaches or salvage of the ear following traumatic avulsion.

Venous drainage of the ear via the complementary veins is into the external jugular vein. Lymphatic drainage is into three surrounding areas via the complex and extensive fine network of lymphatic vessels.

Nerve Supply

The sensory nerve supply is primarily from the anterior and posterior branches of the great auricular nerve. The nerve is an important surgical landmark traveling 8 mm posterior to the postauricular crease. When dissecting in this area, care must be taken to avoid damage to the nerve which can result in near complete anesthesia to the ear. Less important contributions of sensation are made by the auriculotemporal and lesser occipital

nerves to the conchal cavity and external auditory meatus (Figure 71-5B). Regional anesthesia of the auricle is readily accomplished by instilling anesthetic solution along its base anteriorly and posteriorly. Supplemental anesthesia may be needed at the posterior wall of the external auditory meatus supplied by the auricular branches of the vagus nerve (Arnold’s nerve).

Deformities

Ear deformities are common and variable due to the complex embryologic

engineering that takes place in the development of the auricle as described previously. Many classification systems of ear deformities have been attempted. Tanzer classifies congenital ear defects, correlating embryologic development with a surgical approach for correction of the deformity.⁹ Marx has a well accepted classification system subdividing microtia into three groups according to severity.¹⁰ Rogers simplifies classification of congenital ear defects, dividing them into four groups according to various stages of arrested development: microtia, lop ear, cup ear, and protruding ear.⁶ In this chapter addressing the prominent ear, the term *protruding* is used as a general term to refer to any ear that is more prominent than is considered “normal.” It is beyond the scope of this chapter to classify other congenital abnormalities and their correction.

Protruding Ear

In patients with protruding ears, there are two major deformities that individually or in combination account for the majority of the abnormalities. There are several lesser deformities seen that can accentuate the abnormality as well. The most common seen is a poorly developed antihelical fold which can involve both the superior and anterior crura. This eliminates a defi-

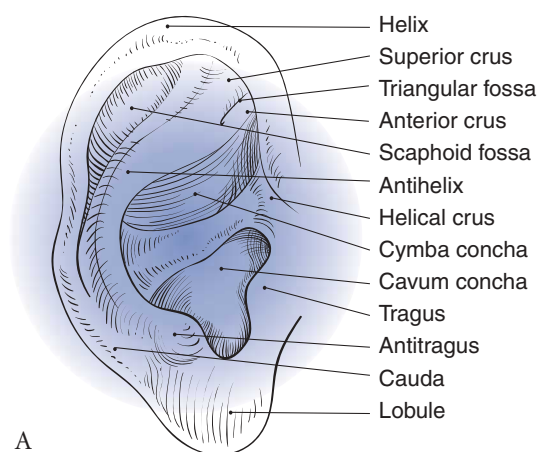

FIGURE 71-4 A, B, Anatomy of the external ear.

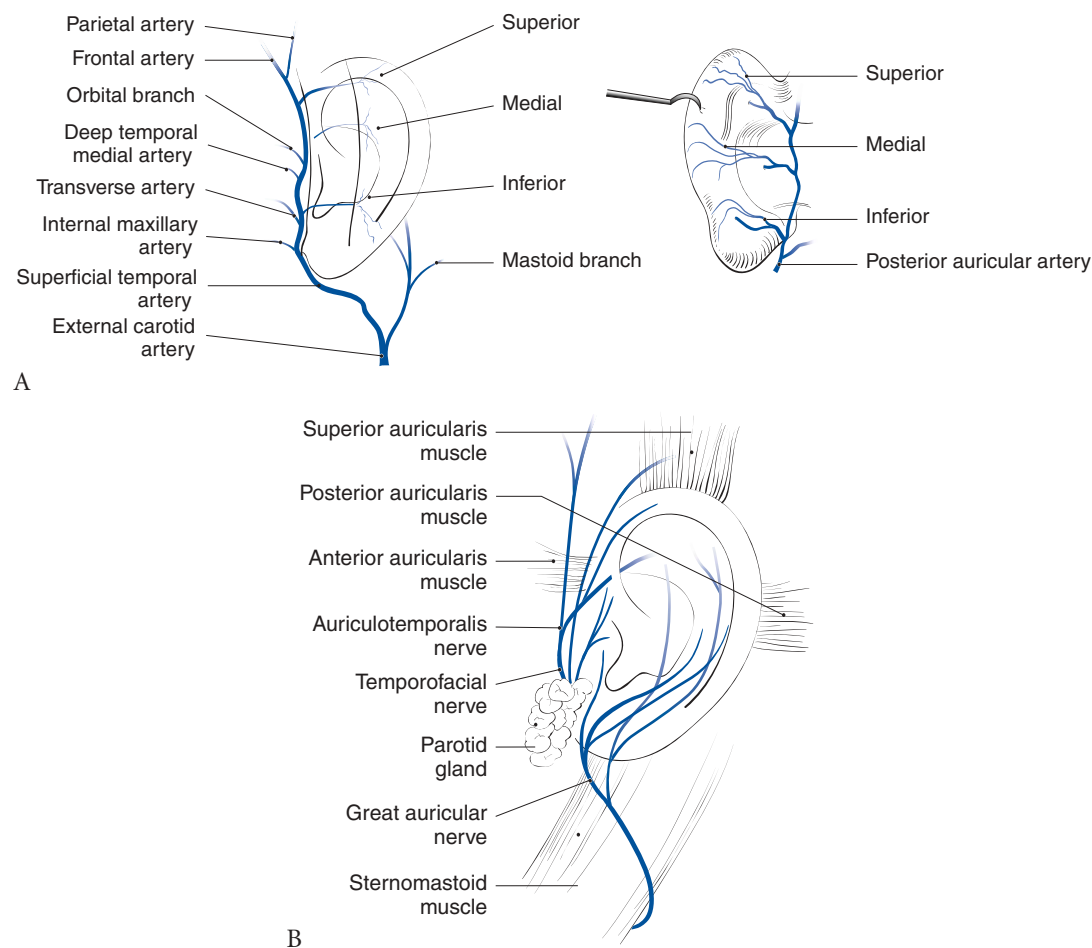

FIGURE 71-5 A, Arterial blood supply. B, Nerve supply. Adapted from Owsley T. *Otoplastic surgery for the protruding ear*. In: Fonseca RJ, editor. *Oral and maxillofacial surgery*. Vol. 6. Philadelphia (PA): WB Saunders; 2000. p. 408–18.

nition between the conchal cavity and scapha resulting in the lateral projection of the upper portion of the helix. The second abnormality seen is the formation of excessive conchal cartilage, in particular the posterior conchal wall. This causes significant protrusion of the auricle. It is not uncommon to recognize some degree of both abnormalities present producing the protruding auricle.

Other potential deformities are a protruding earlobe, irregularities along the helix including an unrolled margin of the helical rim and more recently described an anteriomedially displaced insertion of the postauricular muscle. Of importance, this deformity is often bilateral and can be associated with ossicular deformities and a hearing deficit.¹¹

Obviously, precise recognition of the cause or causes of the protruding ear is crucial in formulating the surgical technique to be employed in correction of the abnormality.

Surgical Correction

Perhaps the most important indication for surgical correction of prominent ears is to eliminate the psychosocial effects that the ear defect produces. Macgregor and others have well documented the irreversible social and psychological consequences that facial anomalies, especially the ears, can inflict.¹² The ridicule by peers begins as early as age 4 to 5 years during development, this leads to problems with social adjustment, self-image

deficit, and ultimately behavioral disorders. Therefore, most patients present at an early age for surgical correction. Most surgeons agree that surgical correction of the ear can be performed safely between 4 years of age and the beginning of school attendance to avoid the ridicule, becoming one of the most common elective procedures performed in young children. Adults also present to correct a lifelong cosmetic defect.

Surgical Techniques

Many otoplasty techniques described in the surgical literature are similar and have evolved over an 80-year experience. Many techniques only address the conchal hypertrophy without mention of the anti-helical fold. The described techniques generally can be subdivided into a “suture-only” technique, cartilage splitting or weakening technique, or a combination of the two.

Furnas (1968) described his suture-only technique for the correction of the prominent ear deformity.¹³ This technique consisted of a postauricular approach, removing the skin, connective tissue, and vestigial posterior auricular muscle and its ligament down to the underlying mastoid fascia. A total of 2 to 3 nonresorbable sutures are placed through conchal cartilage and mastoid fascia and tightened to the new desired retracted position of the ears. This remains a commonly used technique to set back the ears in patients with conchal hypertrophy alone. Problems associated with this technique have been relapse secondary to the cartilaginous memory, a shallow conchal bowl, and irregularities created in folding the conchal floor. Another difficult problem seen is displacing the conchal bowl anteriorly, creating narrowing of the external auditory canal.

The Converse-Wood-Smith technique is used to correct and create an anti-helical fold using a cartilage cutting and suture method.¹⁴ Several full thickness

cuts through cartilage are placed in the scaphoid fossa. The cartilage is then folded on itself, described as “tubing,” and permanent horizontal mattress sutures are placed forming the new antihelical fold. Additionally, if excessive conchal cartilage is present, it can be addressed with a cartilage incision added at the rim of the bowl to reduce the bowl and retract the ear. A new antihelical fold is formed, however, typically with sharp cartilaginous ridges seen through the thin anterior auricular skin.

This chapter will describe two techniques that address the two fundamental abnormalities in protruding ears and have

produced consistent, satisfying cosmetic results, and have essentially eliminated the fear of relapse. The Davis method addresses the protruding ear caused by a hypertrophic posterior wall of the conchal bowl. The Mustarde method is used to create a new antihelical fold (Figure 71-6).

The refinement of other abnormalities such as the prominent earlobe will also be discussed.

Davis Method

The Davis method, for the correction of conchal hypertrophy, is a cartilage excision technique performed in a step-wise fashion.^{8,15}

1. Marking the cartilage excision: Initially, the area of cartilage to be removed is marked on the skin of the anterior surface of the conchal bowl. Methylene blue transfixion tattoos are preferred and demonstrated to mark the posterior surface of the conchal cavity. The line lies just below the lower crus border, carries forward into the cymbal fossa, and continues around as an “arrowhead” to preserve a well-defined, helical radix. The tracing should continue forward against the posterior edge of the external auditory canal. From that location, it curves posteriorly

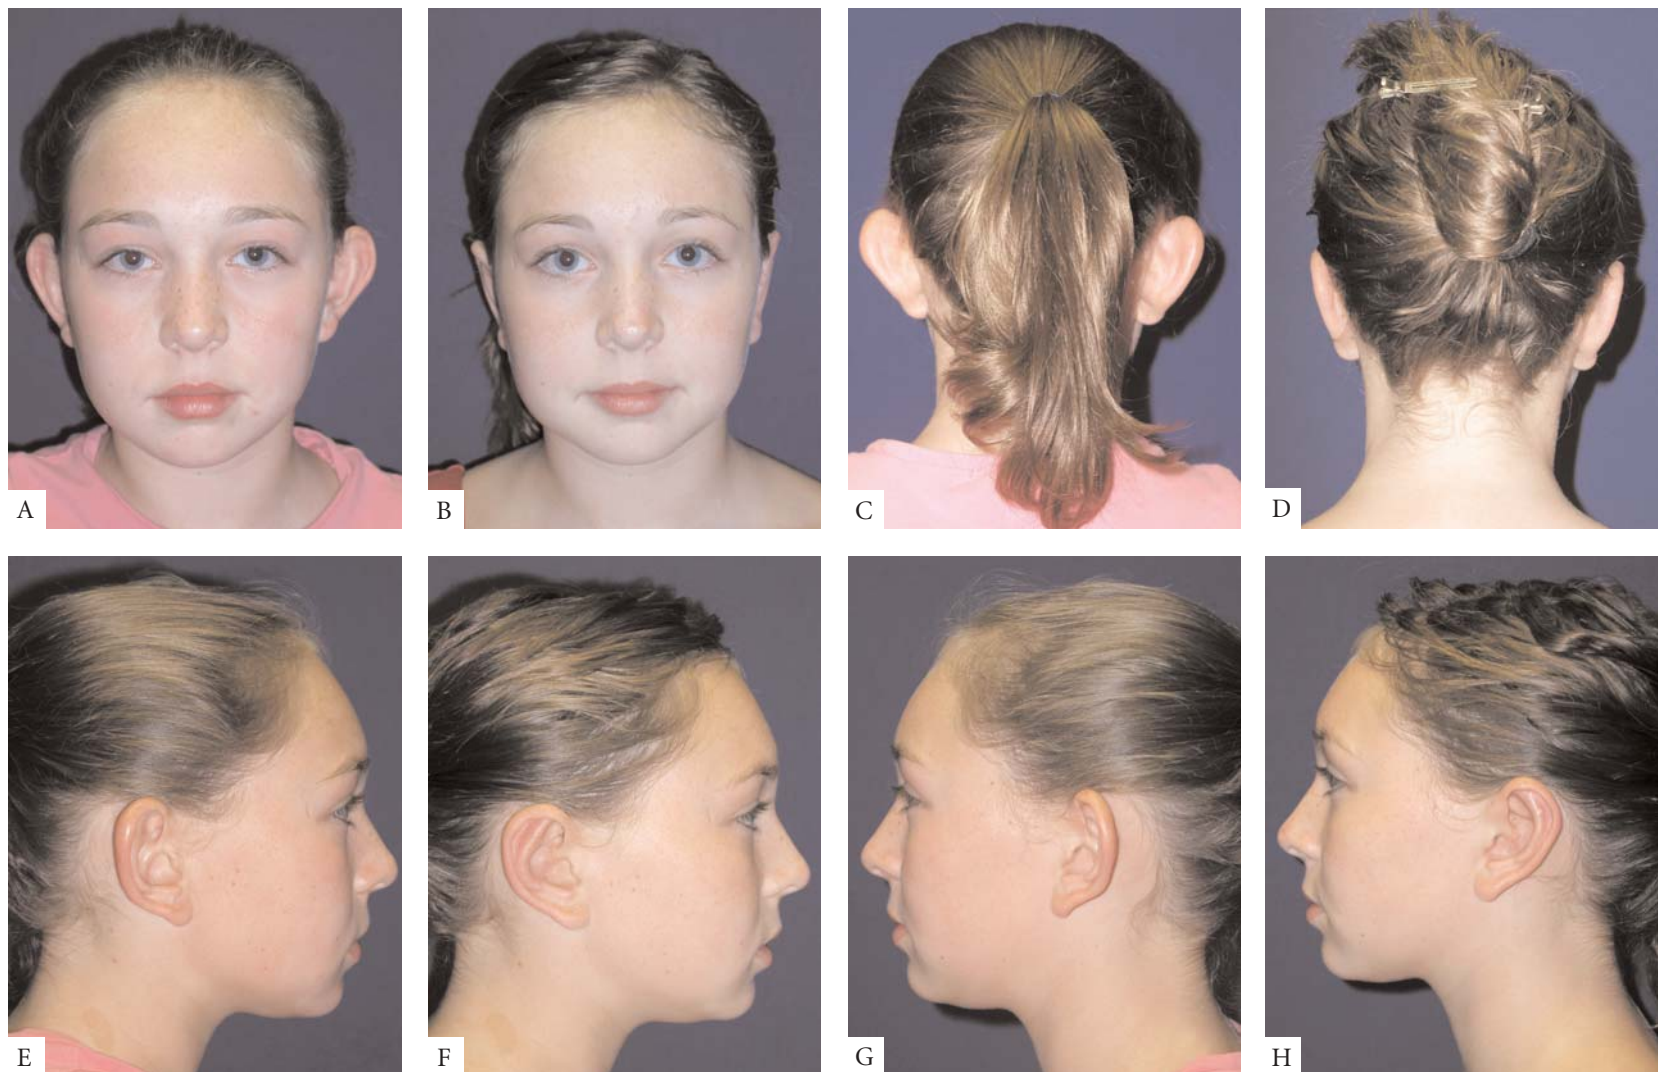

FIGURE 71-6 A–D, Preoperative and postoperative photographs of an 11-year-old girl who presented for correction of protruding ears. Her diagnosis was a combination of conchal hypertrophy and lack of antihelical fold formation bilaterally. The Davis and Mustarde techniques were used on both ears. E–H, Lateral views of both ears demonstrating a natural-appearing, new antihelical fold and a deepened conchal bowl.

into the cavum concha, continuing onto the posterior conchal wall, leaving 8 mm of posterior conchal wall height measured from the conchal scaphal junction. This should complete the circle which should appear “kidney bean” shaped including the entire conchal bowl. The exact height of the posterior wall is important and must be measured for each case individually (Figure 71-7A–C).

2. Removal of skin and cartilage: Prior to beginning the actual surgical procedure, local anesthesia is used for hydrodissection of the tightly adhered anterior auricular skin along the conchal bowl. This simplifies the dissection of cartilage from the overlying skin. The concha is exposed through a postauricular elliptical skin excision. The width of the ellipse is only to remove the predicted excess skin that is produced with ear repositioning. The closure of the incision should be passive. This area is predisposed to hypertrophic or keloidal scarring when closed under tension. Once having removed the postauricular skin, the conchal cartilage is visualized along with the previously placed tattoo marks. The marks are used as a guide for incising through the cartilage, taking care to avoid perforation of the anterior skin. The dissection is then carried onto the anterior conchal cartilage surface subperichondrially. The hydrodissection along with a small, sharp Freer elevator allows separation between the skin and cartilage. The cartilage is then removed which includes the entire conchal bowl with the exception of the 8 mm left along the posterior conchal wall. The ear is then placed passively onto the mastoid surface, and the new projection of the helical rim is observed and carefully measured. Any defective prominence can be revised with further cartilage removal. The postauricular muscle

and underlying connective tissue are removed down to the underlying mastoid fascia to allow for passive skin draping of the conchal floor, producing a natural-appearing, deepened conchal bowl. Any excessive postauricular skin can be removed at this time (Figures 71-7D–F).

3. Ear fixation: The ear is fixed in its new position with 3 to 4 mattress transfixion sutures of 3-0 silk that perforate the skin anteriorly, anchor deeply into the postauricular muscle stump, and pass back through the anterior skin. The mattress sutures are then gently tied over a dental cotton roll, moistened with a triple antibiotic ointment, which has been placed into the cymbal and caval fossa, making sure to place one end of the cotton roll into the external auditory canal to avoid postoperative stenosis. The sutures and cotton roll hold the ear in place during healing, stretch and flatten the skin uniformly over the conchal floor, and give depth to the conchal bowl. The postauricular incision is then closed in a running fashion with a resorbable suture, leaving a small opening inferiorly for drainage. The cotton roll dressing is left in place for a minimum of two weeks for optimal healing (Figures 71-7G–I)

Mustarde Method

The Mustarde method, first described in 1959, is indicated for the prominent ear with a poorly formed or lack of an antihelical fold.¹⁶ This cartilage weakening technique relies on precisely placed horizontal mattress sutures, creating a new antihelical fold. It is rarely performed alone and used commonly in combination with the Davis method described above.

1. Antihelical fold markings: The scapha is folded back against the underlying scalp by applying digital pressure on the superior helical rim,

which creates an antihelical fold. The crest of the fold is marked with a surgical marker. To prepare for placement of the mattress sutures, marks are placed parallel to the crest at least 7 mm apart to avoid creating too narrow of a fold. The lateral marks placed on the skin are transferred to the underlying cartilage with a hypodermic needle dipped in methylene blue (Figures 71-8A and B).

2. Dissection and cartilage weakening: Local anesthetic solution is infiltrated along the scaphal fossa beneath the anterior auricular skin, hydrodissecting the skin from the underlying cartilage. This is to facilitate the anterior dissection and mattress suture placement. The postauricular skin is then removed in an identical fashion as described with the Davis method. Once having identified the marks placed on the posterior surface of the scaphoid cartilage, a Freer elevator is passed through a small horizontal incision created through the cartilage at the most inferior aspect of the new antihelical fold. The anterior auricular skin is then dissected from the underlying cartilage corresponding to the crest of the new antihelical fold. Through the tunnel dissected along the anterior surface of the cartilage, the body of the new antihelical fold is weakened to facilitate folding and remove the inherent memory. Many methods have been described, however cartilage weakening can be performed adequately using a Brown-Adson forceps, a nasal rasp, or a dermabrader with a small diamond fraise (Figures 71-8C–E).
3. Suture placement: Nonresorbable, horizontal mattress sutures (4-0 Mersilene) are placed. The sutures are all placed through the medial perichondrium, cartilage, and lateral perichondrium, being careful not to include the anterior skin. The sutures should be

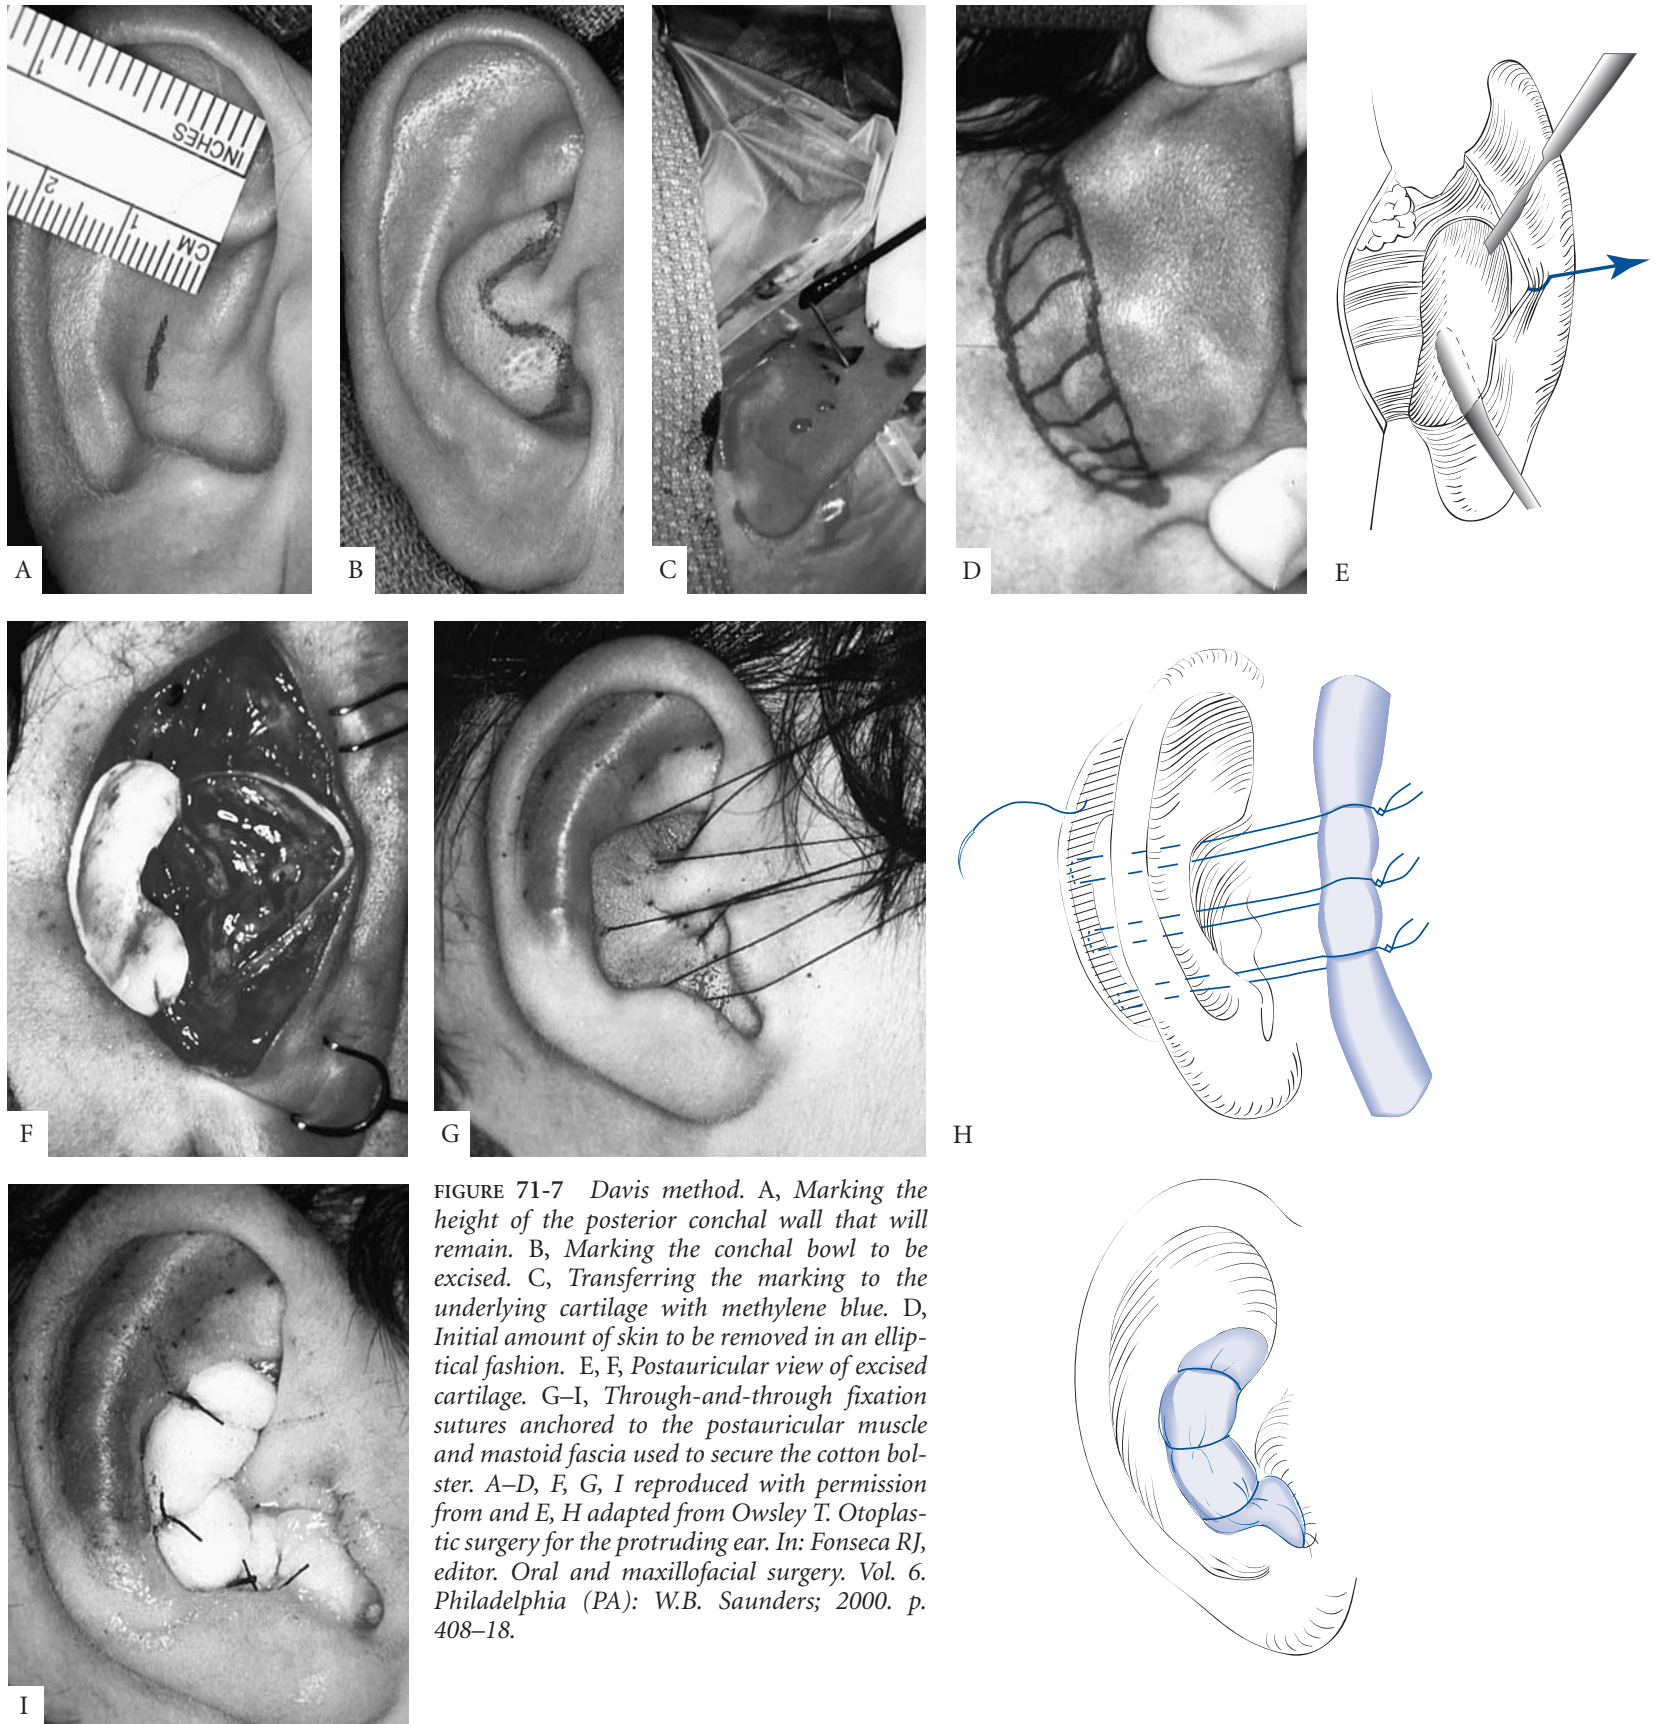

FIGURE 71-7 Davis method. A, Marking the height of the posterior conchal wall that will remain. B, Marking the conchal bowl to be excised. C–E, Dissection of the scaphoid fossa beneath the anterior skin for weakening and creation of the desired antihelical fold. (CONTINUED ON NEXT PAGE)

placed perpendicularly across the antihelical fold, so that upon tightening, a well-rounded, antihelical fold will be created. The sutures are tightened under direct observation and adjusted accordingly to form the new antihelical fold (Figures 71-8F and G).

4. Dressing: The dressing is important and is placed to provide adequate pressure to obliterate dead space and avoid a postoperative hematoma formation. A carefully layered dressing is placed over the anterior and opposing posterior surfaces of the scaphoid region with a quarter-inch petrolatum

gauze, followed by 4 x 4 inch fluffs, held secure with a pressure-type facial dressing (Figures 71-8H and I).

Correction of the Protruding Earlobe

A protruding earlobe often accompanies a protruding ear. If so, it must be identified and corrected simultaneously. If the lobule of the ear protrudes, an extension of the posterior auricular incision is drawn with a surgical marker in the shape of a V onto the earlobe. Finger pressure on the freshly marked lobe, compressing it to the mas-

toid skin, produces a mirror image imprint forming a W-shaped (fish tail) portion of skin to be excised. After this portion is excised and hemostasis achieved, closure is accomplished with a 4-0 plain gut suture. The two V-shaped incisions are brought together reducing the protruded state of the lobule (Figure 71-9A and B).¹⁴

Complications

The incidence of complications after reduction otoplasty is quite low.¹⁷ The major complications to be avoided are infection and keloid formation. Immediate

Philadelphia (PA): W.B. Saunders; 2000. p. 408–18.

complications include pressure necrosis from an overly tight dressing and hematoma formation. Delayed or long term complications include hypertrophic or keloid scar formation, recurrence of the ear deformity, neurosensory deficits, and unesthetic results.

Hematoma

Postoperative hematoma formation, with an incidence of 2 to 4 %, is the most common problem that requires immediate and aggressive intervention.¹⁷ It is most often related to inadequate hemostasis achieved at the time of surgery. Other factors in hematoma formation include an overly tight wound closure without drainage at the base

of the wound, postoperative trauma, hypertension, and a preexisting bleeding dyscrasia. Persistent pain beneath the dressing or significant bleeding through and around the dressing suggests hematoma formation and demands prompt inspection. The presence of a hematoma is indicated by a tense and bluish swelling beneath the auricular skin, most often in the retroauricular space. Management includes suture removal, blood clot evacuation, hemostasis, and reclosure of the wound with a large pressure dressing reapplied. Large doses of antibiotics are advisable to prevent perichondritis. If this problem remains untreated, it can result in fibrosis, perichondritis, and cauliflower ear deformity.

Perichondritis

Wound infection in otoplasty occurs in the early postoperative period and is usually a sequela to an undetected or inadequately treated hematoma. Symptoms include pain, erythema, fever, and discharge that may or may not be present. Treatment includes high doses of antibiotics following appropriate wound cultures. Common bacteria include *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Adequate drainage is achieved by opening all sutures and carefully irrigating necrotic debris from the wound. All correction sutures must be removed and the cosmetic deformity addressed at a later

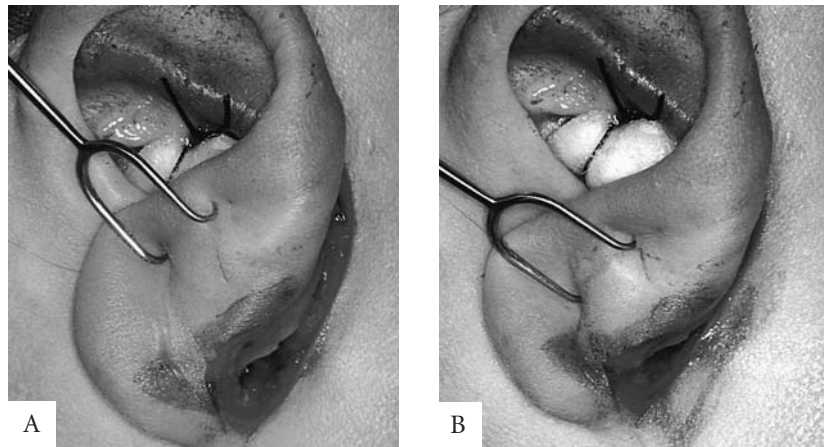

FIGURE 71-9 A, B Marking of skin to correct protruding lobule. Areas marked are excised in “fishtail” fashion and closed. Reproduced with permission from Owsley T. *Otoplastic surgery for the protruding ear*. In: Fonseca RJ, editor. *Oral and maxillofacial surgery*. Vol. 6. Philadelphia (PA): W.B. Saunders; 2000. p. 408–18.

date. The complication can be devastating, causing massive cartilage destruction with a severe deformity resulting, even with aggressive therapy. Prophylactic antibiotics have not been scientifically proven to be beneficial, but are often used in the preoperative and postoperative period to avoid this devastating complication.

Keloid and Hypertrophic Scar Formation

The closure line of the skin incision in the postauricular region is susceptible to scar formation, especially closed under tension. It is most commonly seen in younger patients and patients with deeply pigmented skin. Keloid formation, one of the most frustrating of all postoperative complications, requires aggressive therapy. In the early stages of keloid formation, intralesional triamcinolone acetonide is injected weekly until regression or significant improvement is evident. Most hypertrophic scars improve with steroid infiltration, but some keloids can progress into significant unesthetic lesions. Low dose radiation, although potentially dangerous, may provide the only effective means of control of some keloids. The more advanced lesions require surgical excision combined with radiation and delayed skin grafting of the irradiated area, with final

aid from intralesional triamcinolone. The risk can be minimized by ensuring that the skin incision is closed passively.

Esthetic Complications

Inadequate correction of the ear deformity is the most common untoward result of otoplasty, often more obvious to the surgeon than to the patient. Calder and Nassan described at least one complication or residual deformity in 16.6% of all the patients who underwent otoplasty using all techniques.¹⁸ Recurrence of the ear deformity is a more common complication of reduction otoplasty, but is less likely to happen after excising a portion of the cartilage as well as a segment of skin, as described in the Davis method. Depending on sutures alone for achieving correction carries a greater risk of recurrence.

Telephone Ear Deformity

Telephone ear deformity occurs when the root of the helix and the ear lobule remain protruded while the middle half, or third, of the ear is set back against the head. This is more common in a large ear with a wide scapha. The incidence has been reported to be 3%.¹⁹ Reverse telephone ear reveals a pronounced conchal bowl with respect to the lower and upper poles. These deformi-

ties can be avoided by carefully checking the position of the helical root, the upper helical rim, and the lobule at the completion of surgery.

Scapha Buckling

Scapha buckling or a transverse fold can develop in the Mustarde technique. This deformity can be avoided by placing the horizontal mattress sutures closer together where the scapha is widest, combined with adequate anterior scoring or weakening.

Narrowed Meatus

A constricted external auditory meatus can occur if the conchal bowl is rotated anteriorly in setting the ear back in any technique in which the conchal bowl is not excised. This problem is eliminated in the Davis method in which the floor of the conchal bowl is excised. Care must also be taken in placing the inferior end of the cotton roll bolster dressing into the external auditory canal to avoid stenosis.

Summary

Reduction otoplasty carries few complications and can provide satisfying results for both the patient and surgeon in the majority of cases. As in all cosmetic procedures, proper patient selection is imperative. Accurate preoperative assessment of the individual deformities and the appropriate choice of a surgical correction will minimize unfavorable esthetic results. The single greatest cause of an unfavorable result in this procedure is inaccurate diagnosis.

The surgeon must understand the normal external anatomy of the ear and learn to recognize the pathological characteristics of the abnormal ear. Having accurately assessed the deformity, the surgeon needs to be familiar with the various surgical approaches available to correct them. Finally, it is important to have a working knowledge of the potential complications of otoplasty and their prevention and treatment.
