The medial wall of the orbit is by far the most complex and potentially problematic to manage in severe trauma. The medial orbital wall is composed anterior-to-posterior by a portion of the maxillary, lacrimal, ethmoid, and sphenoid bones.

The majority of the medial wall is formed by the extremely thin (0.2–0.4 mm) lamina papyracea of the ethmoid bone. Housed along the frontoethmoidal junction are the anterior and posterior ethmoidal foramina. The anterior ethmoidal foramen is 20 to 25 mm behind the medial orbital rim, and 12 mm beyond this is the posterior ethmoidal foramen. The foramina can be found approximately two-thirds of the way up the medial orbital wall, within the frontoethmoidal suture line, and serve as important surgical landmarks identifying the level of the corresponding cribriform plate. Orbital surgeons use these arteries as the landmarks for the superior extent of orbital wall decompression. The anterior ethmoidal foramen transmits the anterior ethmoidal artery and anterior ethmoidal branches from the nasociliary nerve from the orbit coursing into the nasal cavity. This is why otolaryngologists sometimes use a medio-orbital approach to ligate or cauterize the anterior ethmoidal artery to control recalcitrant nasal bleeding. Although the anterior ethmoidal vessel can be cauterized with few ill effects, the contents of the posterior ethmoidal foramen (posterior ethmoidal artery and, variably, a sphenothmoidal nerve from the nasociliary nerve) are generally allowed to remain intact since they serve as a useful delineation to the posterior extent of safe medial wall dissection.

Once beyond the orbital rims, subperiosteal dissection generally proceeds fairly easily, except for points of nerves or vessels perforating through foramina, orbital

fissures, or muscle origins such as that of the inferior oblique. When encountering resistance, surgeons should attempt to identify the exact anatomic reason for the resistance, such as structures that may need to be preserved or periorbital tissues that have become entrapped in fracture lines. Knowledge of the limits of safe subperiosteal dissection is mandatory. Also important is knowing the distance from the intact orbital rim, where vital structures can be identified. Generally, a subperiosteal dissection from the inferior lateral rims can be safely extended for 25 mm. An exploration distance of 30 mm from the superior orbital rim or anterior lacrimal crest (found on the frontal process of the maxilla) can be safe.⁵ A high medial wall dissection places the orbital apex and optic canal at risk. One caveat to these "safe surgical exploration distances" is that they are averages of known landmarks to intact adult orbital rims. When traumatic forces displace a portion of a rim, it is generally in a posterior or medial direction, which effectively reduces these distances. Knowledge of the bony orbital anatomy, with its foramina, fissures, and attachment areas, helps the surgeon to avoid injuries to vital structures contained within them.¹ Average distances for locating these critical structures as they relate to identifiable bony landmarks are contained in Table 24-2. Surgeons should avoid disrupting the medial canthal tendon, lacrimal apparatus, pulley of the superior oblique muscle, supraorbital nerves and vessel, attachments to Whitnall's tubercle, and the origin of the inferior oblique muscle.

Table 24-2 Distance of Vital Orbital Structures from Bony Landmarks

<i>Structure</i>	<i>Reference Landmark</i>	<i>Mean Distance (mm)</i>
Midpoint of inferior orbital fissure	Infraorbital foramen	24
Anterior ethmoidal foramen	Anterior lacrimal crest	24
Superior orbital fissure	Zygomaticofrontal suture	35
Superior orbital fissure	Supraorbital notch	40
Optic canal (medial aspect)	Anterior lacrimal crest	42
Optic canal (superior aspect)	Supraorbital notch	45

The anterior boundary of the orbit is defined by the orbital septum. The upper and lower eyelids are anatomically similar in their composition, with corresponding layers anteriorly to posteriorly. When one is looking downward, the lid retractors enable the lower eyelid to roll with the globe, thus avoiding a visual field cut. The lids have a very thin keratinized epithelium that is loosely attached to the underlying orbicularis oculi muscle (Table 24-3). The orbicularis oculi muscle is innervated by cranial nerve VII and acts as a sphincter and closing force for the eyelids. In the relaxed state the orbicularis oculi is opposed in the upper eyelid by the levator palpebrae superioris, which is innervated by cranial nerve III. The resting tone and level of the upper eyelid are partly determined by the amount of sympathetic input to Müller's muscle. The orbicularis oculi has two distinct layers: the outer superficial fibers (orbital portion) and the deeper fibers (palpebral portion). The palpebral section medially has intricate insertions and envelops the lacrimal sac by dividing into intertwined deep and superficial heads. The superficial portion inserts onto the anterior lacrimal crest. The inner deep head inserts into the fascia of the lacrimal sac and posterior lacrimal crest. The medial canthal tendon is formed by the condensation of the orbicularis muscle fibers. It is the superficial head of the canthal tendon that has a tenacious insertion into the anterior lacrimal crest. This is beneficial during orbital approaches since

the anterior insertion offers considerable resistance to dissection, which helps one avoid inadvertent injury to the lacrimal sac. At the lateral edge of the orbicularis oculi, the superficial fibers form an indistinct raphe, and it is the deeper fibers that comprise the lateral canthal tendon, inserting onto Whitnall's tubercle.⁹ The upper and lower lids should form a 30 to 40° angle at the lateral canthus, which is situated 1 cm below the frontozygomatic suture. Typically, the lateral canthus is situated 2 to 4 mm above the medial canthus.

Just posterior to the orbicularis oculi is the orbital septum. The orbital septum is continuous with the orbital periosteum and the periosteum of the facial bones overlying the rims. One to two millimeters below the inferior rim, where these layers converge on the facial aspect, is a periosteal thickening called the arcus marginalis.⁵ This is a useful landmark when performing an infraciliary or preseptal transconjunctival approach to the inferior rim. If one stays in front of the orbital septum and incises below the arcus marginalis, then orbital contents and fat do not herniate into the field. The distal edges of the orbital septum insert into the superior edge of the tarsal plates. The orbital septum and these insertions prevent the preaponeurotic orbital fat from herniating out into the eyelids. Superiorly there is a central and medial fat pad, and inferiorly there are three distinct fat pads (medial, central, and lateral). With aging, the orbital septum can become lax and, particularly in the lower lids, result in "baggy lids." Severe sagging of the lower lids is referred to as festooning.

The primary elevator of the upper eyelids is the levator palpebrae superioris muscle. Inferiorly it forms an aponeurosis below Whitnall's ligament that attaches broadly over the anterior tarsal plate. Approximately 15 to 20 mm above the tarsal plate, the aponeurosis consists of a thickened fascial band, which is termed Whitnall's ligament. This is a suspensory

ligament of the lid. Müller's muscle arises beneath the levator muscle and inserts into the superior border of the tarsal plate. Müller's is a smooth muscle that receives sympathetic input for its tone and helps regulate the resting position of the upper eyelids while the eyes are open. Increased stimulation or sympathetic input causes a "wide-eyed" look and a more alert appearance.¹⁰ The capsulopalpebral fascia and the inferior tarsal muscle in the lower eyelids are also termed the lower lid retractors. The lid retractors are formed from the fibrous attachments of the inferior rectus and inferior oblique muscles, and fuse with Lockwood's inferior suspensory ligament.

The tarsal plate is formed by dense fibrous connective tissue and is primarily responsible for the convex form of each of the lids. The tarsal border parallels the free margin of the eyelid. The horizontal length of each tarsus is approximately 30 mm. The height is greatest in the mid-portion of the lid. The height of the upper tarsus is 10 mm, whereas in the lower lid it is 4 mm. Embedded within the tarsal plates are a fine network of meibomian (sebaceous) glands. When obstructed and chronically inflamed, these glands can form a cyst-like mass called a chalazion.

The lacrimal system is responsible for the lubrication and wetting of the globe. Accessory lacrimal glands perform normal wetting of the eye, and the lacrimal gland produces reflex tearing. The lacrimal gland, which is situated in the anterior aspect of the superior lateral orbit, is divided into two lobes by the levator aponeurosis. The larger orbital lobe lies above the levator aponeurosis, and its tear ducts traverse the palpebral lobe, which has 6 to 12 tear ductules that empty into the superior lateral fornix. When drilling in this region, such as during a repair of a frontozygomatic fracture, one must take care not to injure the palpebral lobe or to inadvertently remove it, thinking that it is herniated fat; this error often results in a problematic dry eye. Lacrimal secretions,

Table 24-3 Eyelid Layers: Cutaneous (Anterior) to Conjunctival (Posterior)

Mucous membrane or conjunctiva

or tears, traverse medially and inferiorly across the globe, wetting the cornea, and accumulate at the medial inferior aspect of the eye. The fluid is then either drawn or pumped into the lacrimal puncta of the upper and lower eyelids. These puncta are only 0.2 to 0.3 mm in diameter. The upper punctum is usually just slightly medial in relation to the lower punctum. When the lids close, the puncta come into contact. The upper and lower canaliculi travel within the lids, first vertically (2 mm), then horizontally for 8 to 10 mm, paralleling the lid margin. They join to form a common canaliculus just before entering the lateral aspect of the lacrimal sac, which is one-third of the way down from the upper portion of the sac. Typically, the lacrimal sac is 1 cm in length and 5 mm in diameter. The palpebral portion of the orbicularis oculi has dense intertwined insertions that envelope the lacrimal sac. Inferiorly, the sac drains into the nasolacrimal duct, which has a 12 mm intrabony canal coursing inferiorly and posteriorly that opens into the inferior meatus of the nasal cavity below the inferior concha. This opening is 30 to 35 mm from the edge of the external nares. Reflux of tears and nasal mucus back up into the nasolacrimal duct is prevented by a mucosal fold called Hasner's valve. With persistent epiphora following trauma or surgical intervention, it is important to establish the precise point of mechanical obstruction that exists within the lacrimal drainage system. Irrigation of the inferior canaliculus may relieve temporary obstruction owing to dry or thickened secretions. A dye disappearance test, Jones I or II, nasolacrimal irrigation, or dacryocystography can help one determine the precise point of obstruction and guide surgical planning. Following trauma or operative intervention, epiphora may be due to hypersecretion from a corneal abrasion, lash ptosis, foreign bodies, or entropion, all of which serve as persistent stimuli leading to reflex lacrimal gland secretion.

Fracture Configurations

Isolated orbital wall fractures account for 4 to 16% of all facial fractures. If fractures that extend outside the orbit are included, such as those of the zygomatic complex (ZMC) and naso-orbitoethmoid (NOE), then this accounts for 30 to 55% of all facial fractures.^{11,12}

ZMC fractures are the most commonly occurring facial fracture, second only to nasal fractures. By definition, ZMC fractures are the most common fracture with orbital involvement.¹³ The ZMC, or tripod, often hinges about the frontozygomatic suture with a medial, inferior, and posterior vector of rotational displacement. This is due to the direction and force of blunt trauma and the variable thicknesses of the components of the ZMC. The frontozygomatic area offers the thickest pillar. When fractured there is usually a slight vertical displacement with a reasonable anteroposterior alignment. The much thinner anterior maxillary and lateral orbital floor offers little resistance to fracture and displacement.

Fractures of the NOE are most often due to severe blunt midface trauma. These fractures create cosmetic deformities with a flattening of the nasal dorsum and a widening of the intercanthal distance; they can also be accompanied by a violation of the underlying dura with a cerebrospinal fluid (CSF) leak. Any persistent or copious clear nasal drainage should be tested to determine a β_2 -transferrin level to rule out a CSF leak. It is uncommon for the canthal tendons to become disinserted from the bones. This is particularly true of the lateral canthal tendon. Traumatic telecanthus with NOE fractures is a result of a flattening of the nasal bridge and a lateral splaying of the orbital rims and anterior lacrimal crest. Reduction and fixation of these bony segments and, less frequently, direct transnasal wiring are necessary for adequate restoration of medial intercanthal distance and alignment. In adult Caucasians this is typi-

cally 29 to 32 mm; it is slightly more in black and Asian individuals. Lacrimal drainage problems can also arise from severe NOE fractures owing to canalicular or lacrimal sac disruption or scarring.

Internal orbital fractures occur in numerous patterns. These fractures are typically described by their location and the size of the defect. Three basic patterns of internal orbital fractures have been described: linear, blow-out, and complex.¹⁴ Linear internal orbital fractures maintain periosteal attachments and typically do not result in a defect with orbital content herniation; however, they can result in a significant enlargement of the orbital volume with a resulting late enophthalmos. Blow-out fractures are the most common. By definition, these are limited to one wall and typically are 2 cm or less in diameter. The most commonly involved wall with a blow-out fracture is the anterior medial orbital floor, followed by the medial wall and, less frequently, the orbital roof, which can present as a *blow-in* fracture. Exploration, repair, or reconstruction of an orbital roof fracture may be indicated if a dural tear is suspected or to prevent a "pulsatile globe." This rhythmic inward and outward movement of the eye is due to the cerebrovascular pulsation and the influence of respiration on the overlying cerebral hemispheres. This phenomenon is typically not present acutely but occurs after resolution of edema, with the recovered patient complaining of persistent blurred or double vision. Complex internal orbital fractures consist of extensive fractures affecting two or more orbital walls; they often extend to the posterior orbit and may involve the optic canal. These complex fractures are usually associated with more severe trauma and surrounding fractures such as Le Fort II, Le Fort III, and frontal sinus fractures.

Clinical Examination

Even in the most severely injured patient, the mechanism of injury and surrounding

history should be ascertained before performing a clinical examination of the orbit and globe. A systematic approach assessing both the globes and orbits further defines functional and cosmetic defects. The initial ophthalmologic evaluation should include periorbital examination, visual acuity, ocular motility, pupillary responses, visual fields, and a fundoscopic examination.

Visual acuity should be independently tested on each eye using a Snellen chart at a standard 6 m (20 ft.) distance or with reading of standard-type print at 40 cm (16 in.). The patient should wear their corrective lenses during this examination. If over 40 years of age, the patient should be wearing his or her reading glasses. The eyelids and periorbital region should be inspected for edema, chemosis, ecchymosis, lacerations, ptosis, asymmetric lid drape, canalicular injury, and canthal tendon disruption. With significant acute periorbital ecchymosis, there should be an increased suspicion of a direct blunt globe injury or an internal orbital wall fracture. A lid retractor (Desmarres) is useful for separating swollen tight lids so that the globe and pupil can be adequately examined. Also, this retractor may serve to lift the edge of the lid to examine its inner aspect. With an upper eyelid laceration, any fat that is herniating below the level of the brow through the wound should cause concern that an underlying injury has occurred to the levator muscle. Likewise, if the palpebral conjunctiva has been violated, it is prudent to consult an ophthalmologist to rule out a globe perforation. With a medial vertical laceration of the lids, particularly the lower, gentle lateral retraction may reveal a cut canaliculus or medial canthal tendon disinsertion. Canalicular disruption warrants an urgent ophthalmology consult and usually requires surgical reanastomosis and silicone tube placement into the nasolacrimal system and surrounding supportive repair to prevent outflow obstruction and epiphora.

Extraocular movements are evaluated to rule out mechanical entrapment or paresis. Diplopia, and the field of gaze in which it occurs, should be noted (Figure 24-3). Of greatest concern is diplopia in the primary (straight-ahead) and downward gazes. These are the two fields that are used most often. Mild or equivocal restriction ($< 5^\circ$) in extreme fields of gaze is common in the setting of severe orbital trauma with hemorrhage or edema. Computed tomography (CT) scan findings should be correlated with any clinically noted entrapment. If mechanical entrapment is suspected, then the eye should be topically anesthetized and a forced duction performed with a fine-toothed forceps. Typically, an Adson forceps is used at the inferior fornix with the beaks open, pressing inward against the depth of the fornix and toward the globe side, until the globe rolls downward slightly. The beaks are then pressed together, grasping the insertion of the inferior rectus. Upward, downward, and lateral motions can be evaluated. The point of doing a forced duction test is to determine whether the diplopia is due to a restriction of a muscle or paresis of a muscle.

Pupillary light reactivity, size, shape, and symmetry should all be assessed and noted. If unequal pupils (anisocoria) or an irregularly pointing pupil is found, then the patient should be queried regarding previous ocular trauma or eye surgery (cataracts). An irregular pupil often points toward the site of a globe penetration or injury. This is often teardrop shaped, with the narrow portion pointing toward the perforated side of the globe, which is usually concealed beneath the lid (Figure 24-4). An ophthalmologist should be consulted immediately and precautionary measures instituted, including protective Fox shield over the eye, head-of-bed elevation, bed rest, analgesics, and antiemetics to avoid sudden increases in intraocular pressure owing to Valsalva forces.

Both globes should be evaluated for any acute enophthalmos, exophthalmos, or

vertical dystopia. This is often ascertained from above or by standing directly in front of the patient. Visual fields are tested for each eye, one at a time, by confrontation. The examiner and patient faces should be positioned directly toward each other, 0.6 m apart. The patient is asked to stare directly into the examiner's eyes, while the examiner's hand is held in their own extreme field of gaze, midway between the patient and the examiner. The patient is then asked to detect numbers of fingers showing, motion, or the digit displayed. In essence, the examiner's peripheral field of gaze is serving as a control for the patient.

Quadrant defects are indicative of post-chiasm injury. A fundoscopic examination should be performed in a dimly lit room to help maximize pupillary dilatation and ease of the examination. Lens dislocation, vitreous hemorrhage, retinal detachment, and foreign bodies may be noted or may be the cause for not being able to view the fundus. If history and initial clinical findings warrant a dilated fundoscopic examination, then neurologic status should be reevaluated and confirmed, and clearance from the primary treating physician or neurosurgeon first obtained. A dilated fundoscopic examination with indirect ophthalmoscopy is generally performed by an ophthalmologist to rule out more occult injuries or examine a greater portion of the globe toward the equator. The ophthalmologist may elect to perform tonometry or a slit-lamp examination. Tonometry indirectly measures intraocular pressure by placing the instrument on the surface of the eye. Normal (10–20 mm Hg) or symmetric bilateral readings are reassuring. However, this does not rule out a penetrating injury. With elevated pressures but an otherwise unremarkable examination, a history of glaucoma should be elicited. An acute abnormally high intraocular pressure with exophthalmos, limited globe movement, and resistance to retropulsion is indicative of a retrobulbar hematoma, which may

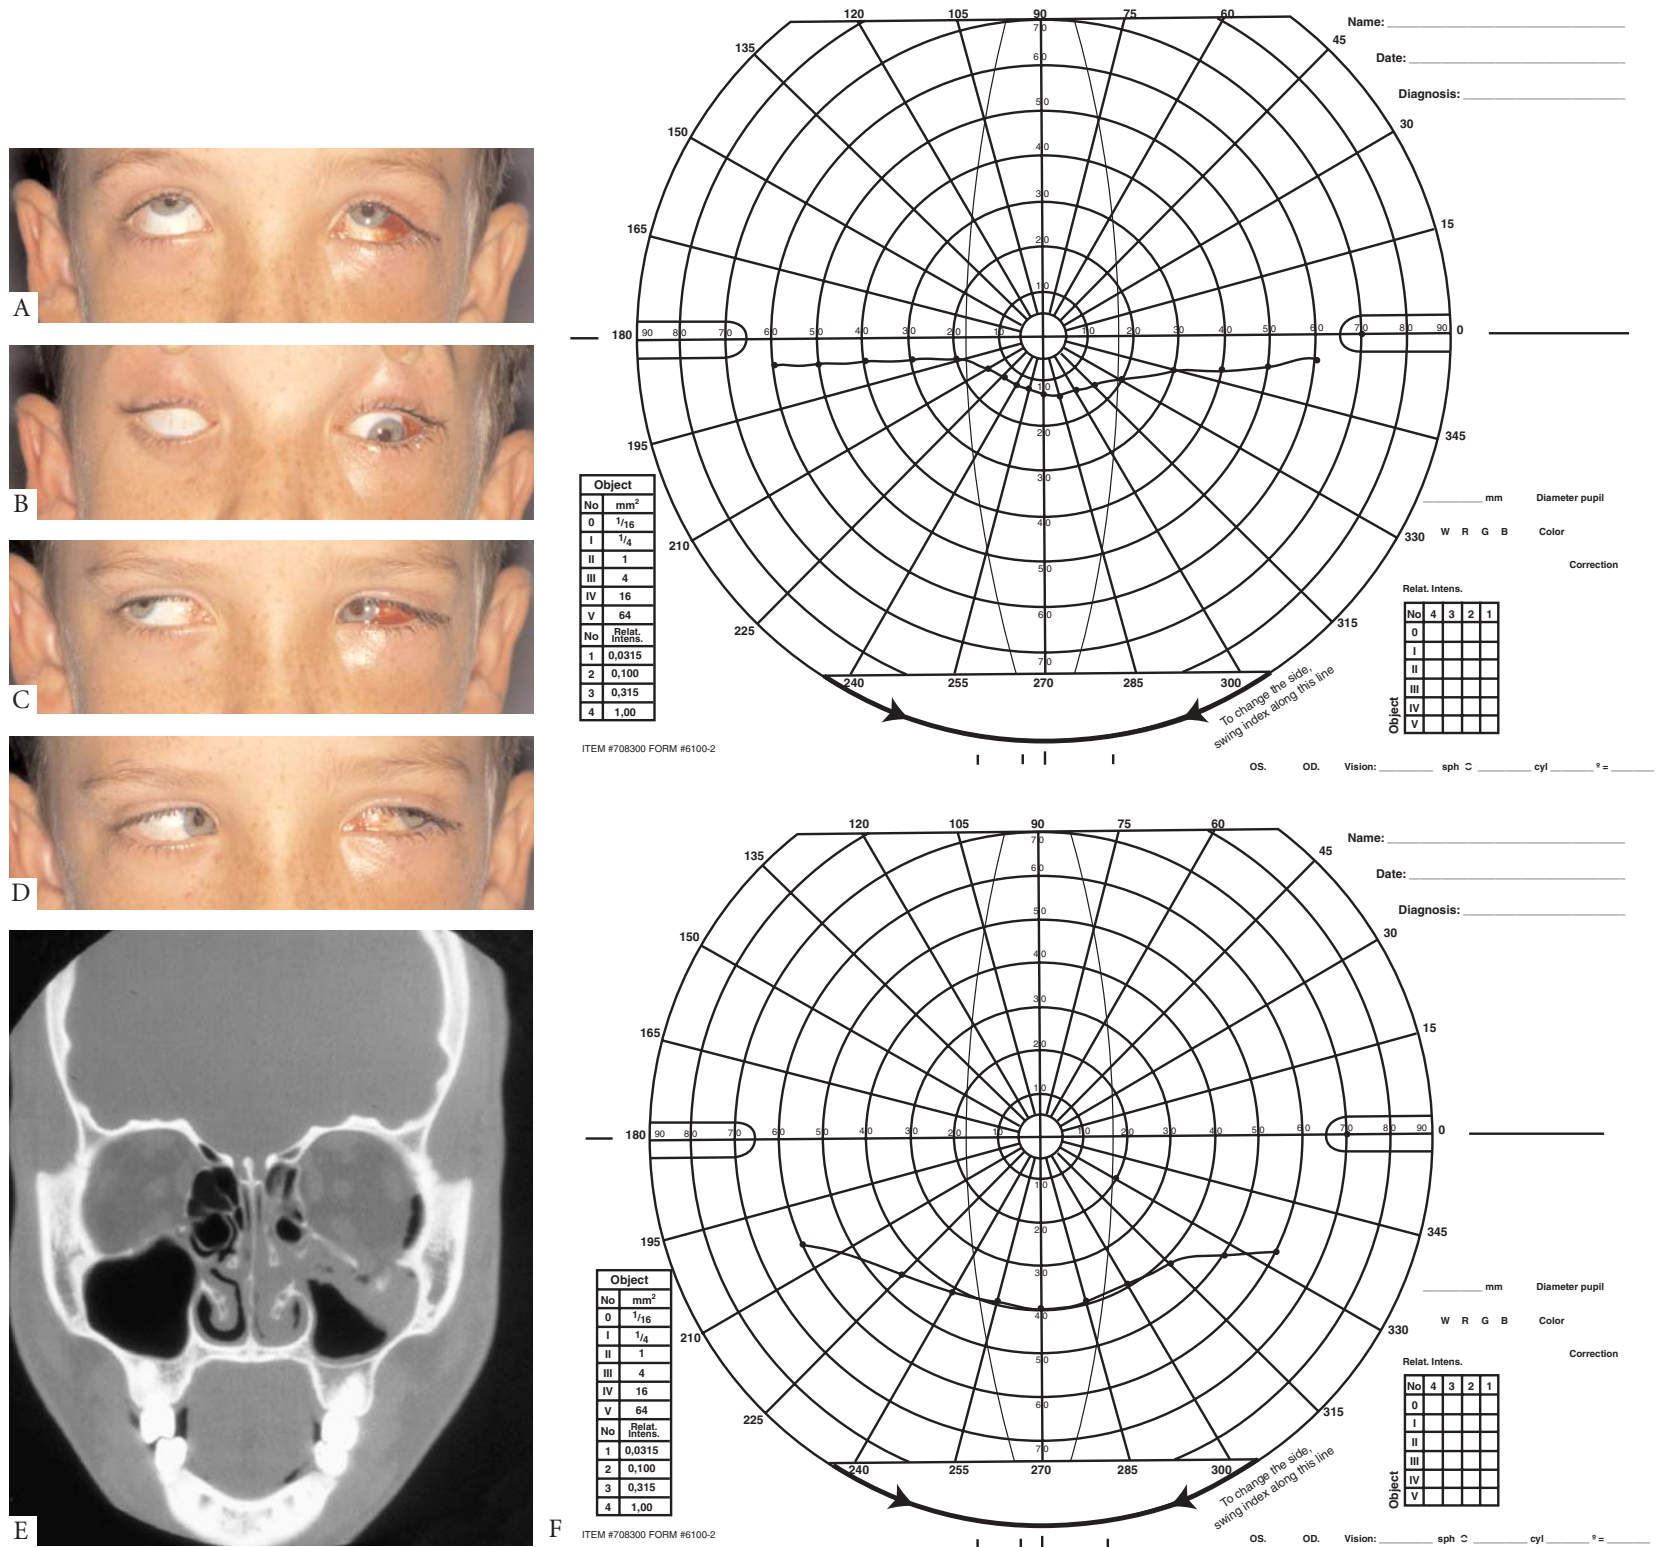

FIGURE 24-3 This 9-year-old child presented with complaint of “double vision and cheek numbness” after being struck in the left orbital region with a hardball. A, Note the lateral subconjunctival hemorrhage and that there was no difficulty in the upgaze. B, In downgaze he had severe firm fixed restriction of the left eye that was positive to a forced duction test. C, The right lateral gaze had trace restriction. D, The left lateral gaze was unremarkable. E, Direct coronal computed tomography (CT) scan of the bony window revealed a trapdoor fracture of the left orbital floor with herniation and a probable impingement of the inferior oblique muscle and fascial framework. F, Diplopic visual fields (Goldman visual field test). With binocular testing, patients are asked to look at the grid and track a pointed light that is shown from behind the chart. When patients experience double vision, they respond to the examiner who charts the abnormality. In this case, the upper grid was recorded at the initial presentation. Diplopia was experienced in all areas below the line (10–12°). This child’s severely limited downgaze, correlated with the CT findings, prompted surgical exploration and orbital floor repair within 12 hours. The lower grid was recorded at 10 days postoperatively and showed marked improvement in the downgaze, with diplopia occurring at 40° inferiorly.

FIGURE 24-4 Laceration of the right lower medial eyelid that extends through the margin. At first the examiner thought there was simply a strand of clotted blood on the medial globe. Recognition of the irregular-pointing pupil led to the suspicion of a globe perforation, which was confirmed with a dilated ophthalmologic examination.

require acute evacuation via a lateral canthotomy. A “soft eye” with a relatively low pressure or deep anterior chamber is suggestive of a posterior scleral rupture.

A slit-lamp examination is generally performed with the patient in an upright position; if the patient is confined to a bed, a modified examination can be performed with a penlight. A handheld portable slit lamp can be used in the trauma setting. The purpose of this examination is to evaluate the surface contour of the globe and cornea to rule out conjunctival chemosis (swelling), hemorrhage, emphysema, and foreign bodies. The anterior chamber should be evaluated for depth, clarity, and hyphema (blood in the anterior chamber). Hyphema, if found, should be evaluated by an ophthalmologist so that surgical evacuation or medical management may be instituted in an effort to avoid occlusion of the trabecular meshwork, which may lead to glaucoma or a fixed iris. The iris’s shape and reactivity should also be noted. If a corneal abrasion or laceration is suspected, this may be more thoroughly evaluated with fluorescein dye and a Wood’s lamp (cobalt blue light). The fluorescein dye pools in the laceration or abrasion and fluoresces with a bright lime-green hue under the lamp-light (Figure 24-5).

Finally, the bony orbital rim should be palpated for steps, crepitus, and mobility. The patient should be queried about altered or lack of sensation, and neurosensory testing should be performed to evaluate the supraorbital, supratrochlear, and infraorbital nerves.

Imaging

Once a complete ophthalmologic and oral examination has been performed, selected studies such as CT or magnetic resonance imaging (MRI) can be ordered with defined parameters to provide meaningful results. Imaging is essential for proper diagnosis and treatment of orbital trauma. Noncontrasted CT is the primary imaging modality currently used for evaluating injuries from blunt or penetrating trauma, as well as for localizing most orbital foreign bodies.¹⁵ Other imaging modalities, such as plain radiography, reconstructed three-dimensional CT, MRI, ophthalmic ultrasonography, color Doppler imaging, and angiography, may provide necessary additional information in select instances. CT scans have become the standard of care in evaluating acute orbital injuries. Standard radiography is a readily available and inexpensive method for primary evaluations of orbital fractures. Plain radiography, however, is inadequate when used in evaluating internal orbital fractures, and it is difficult to localize foreign bodies with plain films

FIGURE 24-5 A broad corneal abrasion of the right eye illustrated with the pooled fluorescein dye under a cobalt blue (Wood’s) lamp.

alone. Waters’ projection allows visualization of the orbital roof and floor and is particularly useful for evaluating orbital floor blow-out fractures (Figure 24-6). With this 23° (preferably posteroanterior) view, the petrous portion of the temporal bones is projected below the maxillary sinuses and indirect signs of fracture can be noted, such as a teardrop formation or air-fluid levels. This is also an excellent view to assess a ZMC fracture.

If plain films reveal an internal orbital fracture that possibly warrants surgical intervention, then CT scans should be obtained. The fracture can then be fully evaluated for surgical treatment planning. CT allows excellent visualization of orbital soft tissues and permits one to simultaneously assess the cranial vault and brain during a “trauma scan.” A trauma CT scan series generally involves 10 mm axial cuts of the cranium and 5 mm cuts through the facial region. If finer detail or three-dimensional reconstructed images are desirable, then 1 mm fine cuts can be ordered. Internal orbital fractures are best evaluated when the imaging plane is perpendicular to the fracture line. Thus, images are usually obtained in

FIGURE 24-6 Waters’ view demonstrating opacification of the left maxillary sinus and a medially displaced left zygomatic buttress and arch.

both the axial and coronal planes to fully evaluate the fracture lines, patterns, and volume changes. This is particularly useful for comparison to the contralateral or uninjured side. The standard imaging approach for facial trauma is to obtain direct (non-reformatted) 3 to 5 mm sections in the axial and coronal planes. Intravenous contrast offers no advantages to the evaluation of acute bony facial injuries. Direct coronal views with 3 mm sections are preferred for evaluating orbital roof or floor fractures; however, they may be unobtainable owing to cervical spine precautions or the patient's inability to extend the neck and adequately position him- or herself for the coronal CT. In these patients, reformatted coronal images can be obtained based on the axial image data set. However, with this technique, there can be a loss of spatial resolution on the reformatted images. The axial images with fine detail (1 mm slices) must be obtained to allow for meaningful reformatted image quality. If an optic canal fracture is suspected, then 1 to 1.5 mm axial cuts should be obtained.^{16,17} This allows a better determination and correlation of any afferent visual defect owing to possible bony impingement.

Although MRI is generally accepted as a superior soft tissue imaging modality, CT scans adequately assess lens dislocation, vitreous hemorrhage, ruptured globe, retrobulbar hemorrhage, or avulsion of the optic nerve. CT is the imaging of choice in localizing metallic and most nonmetallic foreign bodies in relation to the globe, muscular cone (area inside the extraocular muscles), and the optic nerve.^{15,18} The location and extent of any subperiosteal hematoma formation, with possible mass effects, can also be adequately assessed with CT imaging. Computer-generated three-dimensional CT imaging can provide superior views and spatial orientation of fragments for complex orbital and facial fractures. In the majority of acute facial fractures, three-dimensional CT scanning is unnecessary. However, with complex facial trauma with

severe displacement, or for secondary reconstruction, three-dimensional CT scanning is invaluable for surgical treatment planning.¹⁹ Generally, 1 to 1.5 mm fine axial cuts are obtained; the patient must remain motionless for the entire scan, which may include more than 100 slices.

CT imaging has some drawbacks. As previously mentioned, patients may be unable to position themselves comfortably for direct coronal imaging. Sedation may be warranted in pediatric or uncooperative trauma patients. However, with facial bleeding, possible concomitant mandible fractures, or obtundation from alcohol or street-drug use, a secure airway must be maintained throughout the radiology procedure. This may require endotracheal intubation. CT scans may fail to reveal radiolucent foreign bodies such as wood or vegetative matter.²⁰ In these instances ultrasonography and MRI are most useful in detecting the radiolucent foreign body and localizing it. These studies should be obtained when the CT scans are equivocal or when physical examination suggests the presence of foreign bodies.

MRI can be useful in the setting of orbital trauma to assess soft tissue injury or entrapment of extraocular muscles in the area of the orbital suspensory framework. Standard radiographs or CT scans should be obtained before MRI is performed on patients with suspected intraocular or intraorbital ferromagnetic bodies because of the potential for displacement of the metallic fragments, resulting in further significant ocular or brain injury.^{21,22} With CT imaging, wood can appear isodense with fat or mimic intraorbital air. If the history or clinical examination indicates that fragments of wood may have penetrated the orbit or globe, then an MRI should be ordered. An MRI should also be performed when an apparent orbital emphysema (focal air collection) fails to resorb rapidly (within several days); this may suggest a space-occupying foreign body.²³

Ophthalmic ultrasonography is seldom used but is a readily available, safe, inexpensive, and noninvasive imaging modality.²⁴ Foreign bodies located in the orbit can be identified with ultrasonography but are much more difficult to detect when located in the orbital apex owing to signal reflection. Wood and other radiolucent materials can be detected with ultrasonography.²⁵ Color Doppler imaging is an ultrasound technique that provides simultaneous two-dimensional images and visualization of blood flow.²⁶ It can be useful in evaluating a post-traumatic high-flow carotid cavernous fistula. However, angiography remains the study of choice for definitively establishing this diagnosis.

Ocular Injuries and Disturbances

Patients who sustain midfacial trauma, particularly in motor vehicle accidents, often have concomitant neurologic and multisystem injuries. A neurologically impaired or uncooperative patient presents additional challenges in performing an adequate orbital and ophthalmologic examination. It is paramount that the primary tenets of advanced trauma life support be adhered to in securing the airway and protecting the cervical spine. When orbital fractures caused by severe blunt force trauma are detected, additional associated injuries should be sought, such as orbital canal or apex involvement, retrobulbar hematoma, or globe perforation. When there are multiple midface fractures, such as those of the ZMC, NOE, and frontal sinus, and Le Fort II or Le Fort III fractures, then more severe intraorbital injury, bleeding, and globe perforation are likely. Basilar skull fractures, as evidenced by clinical signs such as CSF otorrhea or rhinorrhea, Battle's sign, or CT evidence such as fracture lines or intracranial air, are generally caused by high-velocity impact and are often associated with severe neurologic injury.

Superior orbital fissure syndrome is characterized by impairment of cranial nerves III, IV, V, and VI secondary to compression by a fractured bony segment or hematoma formation in the region. Orbital apex syndrome has all the hallmarks of superior orbital fissure syndrome, with the addition of optic nerve (cranial nerve II) injury. Between 0.6 and 4% of patients suffering orbital fractures have a globe injury or optic nerve impairment, resulting in a significant or total loss of vision in one eye.^{27,28} This fact highlights the need for a thorough initial ophthalmologic and visual acuity assessment, with follow-up serial examinations as indicated.

Visual Impairment

Visual impairment or total vision loss can occur at various levels along the optic pathway. Direct injury or forces transmitted to the globe by displaced fracture segments can result in retrobulbar hematoma, globe rupture, hyphema, lens displacement, vitreous hemorrhage, retinal detachment, and optic nerve injury. Patients with orbital fractures and any degree of visual impairment who complain of severe ocular pain should be evaluated for retrobulbar hematoma. It is often the “less impressive” orbital fracture that leads to retrobulbar hematoma formation (Figure 24-7). This is due to bleeding within a relatively closed compartment

FIGURE 24-7 Axial computed tomography scan of a right retrobulbar hematoma. This diffuse infiltrative pattern is characteristic, whereas the discreet clot mass is less common.

and the lack of a potential drainage pathway through paranasal sinuses, such as the ethmoids or maxillary sinus. In essence, there is a compartment syndrome resulting from elevation of intraorbital pressure, which leads to central retinal artery compression, or ischemia of the optic nerve. The increased intraorbital pressures can secondarily raise the intraocular pressure, which, in turn, compromises the ocular blood supply.^{29–31} In most instances requiring emergent treatment, there is a degree of exophthalmos and excessive tension of the lids. Although CT scanning to confirm the diagnosis is desirable, there should not be unnecessary delay in the surgical management. The immediate or urgent surgical management for retrobulbar hematoma evacuation consists of a lateral canthotomy, with or without inferior cantholysis, and disinsertion of the septum along the lower eyelid in a medial direction. A small Penrose drain is left in place for 24 to 48 hours to ensure adequate drainage and to prevent reaccumulation. Additional maneuvers to lower the intraocular pressure include administration of intravenous mannitol or acetazolamide or application of various glaucoma medications. Typically, blow-in fractures or inward rotation of the ZMC does not result in increased intraorbital or intraocular pressures with visual impairment. This is most likely due to pressure relief and volume expansion provided by additional orbital wall fractures such as the medial wall into the ethmoid or the floor sagging into the maxillary sinus.

A penetrating globe injury can result from what appears to be an innocuous small laceration or from horrific blunt-force trauma. When an eyelid laceration is accompanied by an asymmetric pupil, without a prior history of surgery, then a globe perforation likely exists (Figure 24-8). Blunt trauma can lead to globe perforation owing to a scleral rupture from the sudden instantaneous increased intraocular pressure. The most common site for

FIGURE 24-8 A full-thickness corneal laceration and an irregular pupil of the right eye is seen during a slit-lamp examination.

scleral rupture is at the site of previous cataract surgery, at the limbus, or just posterior to the insertion of the rectus muscles onto the globe, which is 5 to 7 mm from the edge of the limbus. The area under the muscle insertion is anatomically the weakest and thinnest portion of the sclera. With suspected globe perforation, pupillary dilatation and inspection by an ophthalmologist is mandatory. The inspection may be difficult—the injury may not be visible on fundoscopic examination since it is anterior to the equator of the globe and externally may be hidden underneath the rectus muscle insertion. Detection and surgical access for repair may require dissection of the bulbar conjunctiva with retraction of the extraocular muscles and external globe inspection. The penetrating injuries should be treated emergently, or within 12 hours, to decrease the risk of infection or ocular content herniation. The ultimate visual outcome directly correlates with the presenting visual acuity. Few eyes that cannot detect hand motions or have no light perception (NLP) regain useful vision. Globe injuries should be addressed before any facial lacerations are repaired. The exception is significant active blood loss from a severed vessel.

Hyphema is blood in the anterior chamber of the eye. It can be as severe as complete obliteration of the anterior chamber, termed “eight-ball hyphema,” or

more commonly a thin 1 to 2 mm layering at the inferior margin in the upright position (Figure 24-9). Some hyphemas are termed microhyphemas, with red blood cells floating in the anterior chamber and not layering out. The level and severity of the hyphema should be noted and recorded. The bleeding is from the rupture of an iris or ciliary body vessel and usually is the result of blunt trauma. Patients often complain of eye pain and, occasionally, visual loss if the amount of bleeding is severe. Medical management of hyphema is aimed at preventing rebleeding and venous congestion and promoting clearance of the existing blood. This may include hospitalization, bed rest, head-of-bed elevation, and longer-acting cycloplegics (topical agents such as scopolamine or atropine). Cycloplegics maintain a dilated pupil and thus immobilization of the iris, which discourages further rebleeding. Topical steroids may be administered to decrease further rebleeding and reduce intraocular inflammation. Oral aminocaproic acid is an antifibrinolytic recommended to reduce the incidence of rebleeding into the anterior chamber. In moderate to severe cases there should be daily monitoring of intraocular pressures and control of any high pressure increases with intravenous carbonic anhydrase inhibitors (acetazolamide, which

FIGURE 24-9 This partial hyphema of the right eye resulted from a punch to the face; a computed tomography scan showed a minimally displaced orbital floor fracture. The slit-lamp examination shows early layering. This patient received nonoperative management.

limits aqueous humor production) or hyperosmotics (mannitol). With severe hyphema, intraocular surgery to irrigate, aspirate, and evacuate the clot may be necessary to prevent optic atrophy owing to elevated pressures, or to avoid permanent corneal blood staining.³² The anterior chamber washout is the most commonly performed procedure for this purpose.

Vitreous hemorrhage can result from blunt trauma with the rupture of ciliary, retinal, or choroidal vessels. If, during fundoscopic examination, the retina cannot be visualized despite a normal-appearing anterior chamber and lens, vitreous hemorrhage is most likely present. As with hyphema, initial management typically involves hospitalization, bedrest with head-of-bed elevation, and serial clinical examinations. Vitreous hemorrhage is slow to resolve, and it may take months for this to clear, with symptomatic visual improvement.³³ A vitrectomy may be required after 6 months if satisfactory resorption has not occurred.

Lens dislocation may be detected by fundoscopic or slit-lamp examination. The lens, in its normal anatomic position, physically separates the anterior and posterior chambers, but it can be dislocated either partially or totally into either one. Symptoms include monocular diplopia and blurred vision; thus, it is important to check each eye's visual acuity independently. Posterior dislocation may be well tolerated; however, complete anterior dislocation can result in glaucoma and usually requires emergency extraction of the lens.

Rhegmatogenous retinal detachment and peripheral tears result from blunt force trauma. Characteristic symptoms include flashing lights and a field loss best described as a curtain or window shade coming over the eye. On fundoscopic examination, the retina may not be clearly visualized, or undulations may be present. Retinal detachments require surgery.³³ An emergency consultation with an ophthalmologist and initial maneuvers should be

instituted. Maneuvers involve bedrest in a head-up position and assurance that there is no Valsalva-type exertion; these prevent further extension of the detachment. Operative management may include any or all of the following: a scleral buckle, cryotherapy a vitrectomy, or endolaser. In-office pneumatic retinopexy works well with superior detachments: an inert expandable gas is injected into the vitreous and indirect laser treatment is applied.

Optic nerve injury or compromise can result from orbital fractures in the posterior region or optic canal. Optic nerve injury or vascular compromise is characterized by decreased visual acuity, diminished color vision, and a relative afferent pupillary defect. It is possible to retain very good vision and yet still have an optic nerve injury manifested by color deficits, afferent papillary defect, and visual field loss. Detection of early subtle changes require that a cooperative patient undergoes visual acuity testing, consisting of testing with a Snellen chart, finger counting, detection of motion, or light perception. Patients may present with NLP, which mandates an emergency consultation with an ophthalmologist and a fine axial CT imaging of the orbital apex. If NLP persists > 48 hours, then rarely does any meaningful vision return to the affected eye. Patients with NLP or severely decreased visual acuity may be suffering from traumatic optic neuropathy and should be given high-dose systemic methylprednisolone therapy for at least 48 to 72 hours (initial loading dose of 30 mg/kg IV methylprednisolone sodium succinate, followed by 15 mg/kg IV 2 h later and q6h thereafter).³⁴⁻³⁶ If the patient is uncooperative, heavily sedated, or unconscious, pupillary reaction can be monitored and followed as a sensitive test of optic nerve (cranial nerve II) function. This is best achieved in a dimly lit room; a penlight is moved alternating from one eye to the other every 2 to 3 seconds, and the pupillary response is observed. With

the light shining into the normal eye, both pupils should exhibit a brisk constriction. If the light is then directed from the uninjured to the injured eye the pupil on the injured eye will dilate. This is indicative of an optic nerve injury (relative afferent pupillary defect). A unilateral, fixed, dilated pupil is usually due to an efferent pathway injury (cranial nerve III), or some form of intracranial injury or bleed, which is usually accompanied by other neurologic lateralizing signs.

Diplopia

When a patient complains of seeing a double image of the same object, the examiner should first test each eye independently by covering the opposite eye to determine whether the diplopia is monocular or binocular. Monocular diplopia is usually due to lens dislocation or opacification, or another disturbance in the clear media along the visual axis. Acute binocular diplopia, secondary to trauma, derives from one of three basic mechanisms: edema or hematoma, restricted motility, or neurogenic injury. The most common cause of binocular diplopia following trauma is orbital edema and hematoma. This is usually found in peripheral fields of gaze, and, if other findings are absent, diplopia in the primary and downward gazes usually resolves along with the edema in 7 to 10 days. Slight diplopia in extreme peripheral fields of gaze may persist for months but is rarely problematic since individuals seldom require these extreme views for everyday function. Also the patient may complain that the phenomenon is transitory and that sudden looking “upward and outward” (superiorly and laterally, such as when looking in a rearview mirror) may cause instantaneous but brief diplopia. Binocular vision without diplopia is most important in the primary (straight-ahead) and downward fields of gaze. The majority of our daily activities, such as conversing, reading, and walking, use these visual fields. If diplopia

persists, an ophthalmologic consultation should be sought. Systemic corticosteroids hasten the resolution of orbital edema and the resulting diplopia, which is fairly common following blunt trauma to the orbit.

Persistent post-traumatic diplopia is best evaluated by an ophthalmologist. It is important to establish an accurate diagnosis and precise etiology. The basic evaluation should include assessing symmetry of the corneal light reflexes and testing of ductions (following a finger in all eight fields of gaze) including a selective forced duction. The forced duction helps distinguish between restricted motion from entrapment, scarring, or fibrotic contractures versus a neurogenic motility disorder (cranial nerves III, IV, or VI). Ophthalmologists use diploic visual fields (see Figure 24-3F) to quantify and categorize the diplopia; serial examinations allow accurate tracking of spontaneous recovery or postsurgical progress. In the acute setting, restrictive disorders are managed with early bony orbital surgery and reconstruction, whereas neurogenic disorders are managed with the injection of botulinum toxin into select extraocular muscles whose forces are unopposed by the injured or restricted muscles. Following bony orbital reconstruction or selective botulinum toxin injections, there should be a 6- to 12-month waiting period for the diplopia to stabilize. Then, any residual and stable diplopia can be addressed with strabismus (extraocular muscle) surgery. Strabismus surgery has two basic maneuvers: a repositioning of muscle insertions onto the sclera or a weakening of the opposing muscles. After a period of healing, selective botulinum toxin injections or more minor revision strabismus surgery may be required to fine-tune the result. The important point to stress is that a healed abnormal bony wall position or orbital volume changes, resulting in enophthalmos or vertical dystopia, typically do not cause stable significant diplopia. In fact, vertical dystopia of up to

1 cm can be accommodated by the brain and should not result in diplopia in the primary fields of gaze. Therefore, any bony wall revision or reconstruction should be performed to correct a cosmetic or other functional defect without promise of correction or improvement in any coexisting diplopia. These reconstruction procedures should be performed and allowed to heal, and the diplopia allowed to stabilize for 6 months prior to the strabismus surgery, which would address the diplopia.

In the trauma setting, diplopia may be due to restricted ocular motility from a prolapse of the periorbital contents into the medially fractured ethmoid air cells or underlying maxillary sinus. Such diplopia may also be due to entrapment or direct impingement on the fine suspensory ligamentous system of the orbit or, less frequently, of the extraocular muscles. Restricted motility or entrapment is commonly found with orbital floor and medial wall fractures, less frequently with roof fractures, and rarely with lateral wall fractures. Significant medial wall fractures are manifested primarily by enophthalmos owing to volume expansion.

When testing range of motion, if there is repeatedly a firm fixed limited stop of unilateral eye motion, the eye should be anesthetized topically and a forced duction test performed. Occasionally the entrapment or incarceration of the supporting structures or muscles is mild, and during the forced duction, initial resistance may be encountered and then relieved. In such an instance, the positive forced duction test was both diagnostic and therapeutic. However, if the forced duction test is positive and mimics the voluntary active point of restricted motion, this should be correlated with CT scan findings (see Figure 24-3).³⁷ A repeatable fixed point of limitation is usually due to direct entrapment of the extraocular muscles or the capsulopalpebral fascia (fascia of Tenon). This is more common in linear floor fractures than in comminuted multiple wall fractures.

Patients with muscle or Tenon capsule incarceration confirmed by CT are candidates for urgent exploration and repair (within 12 h). Prolonged muscle entrapment with ischemia can lead to fibrosis (Volkmann's contracture) with permanent diplopia, despite surgical release of the entrapped tissues. When exploring these fractures, the entrapped fascia or muscle can be difficult to release. This classically occurs in the pediatric patient with an anteroposterior linear fracture of the orbital floor with no accompanying rim fracture. When an area of resistance is encountered initially and correlates to this same anatomic location on CT, then consideration should be given to inserting an instrument within the anterior fracture line and gently twisting or prying to open up the fracture, or taking a fine osteotome or instrument to fracture away a small adjacent strip of orbital floor so that a thin blunt malleable retractor on either side of the entrapped area can gently lift and reduce the entrapped soft tissues back into the orbit. Direct grasping of the tissues and tugging to reduce them back into the orbit may result in further contusion and injury.

Diplopia can be due to a central ophthalmoplegia owing to impairment of cranial nerves III, IV, or VI. The fourth nerve is the most commonly injured at the point where it passes over the petrous ridge of the temporal bone. This results in vertical diplopia and a compensatory head tilt to the opposite shoulder. These nerves have fairly long intracranial tracts and can be injured by direct skull fractures or be compressed by intracranial bleeds or diffuse cerebral edema after blunt head trauma. Cranial nerve palsies often spontaneously recover within 6 to 9 months. Recovery is quite variable and is dependent on severity and the type of injury.

Eyelid Lacerations

Eyelid lacerations, particularly those extending to the lid margin and gray line, should be thoroughly evaluated for

lacrimal drainage system injury, canthal tendon disruption, or injury to the tarsal plate and levator aponeurosis. After antibiotics and tetanus prophylaxis have been administered as necessary, the wound should be cleansed and débrided, taking care to protect the globe, possibly with a contact lens. The eyelid laceration should be repaired in a layered fashion, starting with the tarsal plate repair (with 6-0 polyglycolic acid), lid margin (two to three interrupted sutures with 6-0 silk, which is nonirritating to the cornea), orbicularis muscle re-apposition (multiple 6-0 plain gut sutures), and finally skin (with 6-0 nylon or 6-0 fast-absorbing gut). Topical ophthalmic ointment should be prescribed since these agents come in contact with the globe frequently, and sutures should be removed in 5 or 6 days. Patients should be followed up and monitored for potential complications such as scar contracture or lid notching. Several weeks post repair, if significant lid contracture or focal thickening is noted, then selective judicious steroid injections (triamcinolone acetonide, 40 mg/mL) can be administered with accompanying daily massage by the patient.

In my experience, avulsion or loss of eyelid soft tissue is rare. When this occurs, it is usually from an abrasive crushing macerated-type laceration sustained in such accidents as a rollover in an all-terrain vehicle or ejection from a motor vehicle. In evaluating these injuries, the examiner should moisten the rolled edges of the laceration and attempt to gently realign them. One should not abnormally align the tissues, borrowing them from the periphery and shortening them in the vertical dimension. This can result in lid retraction or lagophthalmos, with risks of corneal exposure and ulceration. It is best either to leave a small amount of denuded underlying tissues, which will reepithelialize secondarily, and possibly perform a temporary tarsorrhaphy, or, for larger defects, to harvest a thin

defatted skin graft for primary reconstruction (Figure 24-10).

Lacrimal Injuries

Injuries to the lacrimal drainage system most often result from direct eyelid lacerations at the medial edge of the lid, which traverse the lid margin and disrupt the inferior canaliculus. Canalicular lacerations also occur indirectly when strong forces are applied to the lateral aspect of the lids. This tension directed laterally causes the eyelid to split at the weakest point, which is just medial to the punctum (Figure 24-11). Damage to the lacrimal drainage system can also be seen with severe medial rim and orbital wall fractures. A disruption in the lacrimal system can be detected by passing a lacrimal probe through the punctum and visualizing the blunt-tipped probe within the laceration or wound. It is especially important to detect this with the inferior canaliculus since this system is dominant in the vast majority of patients.

Repair involves reanastomosis of the canaliculus and either mono- or bicanalicular intubation. With bicanalicular intubation, repair is performed by passing a silicone intubation tube through the puncta into the laceration and then locating the distal cut end of the drainage system for passing the tube into the nose, which is retrieved with a hook beneath the inferior turbinate. Typically both the superior and inferior canaliculi are intubated (usually one is uninjured); both silicone tubes are passed into the nose and are tied to each other. This allows for retention of the looped tube for 6 to 12 weeks. Intraoperatively, the silicone tubes are stretched toward the external nares, tied together, and typically oversewn or tied with a fine silk suture to allow for long-term retention. If no tension is applied to the cut ends of the silicone tubing while tying, then, postoperatively, the loop formed at the canaliculi puncta will migrate laterally toward the cornea, causing irritation or an annoying visual field disturbance.

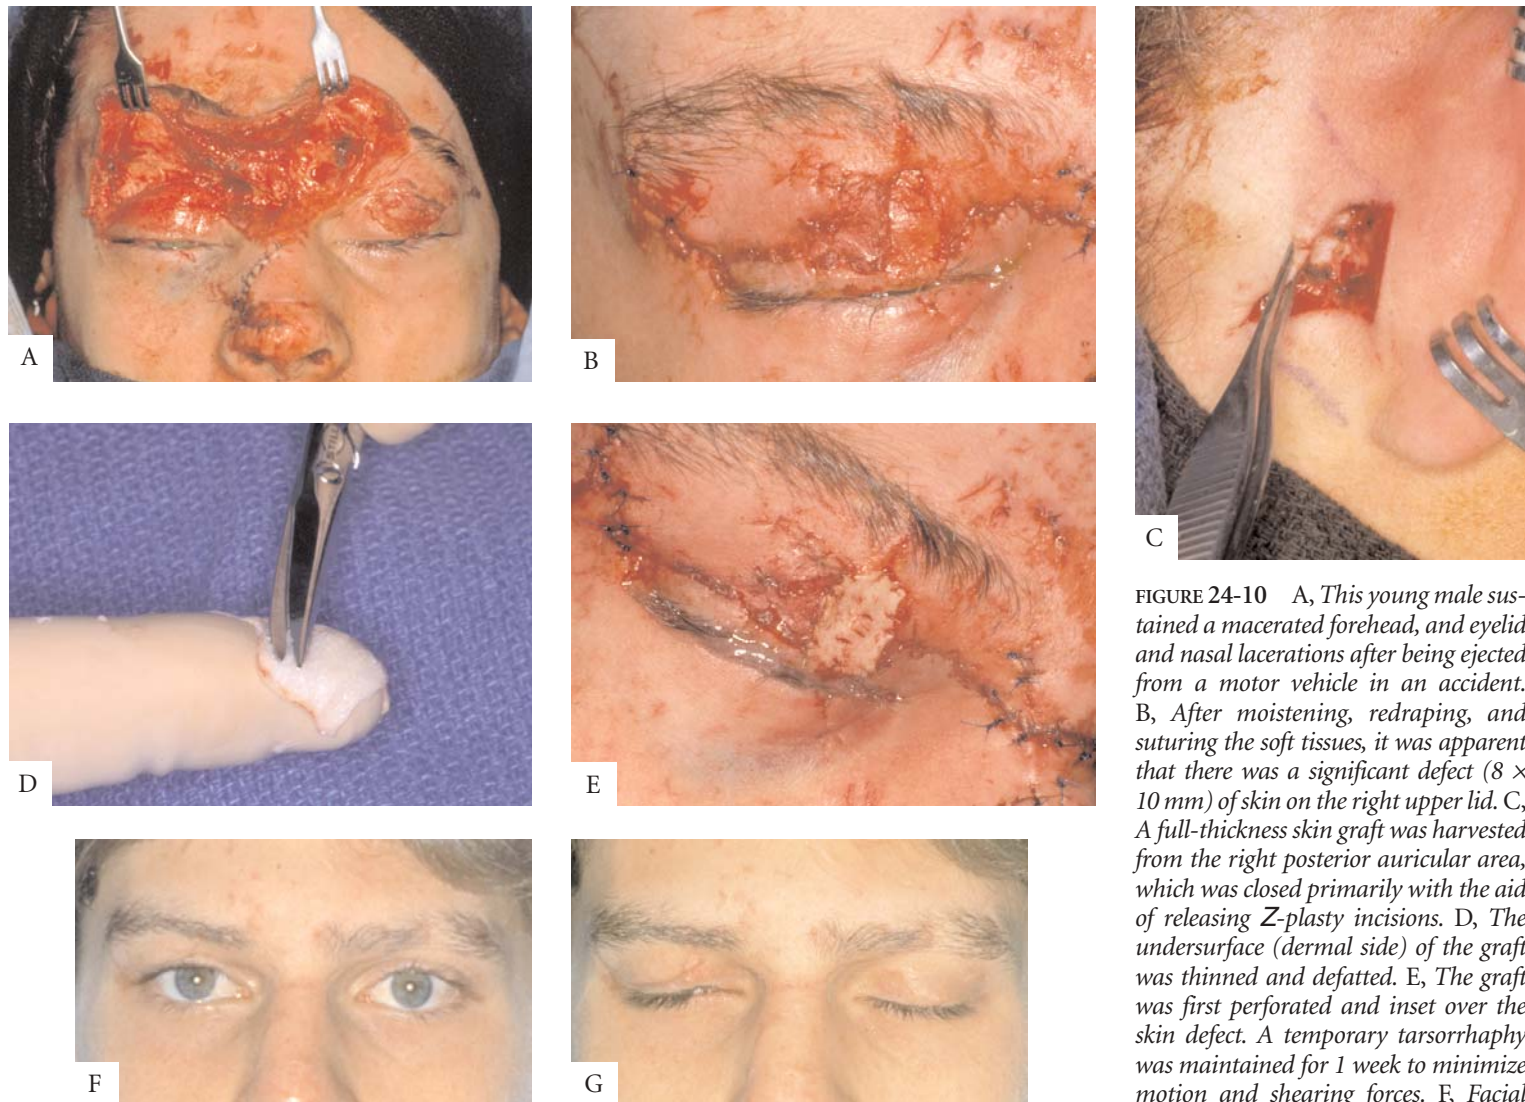

FIGURE 24-10 A, This young male sustained a macerated forehead, and eyelid and nasal lacerations after being ejected from a motor vehicle in an accident. B, After moistening, redraping, and suturing the soft tissues, it was apparent that there was a significant defect (8×10 mm) of skin on the right upper lid. C, A full-thickness skin graft was harvested from the right posterior auricular area, which was closed primarily with the aid of releasing Z-plasty incisions. D, The undersurface (dermal side) of the graft was thinned and defatted. E, The graft was first perforated and inset over the skin defect. A temporary tarsorrhaphy was maintained for 1 week to minimize motion and shearing forces. F, Facial appearance 3 months after repair. G, Passive lid patency was achieved. There was no further revision surgery.

Telecanthus

Traumatic telecanthus typically results from severe midfacial trauma (NOE) with displacement and splaying of the bones that serve as attachments for the medial canthal tendons. It is less frequently due to laceration and actual physical disruption and disinsertion of the canthal tendons from the underlying bone. Therefore, traumatic telecanthus from these injuries is best treated early (within 7–10 d) following injury to prevent scarring and secondary maladaptive changes that compromise the reestablish-

ment of the more normal narrow intercanthal distance. Preoperatively, one should determine whether the increased intercanthal distance is due to either a unilateral or a bilateral injury. Treatment typically includes an approach via a coronal incision, a Lynch (lateral nasal) approach, or a combination, with reduction and fixation of the displaced bones or direct transnasal wiring. External splinting rarely yields satisfactory results.

I have found that direct canthal tendon reattachment with transnasal wire fixation is best performed by passing a doubled-end loop of 30-gauge stainless steel wire

transnasally from the contralateral medial orbital wall and then suturing the medial canthus to the wire loop. The wire is then drawn to the opposite side by gradually twisting the two ends around a short section of titanium microplate situated in the opposite medial orbital wall (Figure 24-12).

Nonoperative Management of Orbital Fractures

Indications for nonoperative or, as it has previously been termed, *conservative* management of orbital fractures has been controversial for many years. Some historic

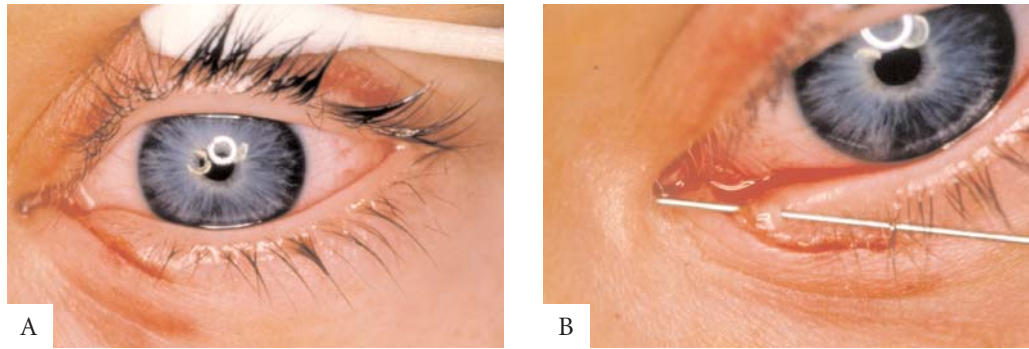

FIGURE 24-11 A, Innocuous-appearing small left lower medial lid laceration sustained from an incidental grab along the cheek during a touch football game. B, Slight lateral traction on the lower lid and probing of the inferior punctum revealed a full-thickness lid laceration medial to the punctum with severance of the inferior canaliculus. An oculoplastic surgeon repaired and managed this injury within 8 hours.

perspective and review is warranted since it provides insight into the evolution and current thinking regarding nonoperative orbital fracture treatment. In 1957 Smith and Regan coined the term *blow-out fracture* and advocated early surgical intervention for orbital floor fracture repair.³⁸ Following this, Converse and Smith endorsed surgical exploration and repair of all orbital fractures within the first 3 weeks of injury.³⁹ Even with surgical exploration and repair, they found that enophthalmos or functional difficulties would develop, and they attributed this to the blunt trauma forces and tissue damage rather than the surgical intervention. Crikelair and colleagues in 1972 promoted the concept that orbital floor fractures were overdiagnosed on plain films and, thus, were overoperated.⁴⁰ They introduced the concept of repairing only select orbital floor fractures, which were confirmed by tomography and only if diplopia or enophthalmos persisted after an observational period of 2 weeks. This marked an important change in thinking toward a more selective approach for surgical intervention of orbital floor fractures. This change was, in part, prompted by reports and articles documenting unacceptable complications such as a total loss of vision following surgical exploration of asymptomatic floor fractures.⁴¹ In 1974 Putterman and colleagues reported on a series of 57 patients

whom they had observed and on whom they had performed no surgical intervention whatsoever.⁴² Only a few of these individuals had any persistent diplopia, and there were no visual acuity disturbances 4 months following the trauma. This landmark article created a drastic shift in thinking—nonsurgical treatment of all orbital fractures was advocated. Putterman and colleagues proposed that patients with persistent diplopia should be managed by contralateral eye muscle surgery, or contralateral fat resection, to mask the enophthalmos or altered visual access of the injured side. Although this retrospective study and series of patients received much criticism from both the ophthalmology and facial trauma specialties, it did reveal that many orbital floor fractures healed uneventfully without surgical intervention and with the performance of eye-movement exercises.

Following Putterman and colleagues' report were a series of articles by various practitioners who attempted to refine and delineate the indications for surgical exploration and repair of orbital floor fractures. Dulley and Fells reported that only 50% of all patients with orbital floor fractures required surgical intervention.⁴³ All patients underwent a 2-week observational period; an individual would then undergo surgical intervention if one of the following criteria was present: enophthal-

mos > 3 mm, large herniation of tissue into the antrum, entrapment with limited upward gaze, or significant diplopia. Nevertheless, these criteria were somewhat subjective and were limited by the current imaging techniques. Crumley and colleagues used similar indications for surgery to those of the Putterman group, but based on these criteria, almost 90% of all their patients with orbital floor fractures underwent surgical repair.⁴⁴ Converse and Smith developed and further refined these same indications for orbital floor surgery and reinforced the need and importance of serial clinical examinations in patients who had shown no initial indications for surgery.⁴⁵ This group promoted the concept that serial examinations revealing the development of enophthalmos should be the criterion for surgical intervention and not simply that a large or comminuted floor fracture existed. They proposed that the development of significant postinjury enophthalmos is variable and could be due to either resolving hemorrhage and edema or orbital fat atrophy. In 1982 a survey by the American Society

FIGURE 24-12 Reattachment and repositioning of the left medial canthus is fine-tuned by twisting a 30-gauge wire over a section of microplate situated along the right medial orbital wall just behind and above the posterior lacrimal crest.

of Ophthalmic, Plastic and Reconstructive Surgery revealed that two-thirds of oculo-plastic surgeons were operating within 2 weeks of injury with few serious complications or sequelae.⁴⁶ Although this was reassuring that current surgical approaches and techniques were safe, there was no inquiry into what the criteria or determinates were for undertaking surgical repair.

What was helpful was that several ensuing studies began to delineate which patients exhibiting functional deficits might benefit from surgical exploration as opposed to observation. Koorneef, in an anatomic study, showed that fine connective tissue septa surrounded the extraocular muscles.⁴⁷ He advocated eye movement exercises in patients with mild or moderate restrictive motility as long as there was demonstrated serial improvement in motility. He purported that edema, hemorrhage, and connective tissue entrapment were responsible for the majority of limited motility in patients with orbital floor injuries.

In 1984 Smith and colleagues introduced the concept that Volkmann's contracture might occur as a result of elevated intraorbital compartment pressures.⁴⁸ Although this phenomenon was well-known, documented, and proven in the orthopedic literature to occur with extremities, it was unproven to occur in the orbit. Volkmann's contracture is a paresis from muscle shortening and fibrosis that results in limited mobility. Applying this concept to the orbit, Smith and colleagues recommended surgical intervention in the elderly, in individuals who are hypotensive, and for small or linear orbital floor fractures with coexisting diplopia. They felt that these situations left patients at an increased risk for orbital compartment syndrome, thus developing permanent limited mobility owing to Volkmann-like contractures. Concurrent with these theories and recommendations was the report by Hawes and Dortzbach that emphasized the need for surgical repair within 2 weeks following injury in patients with persistent diplopia

within a 30° range of the primary visual (straight-ahead) gaze.⁴⁹ They based this on their findings that there were poor results when late repairs were performed in this patient group.

Clearly the advent and ready availability of CT for use in diagnosing "trapdoor" fractures with mechanical impingement of the orbital structures helped to refine diagnostic capabilities and to aid treatment planning. Several groups of authors emphasized the need for correlating a positive forced duction test with CT evidence of incarceration or impingement.^{50,51} Without specific evidence of a trapdoor phenomenon or direct impingement, orbital floor fractures with limited motility were observed for 2 weeks. Persistent symptoms or findings then prompted surgical intervention. Trapdoor fractures or fine linear breaks without rim fractures are much more common in pediatric patients. When severe limitation of movement is encountered (typically upward or downward gaze, or both) and is correlated with CT findings, this is a true emergency that should be treated surgically to relieve the entrapment as soon as possible.

Since his initial controversial 1974 article, Putterman has revised his indications for surgical intervention.⁵² Putterman and his colleagues' indications are now comparable to those of other surgeons. They advocate 7 days of systemic corticosteroids to speed the resolution of diplopia within the first 3 weeks. This may aid in resolving edema and helping determine who might benefit from surgery. Although persistent functional limitations are usually clear indications for surgery, controversy remains in treating those patients who demonstrate a steady but slow resolution of their diplopia that persists beyond 3 weeks.

When the surgeon is confronted with any orbital fracture, it is helpful to categorize the clinical deficits and goals of surgical treatment as being either functional or cosmetic. Simply operating on a radi-

ographic finding because it exists is not satisfactory. The surgeon, with the assistance of his ophthalmology colleagues, should determine what, if any, functional deficits and cosmetic deformities exist. A specific anatomic reason for these should be sought. Then, if the magnitude of the functional deficit or cosmetic deformity warrants surgery, the type of surgical approach, repair, and materials should specifically address the structural causes. In a patient with the clinical findings of only "soft" indications for surgery, a 2-week observational period seems prudent. Several studies have addressed cosmetic deformities as they relate to orbital floor fractures, offering indications for surgery versus observation. Hawes and Dortzbach used tomography and felt that orbital floor fractures involving > 50% of the surface area should be reconstructed within the first 2 weeks to avoid the predictable development of enophthalmos.⁴⁹ They also stated that patients with smaller orbital floor fractures but with > 2 mm of enophthalmos present at 2 weeks postinjury should undergo orbital floor reconstruction. This recommendation is based on the fact that later repair is technically more difficult with less optimal outcomes owing to scar contracture and muscle shortening. Parsons and Mathog were able to demonstrate, using a laboratory model, that orbital floor fracture and displacement of equal magnitude with the medial wall fracture and displacement had a much greater effect on globe position.⁵³ This study supports the practice of most surgeons, which is nonsurgical and observational management of isolated displaced medial wall fractures.

When orbital fractures are associated with other facial fractures such as Le Fort or ZMC fractures, several authors have advocated orbital floor exploration and repair with any evidence of prolapse of the orbital contents into the sinus.^{54,55} In 1991 Putterman and colleagues advocated following patients closely for the development of

enophthalmos, using objective measurement with a Hertel exophthalmometer, or serial measurements for vertical dystopia by aligning the top of a clear ruler to both undisturbed medial canthi and noting where the ruler bisects each eye.⁵² Despite numerous reports, clinical series, and author suggestions, controversy still remains regarding the management of those patients who develop only mild enophthalmos or hypo-ophthalmos (1–2 mm) without any functional deficits during the acute observational period.

Operative Management of Orbital Fractures

Indications

It is imperative that the surgeon has a complete understanding of the mechanism of injury and potential complications to make a full diagnosis and an appropriate treatment plan in each type of orbital fracture. Patients with a suspected or known orbital fracture should undergo thorough clinical examination, including fundoscopic examination; visual acuity; pupillary reactivity; detection of diplopia, extraocular movement with any limitations noted, enophthalmos, and vertical dystopia; forced duction testing; and recording of paresthesias. Radiographic studies should determine the full extent of the orbital fracture and any surrounding and associated facial fractures. CT scans, especially in the direct coronal plane, are the gold standard for use in orbital surgery treatment planning. Contraindications for surgery are hyphema, retinal tears, globe perforation, the patient sees only with the eye on the injured side, and life-threatening instability.

Indications for surgery can be divided into functional and cosmetic categories. A logical systematic approach is prudent in selecting patients who are suitable for acute or early surgical repair versus those who deserve an observational period with intervention when signs or symptoms warrant it (Figure 24-13). With regard to

function, diplopia and decreased visual acuity are the two main areas of concern. The majority of surgeons and articles in published literature support early surgical intervention in a patient with an orbital floor fracture that has mechanical restriction of gaze and a positive forced duction test with a CT scan that has a trapdoor appearance or suggestions of inferior rectus muscle incarceration.^{56,57} This phenomenon occurs more in children with linear fractures owing to the elasticity of their bones.⁵⁸ Pediatric or adult patients with these findings warrant early intervention to free up the tissues and hopefully prevent any permanent restriction owing to ischemic necrosis or scar contracture. In patients with less impressive restrictive motility (10–15°), a positive forced duction test, and no CT evidence of muscle entrapment, an observational period of several weeks is reasonable. These patients may only have entrapment of some of the fine connective tissue septa supporting the globe, and with routine daily function and/or eye exercises, this restriction typically steadily improves. Clinical follow-up with a series of examinations (two or three) within the first 14 days, steroid therapy, and eye movement exercises should optimize the outcome. In any patient with an orbital fracture that has persistent mechanical restriction or diplopia within 30° of their primary gaze, especially the downgaze (used during reading), surgical exploration is warranted. Prior to undertaking surgery, however, any neurogenic or central component should be ruled out. Although infrequently employed, electromyography can be used to distinguish neurogenic diplopia from mechanical restriction in problematic or brain-injured patients. Neurogenic or neuromuscular injuries are more suitably treated by strabismus surgery. With regard to decreased visual acuity, an ophthalmologist should assess the patient serially for resolution or improvement. In more severe cases—patients who can only see shadows or fig-

ures or who have NLP—the fine-cut axial CT scans of the orbital apex and canal should be reviewed with the radiologist to determine whether there is bony mechanical impingement, hematoma, and/or edema compressing the optic nerve or vascular supply. With the increasing popularity of endoscopic approaches to the cranial base (typically for tumor removal), most major medical centers have neurosurgeons and/or otolaryngology head and neck specialists that are competent in performing transnasal endoscopic optic canal decompression. If at all possible, this should be performed within 12 to 24 hours of the confirmed diagnosis of external optic nerve compression within the canal proper.

Cosmetic deformities such as enophthalmos or hypo-ophthalmos result from a bony orbital volume increase, extrusion of intraconal fat into extraconal spaces, or prolapse of orbital contents into the maxillary sinus or ethmoid air cells. Contrary to long-standing dogma, post-traumatic fat atrophy does not play a significant role in the development of these deformities.⁵⁹ Most surgeons currently undertake surgical intervention in orbital floor reconstruction if there is 2 to 3 mm or greater of enophthalmos or hypo-ophthalmos in the presence of orbital edema or hematoma. The rationale is that early repair offers the most favorable outcome and that the cosmetic deformity only worsens as the edema and hematoma resolve. Orbital floor defects of greater than half of the surface area with concomitant CT evidence of the disruption or prolapse into the underlining antrum generally should be repaired. Again, the rationale for this is that as the edema resolves, eventually there is some degree of enophthalmos or vertical dystopia that creates a cosmetically unacceptable or, less frequently, functional problem requiring surgery. With minimal floor disruption (< 50%) and no entrapment or significant herniation, observation for 2 weeks is prudent. If the patient develops any functional problems or enophthalmos

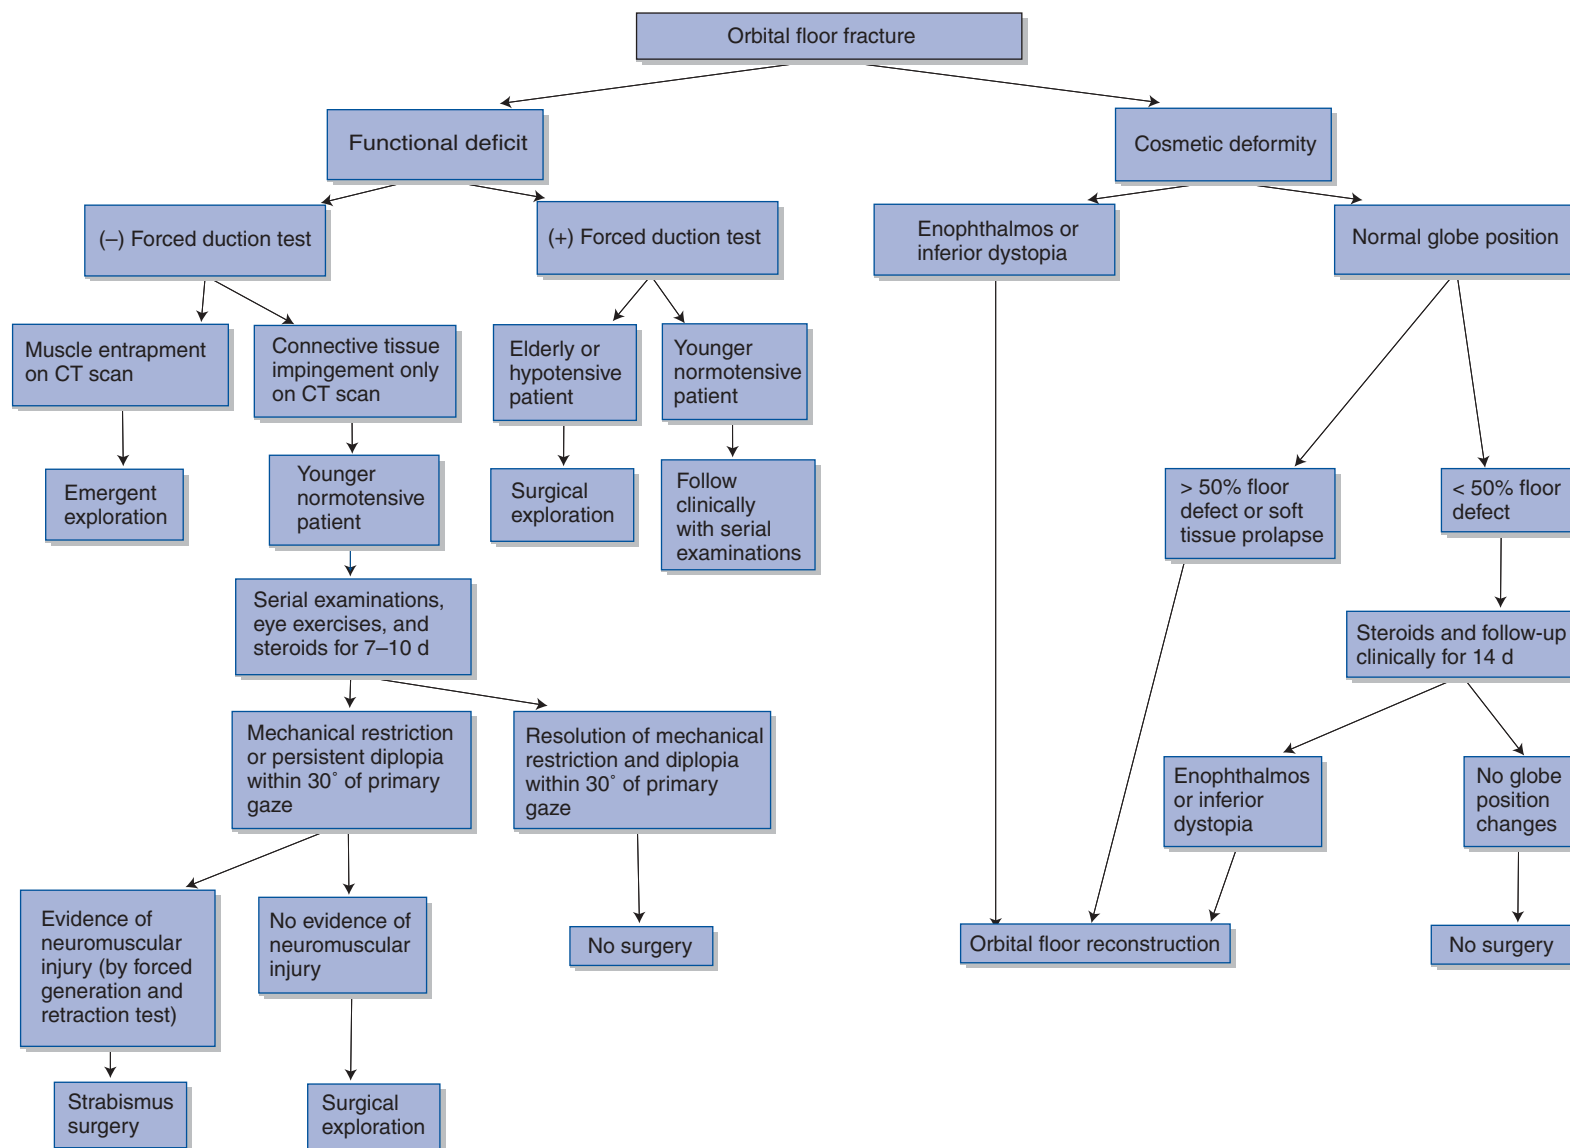

FIGURE 24-13 Orbital floor fracture evaluation and treatment decision diagram. CT = computed tomography; (-) = negative; (+) = positive.

> 2 mm, then surgery can be undertaken to treat the functional or cosmetic defect. Unnecessary delays approaching 6 weeks and beyond make the surgical repair more difficult and the ultimate outcome less desirable owing to scarring and muscle shortening.

Surgical Approaches

Once it has been determined a patient requires surgical intervention, a well-thought-out plan and sequential approach should be developed. Of paramount importance is the determination of which

of the anatomic areas need to be accessed with direct visualization and which intact bony edges or landmarks need to be found or fixated to accomplish the repair. This helps the surgeon determine which soft tissue incision should be employed. In general, most surgeons prefer to first grossly reduce and usually fixate all periorbital and facial fractures prior to accomplishing internal orbital repairs. The most commonly used surgical approaches and methods of reconstruction are presented here so that the surgeon can make an individualized and informed decision.

Inferior and Lateral Orbital Approaches

There are three basic incisions used for accessing the orbital floor: the infraorbital, subciliary, and transconjunctival (Figure 24-14). Although there are three basic approaches, there are numerous technical variations based on surgical training and individual preference. Clearly the subciliary and transconjunctival incisions are the most popular owing to their superior esthetics and generous access, and the fact that surgeons are familiar with their use. It is my opinion that the infraorbital or rim incision results in the worst esthetics and offers no

FIGURE 24-14 Cross-sectional view of the inferior lid and various floor approach incisions. Adapted from Ochs MW, Johns FR. *Orbital trauma*. In: Fonseca RJ, Marciani RD, Hendler BH, editors. *Oral and maxillofacial surgery: trauma*. Vol 3. Philadelphia (PA): W.B. Saunders; 2000. p. 208.

advantages over the two former approaches; therefore, it should not be employed.

The subciliary incision was popularized by Converse in 1944.⁶⁰ Typically a gently curved linear skin incision is made several millimeters below the lid edge or eyelash margin, preferably in a skin crease. The skin flap is then undermined in an inferior direction for several millimeters before traversing deeper inward directly through the orbicularis oculi muscle fibers and stopping when the orbital septum is encountered. The rationale for the division of the skin and muscle at different levels (stepping the incision lines) is that it helps to prevent direct or full-thickness scarring and tethering of the eyelid. Once the orbital septum has been encountered, the preseptal approach is then carried out inferiorly to the orbital rim, and the periosteum is incised just below the arcus

marginalis. The periosteum of the orbital rim is then reflected upward and inward, and dissection is carried out over the orbital rim. One must bear in mind that the orbital floor drops off several millimeters toward the inferior direction prior to heading straight posteriorly. The orbital floor dissection can then be extended posteriorly for a safe distance of 30 mm. With an intact adult rim, the optic canal is only 40 mm from the anterior lacrimal crest, and with any rim displacement inward, this margin of safety is further decreased. A modification of the subciliary approach is the “skin only” incision. This technique is comparable to the technique just described, except that after dividing the skin, the inferior dissection is carried out superficially to the orbicularis oculi muscle fibers until the inferior orbital rim is reached, and then the muscle is divided at

the same level as the periosteal incision. This approach is used less often owing to the amount of stretching on the unsupported large skin flap and the resultant high rate of ectropion (permanent in 8%) and potential skin necrosis, particularly in the elderly patient who has a history of heavy smoking.⁶¹ These complications prompted the development of an alternative technique called the “skin-muscle flap.” With this procedure a similar incision is accomplished 1 to 2 mm below the lid margin but is carried through both the skin and muscle at the same level down to the tarsal plate. Again, the plane of dissection is carried out anterior or superficial to the orbital septum (preseptal) until the orbital rim is encountered. This approach results in excellent esthetics, a simplified dissection, and a decreased incidence of hematoma formation or skin necrosis.

This skin-muscle flap still carries a 6% rate of early ectropion⁶²; however, it is generally temporary and resolves within several weeks with gentle massage. This was confirmed by several investigators who correlated preoperative periorbital edema and increased age positively with the development of this temporary ectropion with the subciliary approach.⁶³ A revision of this approach or technique is to use a relaxed skin tension line incision.

The transconjunctival approach for orbital floor fractures was first popularized by Tessier and Converse and colleagues in 1973 for orbital floor fractures.^{64,65} The two basic variations of this approach to the orbital rim are retroseptal or preseptal approaches. Although the retroseptal approach is a more direct approach to the rim, it exposes the orbital fat, which herniates into the surgical field and may interfere with the surgery and result in more fat atrophy, especially with cautery, and hence enophthalmos. For this reason, the preseptal approach is generally favored.⁶⁶ The preseptal approach (see Figure 24-14) as described by Tessier involves an incision through the palpebral conjunctiva just 2 to 3 mm below the inferior edge of the tarsus that is extended through the inferior lid retractors and orbital septum.⁶⁴ Next, a preseptal vertical dissection is carried out down several millimeters below the orbital rim, and the periosteum is incised. The dissection of the facial aspect of the rim and the floor is then carried out. This obviates orbital fat herniation in a fairly bloodless field. The necessity for a periosteal closure is controversial owing to the possibility of entropion or ectropion with inadvertent suturing of the periosteum to the orbital septum or other layers.^{64,67} Some surgeons advocate a Frost suture for a period of 24 to 48 hours to allow for proper lower lid redraping during early healing. Most surgeons find this unnecessary. If there is any difficulty in identifying opposing edges of the cut periosteum, then no suturing should be

performed rather than an inappropriate tethering of more superficial or superior eyelid layers and structures to the underlying rim. Many instances of “early ectropion” or a “shortened lid” are the result of improper suturing. The transconjunctival preseptal approach enjoys a low incidence of unfavorable scarring with ectropion or entropion (1.2%).⁵⁵ However, one drawback to this approach remains a somewhat-limited view during the preseptal dissection and limited exposure once the orbital floor has been accessed. For this reason, the lateral canthotomy and complete severance of the lower limb of the lateral canthal tendon (inferior cantholysis) was introduced by McCord and Moses in 1979.⁶⁸ This procedure allows for a generous tension-free exposure to the orbital floor, lateral orbital wall, and medial area. The surgical exposure obtained with the transconjunctival approach with the inferior cantholysis is superior to that of a subciliary incision. Also, the much smaller cutaneous incision is placed in a more favorable area of the crow’s-feet.

The majority of surgeons currently use the transconjunctival incision with or without canthotomy or the subciliary incision (preseptal approach) for orbital rim and floor access.⁶⁹ Both of these basic incisions provide good exposure with excellent esthetics and an extremely low rate of complications. Each surgeon’s own training, familiarity, and personal preference should guide which rim approach is used.

Superior and Medial Orbital Approaches

Access to the superior orbital rim and zygomaticofrontal (ZF) suture can be accomplished via a lateral eyebrow incision, upper blepharoplasty incision, coronal incision, or lateral canthotomy incision that is an extension of a subciliary or transconjunctival incision with a superior cantholysis. The eyebrow incision, if performed properly, results in excellent esthetics and is quickly and easily performed; therefore, it is one of the more

common approaches used for the lateral orbital rim or ZF suture area. The other incisions described are used more often when extensive facial fractures are present that require extensive skeletal exposure of the superior rim, cranial vault, or zygomatic arch.

The lateral brow incision is placed on the extreme outer aspect of the eyebrow, usually just superior to the ZF suture. The ZF suture line is usually approximately 1 cm above the lateral canthus. Generally, the skin of the lateral brow is tented over the superior lateral orbital rim, and a 1.5 cm curvilinear incision is made in a beveled fashion paralleling the hair follicles. Double-pronged skin hooks are then placed on the skin margins, and traction is maintained with digital palpation of the internal edge of the orbital rim. The skin incision opening is then gently retracted inferolaterally more directly over the ZF suture, and a needle-tipped Bovie cautery is used to divide the orbicularis oculi muscle fibers overlying the rim and ZF suture. Additional undermining and dissection is carried out in an inferolateral direction to provide full and adequate access to the fracture and enough adjacent bone to allow for rigid fixation. The advantages of not extending the skin incision beyond the brow obviously involve esthetics (placing it in the well-camouflaged and hidden area of the hair follicles) but also include that the skin is stepped and muscle incisions are made in distinct layers, which provide for more favorable healing. This incision also allows access for placing a blunt curved instrument deep to the zygomatic arch for the reduction of the ZMC or arch fractures. Closure should be accomplished in three distinct layers of periosteum, subcutaneous tissue, and skin. The periosteal, muscle, and deep subcutaneous closures are particularly important in that they provide the bulk of soft tissue over any plates and screws in the region.

The upper blepharoplasty incision can also be used for access to the ZF suture.

The incision is placed in one of the upper eyelid skin creases, preferably the deepest crease (which can be marked preoperatively, with the patient awake). The skin incision is then carried down through subcutaneous tissue, retracted somewhat laterally, and extended through the orbicularis oculi and periosteum by sharp dissection. Generally a 1 cm length of the lateral blepharoplasty incision is all that is required for complete access to the lateral orbital rim. This is due to the suppleness and mobility of the thin eyelid skin. Care should be taken to not over-retract the tissue, and the skin incision should be extended slightly laterally if excessive retraction forces are apparent. Separate suturing of the periosteum and skin are all that is required.

The coronal incision allows for excellent access to the entire supraorbital rim, roof, frontal sinus, superior aspects of the nasal bone, lateral orbital rim and wall, medial orbital rim and wall, and zygomatic arch.⁷⁰ This approach is generally necessary for extensive facial fractures involving the zygoma, frontal sinus, and NOE complex and for Le Fort III fractures. Numerous variations of the incision design exist, but generally a curvilinear incision is placed at least 2 cm posterior to the hairline (in the midline) and then extended posteriorly, paralleling the hairline, and finally inferiorly into the preauricular region. It is generally helpful to carry the vertical component of the coronal incision overlying the temporalis muscle just posterior to the junction of the superior helix and the scalp. It is then sharply angled forward, hugging the anterior helix and preauricular skin crease down to the pretragal area. By doing so, the superficial temporal vessels are generally not encountered or violated and retracted forward with the flap, allowing for a much drier field. It is not necessary to shave the scalp, but a 1 cm area of hair can be trimmed at the incision to allow for ease of closure, postoperative hygiene, and suture

removal. Local anesthesia with vasoconstrictors is helpful for hemostasis and often obviates the need for compression (Raney) clips. The incision is carried out through the skin, subcutaneous connective tissue, and galea aponeurotica into the loose areolar tissue in the midline. The subgaleal plane of dissection is contiguous with a plane deep to the parietotemporal fascia in the area of the temporalis muscle. The incision is then extended laterally in the supraperiosteal plane; it is helpful to insert a Metzenbaum or curved Mayo scissors in this plane prior to extending the incision laterally. This prevents inadvertent incising or nicking of the temporalis in an otherwise dry field. The dissection is carried out laterally to the superior temporal line bilaterally. Dissection is then carried anteriorly to the frontal bone, and a horizontal incision is made through the periosteum approximately 2 cm above the superior orbital rim. The incision is carried laterally to the superior temporal line and joined with the preauricular area inferiorly through the superficial layer of the deep temporal fascia to protect the temporal and frontal branches of the facial nerve.⁷¹ The facial nerve courses in a plane superficial to the deep temporal fascia approximately 1 to 3 cm from the tragus along the zygomatic arch.⁷² This approach provides complete access to the medial, lateral, and superior orbital rims. When a more extensive view of the medial orbital wall is required, subperiosteal dissection and release of the superior trochlea can be performed—the flap is retracted more inferiorly over the nasal dorsum, with a direct view of the medial wall. No attempts should be made to re-attach the trochlea since, when the soft tissues are re-draped, the trochlea re-adheres on its own. Sutureing may actually pierce or violate the trochlear tendon and result in ocular motility disturbances. Closure of the coronal flap should include suspending the deep temporal fascia over the temporalis muscle, deep closure of the galea aponeu-

rotica, subcutaneous buried suturing, and closure of the skin. It is important to remember that when a hemicoronal incision is employed, the medial extent of the incision should be carried beyond the midsagittal plane and extended completely to the hairline. This allows for adequate reflection and retraction over the entire zygoma and orbital rim structures.

When a transconjunctival incision is used with a lateral canthotomy, an extension of the dissection superiorly can be used for access to the ZF suture by severing the superior limb of the canthal tendon.⁶⁷ This approach provides good access to the lateral and infraorbital skeleton; however, it is less frequently used because it requires a more complex closure and re-anchoring of the lateral canthal tendon complex. Any misalignment results in canthal dystopia, usually in an inferior direction, and a rounded-out “almond-shaped” eye appearance. If the superior canthal tendon and its origin to the internal rim are allowed to remain intact, it provides a highly reliable landmark to which the inferior canthal limb can be sewn, resulting in excellent sharp-angled (30–40°) esthetics.

The entire lateral wall and rim is easily accessed through a standard blepharoplasty incision that extends only to the lateral orbital rim. This approach is commonly used for lateral orbital decompressions in cases of severe thyroid orbitopathy and it affords excellent exposure also to portions of the orbital roof and to the apex of the orbit laterally.

Medial Orbital Approaches Access to the medial orbital rim and superior aspect of the medial orbital wall can be accomplished through a coronal incision, as previously described. However, a separate lateral nasal incision can be used for isolated medial wall exploration or to access the inferior aspect of the medial orbital floor. This can be a transconjunctival or subciliary approach to the inferior rim and floor. The entire medial wall can be visualized by

extending the transconjunctival incision through the caruncle. The medial orbital wall and rim, by definition, are involved in fractures of the NOE complex, Le Fort II and III fractures, extensive frontal sinus fractures, and, occasionally, large blow-out fractures. The lateral nasal incision is most often used for access to the medial orbital rim to reconstruct a detached medial canthal tendon with direct transnasal wiring. This type of injury often occurs with NOE fractures and Le Fort III fractures. As stated earlier, medial orbital wall fractures generally do not result in any entrapment or ocular mobility problems. Generally the upper one-third of the medial orbital wall is uninvolved or nondisplaced, simply because it is the very thick extension of the cranial base. The lower two-thirds of the medial orbital wall overlies the ethmoid air cells and can be displaced inward, resulting in volume expansion. Unless there is extensive involvement, generally the resulting increase in orbital volume does not result in the development of enophthalmos. If the inferior two-thirds of the medial wall or orbital floor are involved and require surgical repair, then the previously described approaches to the orbital floor should suffice. However, fractures that extend farther superiorly (above the frontoethmoidal suture/anterior ethmoidal foramen) may require a lateral nasal approach or coronal incision. The lateral nasal approach involves a vertical gentle curvilinear 1 cm incision approximately 5 to 10 mm medial to the insertion of the medial canthus. Care should be taken not to place this incision too close to the medial canthus as this can result in a scar contracture with “webbing” and an abnormal epicanthal fold postoperatively. The incision should be placed over the lateral nasal structures properly, and after the skin incision is made, the dissection should be carried straight medially through skin, subcutaneous tissue, and a rudimentary portion of the orbicularis oculi muscle and periosteum. There is no

need to step these layers. The periosteum can then be reflected posteriorly and superiorly to the medial orbital rim and wall. The medial canthal tendon and lacrimal sac lie posterior and just inferior to the incision. The anterior ethmoidal vessels lie posteriorly and superiorly approximately 24 mm from the anterior lacrimal crest. These vessels can be gently divided with bipolar cautery, providing excellent hemostasis and improved access for identifying an intact bony ledge. However, one should bear in mind that any bony violation or entry superior to this line carries the potential risk for entry into the anterior cranial fossa. When an orbital implant is required along the medial wall, anterior fixation of the implant is recommended.

Acute Repair

Internal orbital fractures have varied patterns and degrees of severity. It is helpful to attempt to classify them either as linear, blow-out, or complex fractures. Linear fractures are those in which the bone fragments and walls remain intact. However, owing to angulation or overlap, they may result in either a bony orbital volume increase or decrease. Overlap fractures generally result in a bony defect of one orbital wall (typically the medial orbital floor) and are the most common orbital fracture. Blow-in fractures can occur in any orbital wall but most commonly occur in the roof and are associated with frontal sinus fractures. Blow-in and blow-out fractures of the orbital roof occur with equal frequency. Complex fractures are those that involve two or more walls, are > 2 cm in diameter, or are comminuted with displaced and unretrievable segments. Often these complex fractures are associated with fractures that extend beyond the orbital frame such as Le Fort II or III and frontal sinus fractures. These are termed combined fractures. The goals of acute or primary reconstruction of primary orbital fractures are to alleviate any functional deficit and to restore the facial esthetics.

Linear fractures are generally caused by blunt forces directly to the globe or partially to the rim and most often result in an esthetic deformity such as enophthalmos or hypo-ophthalmos. Functional deformities with entrapment are less common with linear orbital fractures. However, isolated linear fractures can have an instantaneous trapdoor effect owing to momentary expansion and entrap the edge of soft tissues including the inferior rectus. Once tightly pinched between these bony segments, this manifests itself as severe ocular motility restriction that is reproducible on serial examinations at the same point of limitation. There is also a positive result to the forced duction test. This type of fracture necessitates immediate surgical intervention to prevent the ischemic necrosis of the extraocular muscles. The majority of linear fractures in the orbit do not result in esthetic deformities such as enophthalmos or hypo-ophthalmos unless there is an associated facial fracture such as a fractured ZMC with a medial and downward rotation. It is the volume changes that account for the abnormal globe position. The goal of reconstruction is to restore the anatomic position of the bony rim and associated facial bones and to reapproximate, to the best of one's ability, the normal bony orbital volume with a reconstructive material. Numerous materials have been described in the literature for these purposes, such as porous polyethylene, bioresorbable polydioxanone, nylon, gelatin film, titanium mesh, and autogenous bone grafts (split-thickness calvarium and, less frequently, iliac crest).⁷³⁻⁷⁹ Each material has advantages and disadvantages related to the strength, application, reactivity, infection rate, biointegration, and complication rate associated with its use.

For linear and blow-out fractures, I prefer to use thin (0.85 mm) porous polyethylene sheeting. This alloplastic material is extremely biocompatible and nonresorptive. It has more than adequate tensile strength and does not cause any capsule

formation such as that seen with polymeric silicone sheeting. It has considerable flexibility (which can be improved with placement in an autoclaved saline) and little memory properties. The pore size allows tissue ingrowth, which reduces the risk of migration.⁸⁰ However, I still recommend anchoring the porous polyethylene sheeting to the anterior lateral orbital floor with a single titanium screw (Figure 24-15). The greatest advantages of this material are its ease of contouring, in situ carving, burring, and that it can be layered posteriorly behind the orbital equator to achieve proper orbital volume and contour.⁵²

Titanium mesh, with fixation to surrounding intact orbital rims, is quite useful when there are severe or comminuted injuries and a cantilevering is required

FIGURE 24-15 A, Right inferior orbital rim and floor fracture reduced and fixated with a 1.7 mm microplate. A portion of the mid-rim was suctioned away from the antrum and was missing. B, The floor defect was reconstructed with 0.85 mm thick porous polyethylene sheeting secured with a single 4 mm long 1.7 mm screw at the anterior lateral intact floor. A tab extension of the sheeting was fashioned at the rim defect, curved, and secured with a 5-0 nylon mattress suture.

because intact internal medial or posterior bony margins have not been identified or accessed. However, the possibility of unacceptable postoperative scarring to the mesh may occur, resulting in limited ocular motility. Therefore, when titanium mesh is employed, I still prefer to overlay it with either a split-thickness calvarial graft or a sheet of porous polyethylene sheeting. These materials are secured to the underlying mesh with either 30-gauge stainless steel wire or suturing.

Blow-out fractures typically involve one orbital wall (usually the anterior or medial portion of the orbital floor) and are < 2 cm in diameter. Enophthalmos associated with orbital blow-out fractures is due to an enlargement of the orbital bony volume that allows the orbital fat to be distributed within a larger compartment.³⁹ Fat atrophy contributes little, if anything, to the development of early or late enophthalmos.⁸¹ The reverse mechanism, often referred to as blow-in fracture, may result in a decreased orbital volume. Exophthalmos and ocular motility disturbances are uncommon unless there are surrounding severe associated fractures such as ZMC or frontal sinus fractures.

In 1960 Converse and Smith introduced the concept of “pure” (isolated floor) and “impure” (floor and rim) blow-out fractures.³⁹ Pure fractures are thought to be caused by a sudden instantaneous increase in intraorbital pressures from direct blunt-force trauma to the globe itself. Impure fractures are purported to be caused by direct trauma and compression of the bony rim and collapse of the surrounding facial bones, and result in the disruption of the internal orbital walls. What is most disconcerting is the finding of associated globe trauma such as hyphema, iridoplegia (ciliary body paralysis), and retinal hemorrhage in 90% of patients with pure blow-out fractures. This supports the notion that pure blow-out fractures are created by substantial instantaneous direct globe trauma. This fact should heighten

one’s awareness of the potential for serious globe injury when dealing with isolated or pure blow-out fractures.

The goal of primary reconstruction of blow-out fractures is to restore the configuration of the orbital walls, return prolapsed orbital contents to the orbit proper, and eliminate any impingement or entrapment of orbital soft tissues. In contrast to the orbital floor blow-out fractures, isolated blow-out fractures to the roof or medial walls usually do not contribute significantly to the development of cosmetic deformities or result in entrapment or limited ocular motility. As a result, medial and roof defects are managed by observation, serial examinations, and intervention when symptoms warrant. The most difficult area of the orbital floor blow-out fracture to repair is the posterior medial extent, which is beyond the globe axis. Often, an intact bony ledge cannot be identified or the graft material is not extended posteriorly enough to support the orbital contents in this region. This area is often responsible for a failed enophthalmos repair in orbital blow-out fractures. It is the reconstruction of this posterior medial floor to its normal contour that is the key to restoring normal globe position both anteroposteriorly and vertically. It is this scenario that is problematic in delayed reconstructions since attempts to create a normal anteroposterior position of the globe may result in inappropriate overpositioning of the globe in a superior direction. I prefer to use gelatin film as a temporary barrier for small or linear defects, simply to prevent entrapment during normal active ocular motion. This film is resorbed rather rapidly and does not provide much structural support; therefore, it is not used for larger defects in which herniation of contents into the underlying sinus is a possibility. Generally, the orbital blow-out fracture is explored in all of the intact bony walls identified. Once the malleable ribbon or globe retractors have supported the globe and orbital

contents superiorly, then the reconstructive material can be slid underneath them and overlap the intact bony margins slightly at the majority of areas to provide adequate support. I prefer to use porous polyethylene for moderate to large blow-out fractures. The porous polyethylene sheeting can be secured with a single positional screw (usually 1.7 mm external thread diameter) or an extended tab of this material can be sutured to the orbital rim orbital plate (see Figure 24-15). Care should be taken to not extend the grafts up to the orbital rim or over the edge since these will be palpable and would improperly reconstruct the normal anatomic contour to the floor, which should dip down behind the rim for several millimeters before proceeding posteriorly. Also, the extension of semirigid grafts onto the orbital rim has an undesirable ramping effect, which tends to position the globe in an abnormal posterior direction, resulting in enophthalmos. After the floor graft is placed and secured, trimming or smoothing should be accomplished and a forced duction test performed prior to any wound closure to ensure that no impingement of the soft tissues has occurred.

Complex orbital fractures are generally associated with additional surrounding midfacial and frontal sinus fractures. Primary reconstruction of these defects is challenging owing to the extent of these injuries, the lack of any normal identifiable anatomy, and poor surrounding bony support for rigid fixation and anchoring of reconstructive materials. However, it is in this group of individuals that primary repair with normal anatomic realignment is critical for acceptable esthetic and functional outcomes. Delaying the primary repair beyond 7 to 10 days usually results in some secondary soft tissue changes, the inability to completely retrieve small bony segments, and a less-than-desirable outcome. The initial step in the reconstruction of complex facial fractures is adequate exposure of all midfacial structures with adequate alignment and reduction prior to rigid fixation of any components with plates and screws (Figure 24-16). This helps one avoid misalignment, over-reduction, or improper angulation of these segments. Achieving adequate exposure requires more extensive subperiosteal dissection than is done for most other orbital fractures. It may be desirable to

also completely dissect and expose all internal orbital fractures prior to fixation of the surrounding periorbital or midfacial fractures. Generally the orbital rim is plated with 1.7 mm or finer plating systems. Care should be taken at the inferior orbital rim and especially the lateral orbital rim to keep the plates several millimeters from the edge of the rim; otherwise, they will be annoyingly palpable once the soft tissue edema has subsided. Once the orbital rims and midfacial bones have been fixated, the moderate to large orbital floor defects are generally repaired with porous polyethylene and anchored to the anterior inferior floor with a single screw. Sometimes layering of this material with an additional sheet posteriorly is required to achieve correct anteroposterior globe positioning. More extensive defects may require titanium mesh or orbital floor plates with screw fixation to the rims and autogenous bone grafts. Several bone grafts can be secured to the metallic mesh framework to independently reconstruct the floor, medial wall, and, less frequently, the lateral orbital walls. The advantage of having bone overlie the metallic mesh is that remodeling can

FIGURE 24-16 A, An elderly female sustained a severely displaced left zygomatic complex (ZMC) fracture with > 75% orbital floor disruption. She was on warfarin sodium and had moderately decreased left visual acuity with increased ocular pressures. B, Axial CT scan revealed a ZMC fracture with a severe posterior, medial, and moderate inferior displacement. C, The patient was taken urgently (within 12 h) for surgical treatment to reduce the fracture and re-expand the orbital volume. Serial examination and ocular pressure checks were performed every 2 hours pre- and postoperatively. Owing to cardiac risk factors, the anticoagulation was not reversed, nor was the patient treated with fresh frozen plasma. The zygomaticofrontal (ZF) suture area was first approached through a lateral brow incision. After the intraoral vestibular and then transconjunctival approaches were accomplished, the ZF fracture was plated. (CONTINUED)

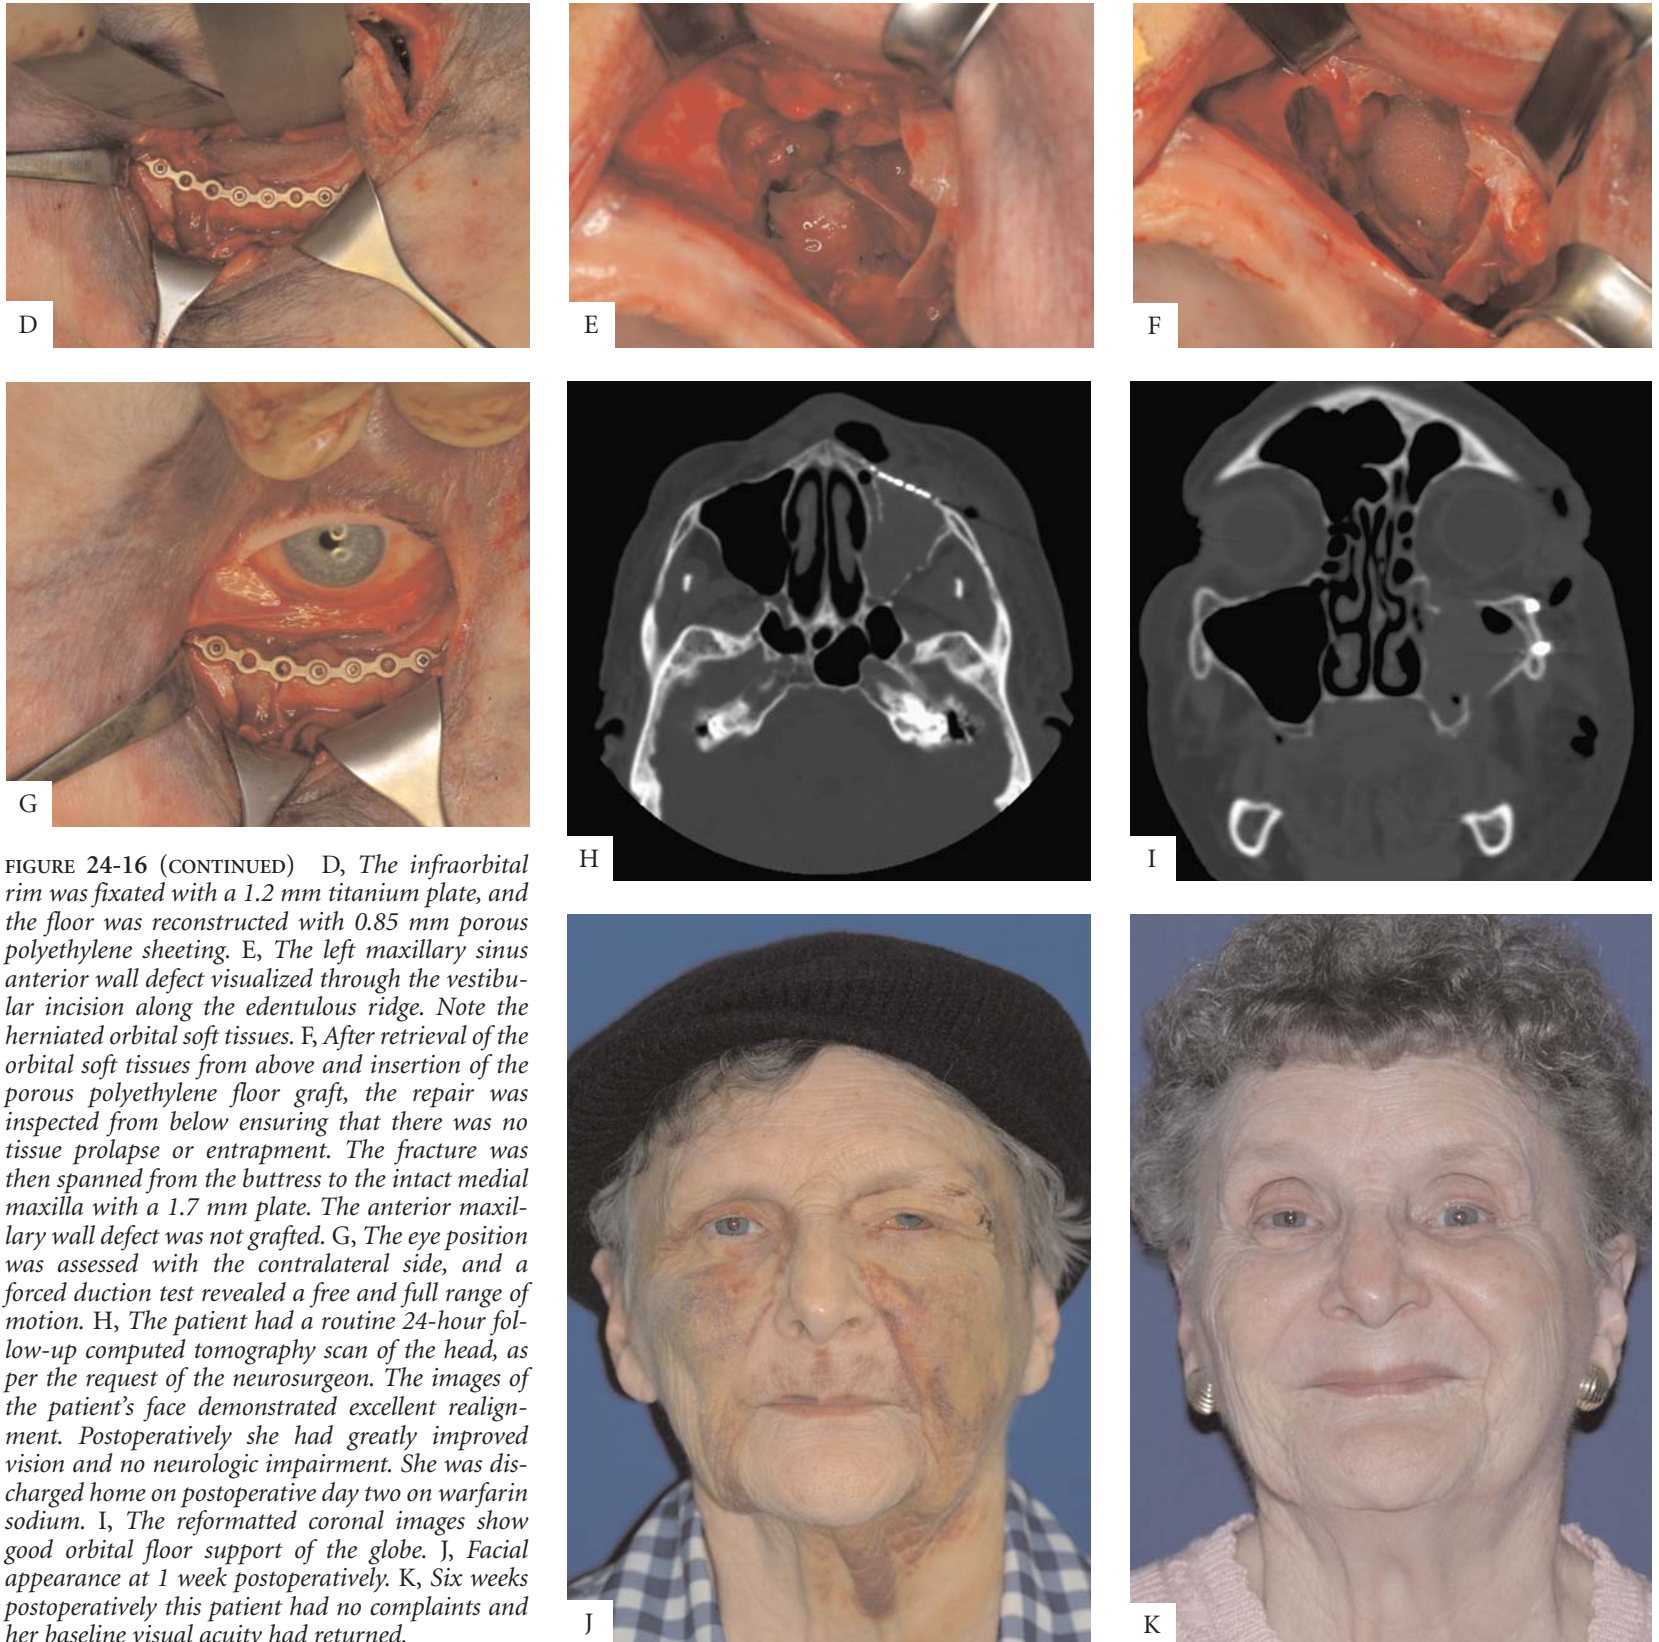

FIGURE 24-16 (CONTINUED) D, The infraorbital rim was fixated with a 1.2 mm titanium plate, and the floor was reconstructed with 0.85 mm porous polyethylene sheeting. E, The left maxillary sinus anterior wall defect visualized through the vestibular incision along the edentulous ridge. Note the herniated orbital soft tissues. F, After retrieval of the orbital soft tissues from above and insertion of the porous polyethylene floor graft, the repair was inspected from below ensuring that there was no tissue prolapse or entrapment. The fracture was then spanned from the buttress to the intact medial maxilla with a 1.7 mm plate. The anterior maxillary wall defect was not grafted. G, The eye position was assessed with the contralateral side, and a forced duction test revealed a free and full range of motion. H, The patient had a routine 24-hour follow-up computed tomography scan of the head, as per the request of the neurosurgeon. The images of the patient's face demonstrated excellent realignment. Postoperatively she had greatly improved vision and no neurologic impairment. She was discharged home on postoperative day two on warfarin sodium. I, The reformatted coronal images show good orbital floor support of the globe. J, Facial appearance at 1 week postoperatively. K, Six weeks postoperatively this patient had no complaints and her baseline visual acuity had returned.

occur—secondary revision surgery is enhanced when dissecting along a healed bony surface versus bare mesh. In severe or

large defects with comminution, overcorrection of the enophthalmos component (but not a hyper-ophthalmic deformity)

by several millimeters is often necessary to take into account the orbital edema that exists. In addition, with bone grafts, some

mild resorption can take place with subtle settling. However, it is the resolution of the edema that accounts for the majority of postoperative globe position changes.

ZMC fractures are second only to nasal fractures in incidence. These fractures are described in greater detail in Chapter 23.2, “Management of Zygomatic Complex Fractures” and Chapter 25, Management of Frontal Sinus and Naso-orbitoethmoid Complex Fractures.” Some discussion is warranted here, as ZMC fractures relate to orbital involvement and appropriate intraoperative sequencing. Nonfragmented or single-piece ZMC fractures are generally displaced in an inferior, medial, and posterior direction, with a pivot-point rotation about the ZF suture. As a result, the orbital floor suffers the most disruption. On initial inspection, the coronal CT scans may not reveal the degree of orbital floor disruption, but if one envisions the outward reduction of the zygomatic buttress and the resulting medial floor void, the magnitude of the injury can be appreciated. Only after reduction and stabilization of the entire external orbital framework and surrounding facial bones should the internal orbital defects be repaired (see Figure 24-16C–G). The internal orbital injuries associated with fragmented ZMC fractures usually involve multiple orbital walls and larger defects. Therefore, more extensive exposure is generally necessary and more rigid materials are usually required for reconstruction.

NOE injuries result mainly from extreme blunt force trauma and have a high degree of associated intracranial and neurologic injuries. Additionally, injuries to the nasal airway and lacrimal system can occur.⁸² Injuries to the lacrimal system can be managed by the placement of small silicone tubes. Even though canalicular disruption is more common with laceration-type injuries, these tubes can still be inserted with blunt trauma when a fair amount of edema is present and the sur-

rounding anatomy is obscured. This prophylactic intubation of the superior and inferior canaliculi and the lacrimal system helps to avoid iatrogenic injury during the extensive dissection required to treat this type of injury. The tubes can be allowed to remain in place several weeks postoperatively during the resolution of edema. Repair of NOE injuries is recommended within the first 7 to 10 days after injury, before the soft tissues have had the chance to re-adapt with significant scarring contracture and generally a flattened and splayed appearance to the orbits and mid-face. NOE injuries generally do not cause entrapment simply because of the orbital walls involved and the degree of comminution. However, entrapment of the medial rectus can occur during reconstruction, fixation, and suturing; therefore, a forced duction test should be performed at the completion of these phases. The primary defects associated with NOE injuries are medial canthal disruption with telecanthus and increased bony volume resulting in enophthalmos. If there are no other indications for coronal dissection, such as frontal bone or zygomatic arch fractures, then the medial orbital component of the NOE fracture is best approached directly through a lateral nasal (Lynch) incision. Often accessing the inferior medial wall or positioning the inferior edge of the medial wall graft requires an additional inferior rim and orbital floor approach, such as the subciliary or transconjunctival approach. Traumatic telecanthus should be treated by direct fixation techniques, using 1.0 to 1.7 mm plating systems. External splinting may provide some reasonable nasal bone molding, but it generally does little to improve traumatic telecanthus. Generally, the medial canthal ligament heals in a position that is too superficial and inferior. Postoperatively the entire area fills with dense scar tissue, and it is difficult to secondarily dissect and reposition the canthus in its normal position. With NOE fractures the medial canthal tendons usually maintain their attachment to

the bony segments. Therefore, proper reduction and fixation of the bony skeleton to the surrounding stable bone (maxilla, orbital, and frontal) often corrects the telecanthus deformity. This should be accomplished and the medial canthal position reassessed. If the canthal position is still unacceptable, then a fine stainless steel wire (30-gauge) can be secured directly to the canthal tendon or preferably, sutured to the wire that has been passed transnasally.

The double-armed wire is inserted from the contralateral orbit to the side that will be anchored, with the entry point on the medial wall being just posterior and superior to lacrimal fossa. This can be accomplished by prethreading the double-armed wire into a gently curved 16-gauge needle, passing it transnasally through small burr holes, retrieving the double-armed wire on the side to be fixated, and withdrawing the needle canula. The canthus is then sutured to the wire loop with a half-round needle (4.0 Mersilene S-2 needle), and the wire is drawn to the contralateral side and the limbs twisted gradually around a short section of plate to fine-tune the canthal position (see Figure 24-12). This is a much easier way to accomplish precise canthal positioning than are direct suturing techniques.

Summary

Orbital fractures are often associated with ocular injuries and midfacial fractures. A thorough ophthalmologic evaluation is mandatory to detect ocular injuries and to preserve vision. Surgical intervention should be based on either a functional deficit or a cosmetic deformity. The surgical sequencing and timing of the repair should be well thought out. When visual compromise exists, an ophthalmologist should be involved in the treatment planning.

Management of Frontal Sinus and Naso-orbitoethmoid Complex Fractures

Larry L. Cunningham Jr, DDS, MD

Richard H. Haug, DDS

Fractures of the frontal bone and the naso-orbitoethmoid (NOE) complex are infrequent, occurring among 2 to 15% of patients with facial fractures.¹⁻⁴ When these fractures occur, they can cause devastating complications because of their proximity to the brain, eyes, and nose. Complications include blindness or other forms of visual disturbance, orbital cellulitis or abscess, meningitis, brain abscess, and facial deformation. Although reports of the surgical management of the diseased frontal sinus have existed for > 100 years,⁵ no consensus has yet been reached on ideal care after traumatic injury.⁵⁻⁷

Most victims are male (66–91%) and young (usually 20–30 yr of age, range 6–72 yr),^{1,7-20} and most frontal sinus and NOE injuries are sustained in motor vehicle or motorcycle collisions (44–85%).^{1,3,7,8,10,11,14-24} NOE fractures can occur in isolation, but they most often occur in association with other midface fractures.^{23,25} As many as 60% of patients with NOE fractures have associated nonfacial injuries.²⁴

The distribution between fractures of the supraorbital rim and fractures of the frontal sinus is almost equal. The pub-

lished frequency of fractures of the anterior wall, the posterior wall, and the floor of the frontal sinus varies rather widely: 43 to 61% of reported patients had anterior table fractures only, 19 to 51% had anterior and posterior table fractures, 2.5 to 25% had injuries to the nasofrontal duct, and 0.6 to 6% had posterior fractures only.^{2,3,8}

Anatomy and Physiology

Embryology of the Sinus

The frontal bone is an intramembranous bone that develops from two paired structures that begin to ossify at the eighth or ninth week in utero.^{10,26} The ossification begins in the frontal processes of the squamous regions, progresses to the orbital and squamous regions, and reaches the frontal and temporal regions by the twelfth week. The metopic suture in the midline closes during the second year of life.²⁷ The forehead is displaced anteriorly by sutural growth, inner table resorption, and outer table deposition.²⁸

The frontal sinus is a small outpouching at birth and undergoes almost all of its development thereafter. The sinus may

develop from one or several different sites: as a rudiment of the ethmoid air cells, as a mucosal pocket in or near the frontal recess, as an evagination of the frontal recess, or from the superior middle meatus.²⁰ Initial pneumatization begins during the fourth month in utero. Secondary pneumatization begins at the age of 6 months to 2 years and develops laterally and vertically. The sinus is radiographically identifiable by the time the child reaches the age of 6 years.²⁹ Most pneumatization is completed by the time the child is 12 to 16 years old, but it continues until the age of 40 is reached.^{5,20,26,30} The configuration of the sinus and the position of the septa are extremely variable.

Physiology of the Sinus

The entire surface area of the frontal sinus is covered with respiratory epithelium ranging in thickness from 0.07 to 2.0 mm.³¹ The mucosa consists of pseudostratified ciliated epithelium, mucus-producing goblet cells, a thin basement membrane, and a thin lamina propria that contains seromucous glands.³¹ When the mucosa is healthy, a blanket of mucin

overlies the epithelium. The cilia flow at 250 cycles/min. The mucin blanket flows in a spiral fashion in a medial-to-lateral direction; the flow is slowest at the roof and fastest at the nasofrontal duct.³² The mucin empties at the nasofrontal duct at a rate of 5.0 g/cm². The physiologic characteristics of the sinus and the status of the nasofrontal duct dictate the treatment of the frontal sinus in trauma.³³

Osteology

The frontal bone is shaped as a concave disk with a horizontal table forming the orbital rim. From the nasion the bone extends approximately 12.5 cm superiorly,

8.0 cm laterally, and 5.5 cm posteriorly. Two frontal tuberosities are noted lateral to the midline and superior to the supraorbital run. The thickest area of the bone is the supraorbital rim from the frontozygomatic process to the nasal bones. The ethmoid plate is bound on three surfaces along the floor of the frontal bone in the midline. As the floor of the frontal bone extends laterally, it becomes concave and forms the orbital roof. The supraorbital and frontal foramen are located at the most superior portion of the orbital rim. The supratrochlear foramen is located medial to the supraorbital foramen or notch and lateral to the nasal bones. A spine or con-

cavity exists on the frontal bone along the medial anterior orbital roof; the trochlea of the superior oblique muscle is attached to this spine (Figure 25-1).^{34,35}

Paired triangular sinuses are found within the frontal bone. These sinuses are asymmetric and are separated by a frontal septum. The average height of the sinuses is 32 mm, and their average width is 26 mm.^{29,35} The surface area is approximately 720 mm².³² The frontal bone is thinnest in the region of the glabella at the anterior wall and floor of the sinus. The duct of the frontal sinus empties into the ethmoid air cells of the middle meatus of the nose.

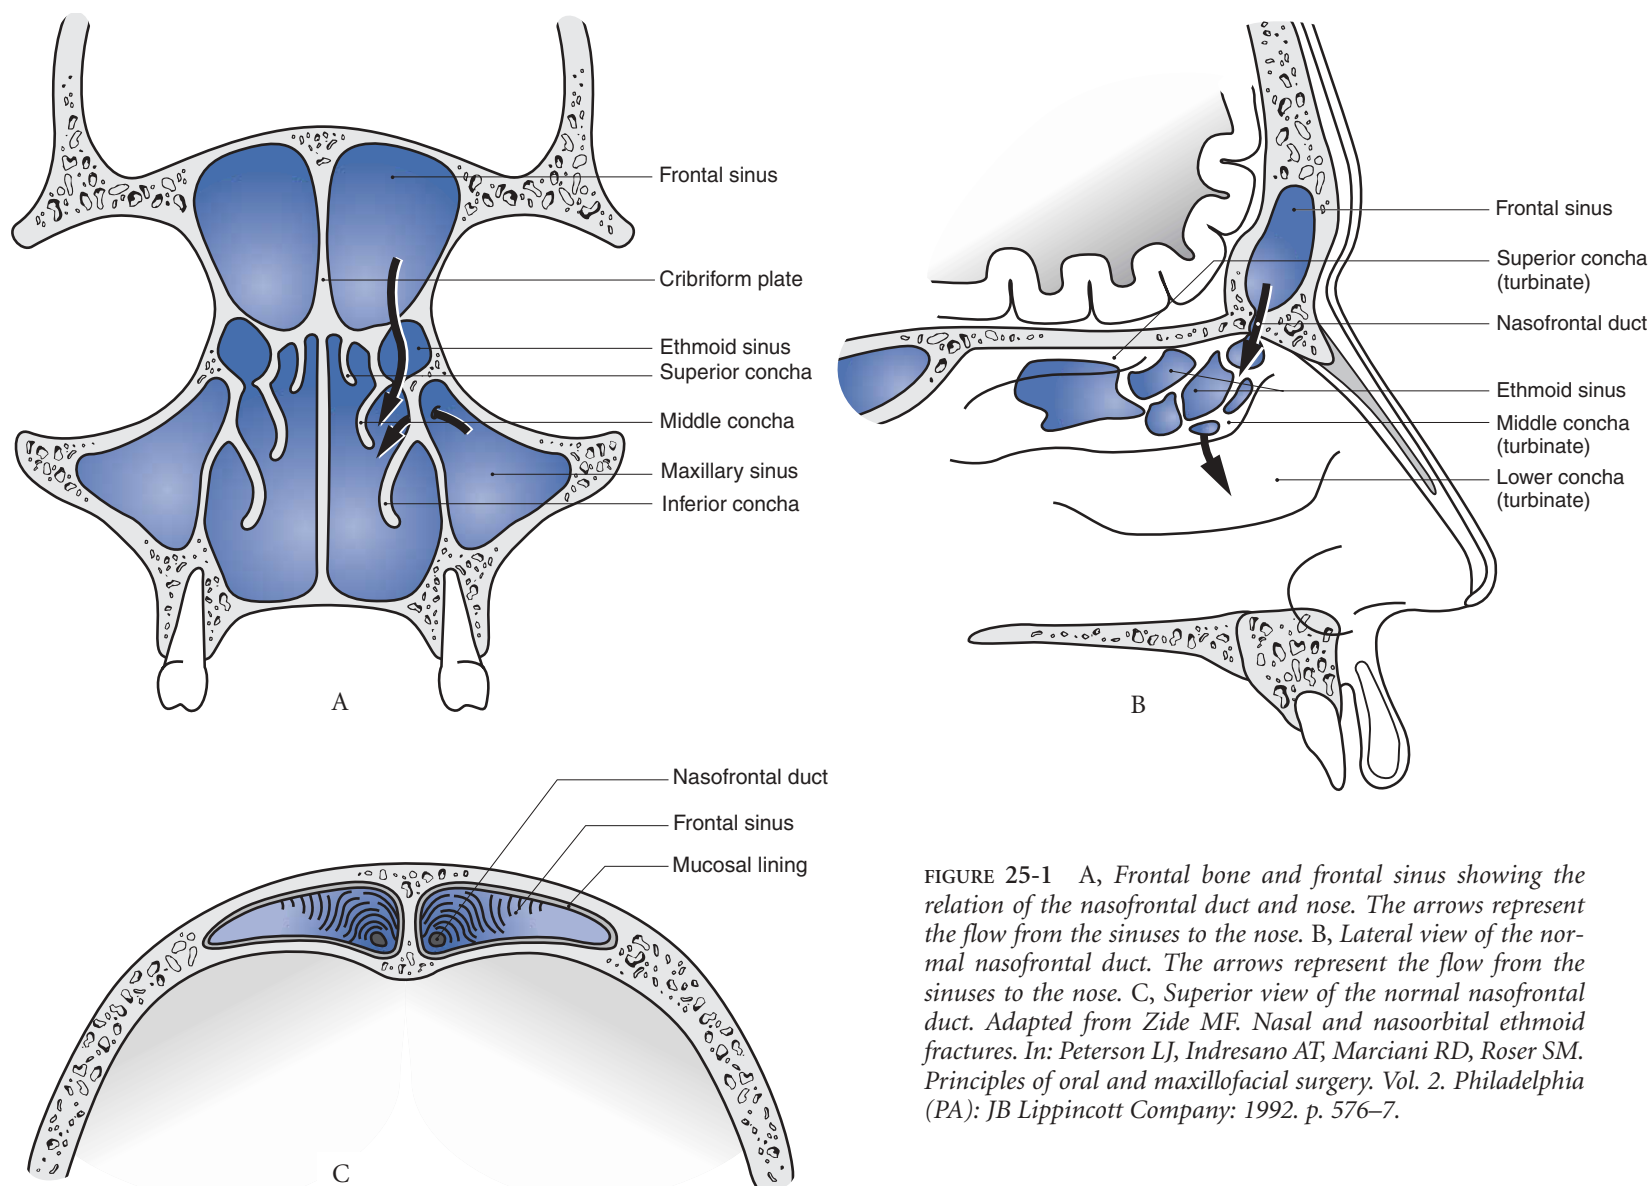

FIGURE 25-1 A, Frontal bone and frontal sinus showing the relation of the nasofrontal duct and nose. The arrows represent the flow from the sinuses to the nose. B, Lateral view of the normal nasofrontal duct. The arrows represent the flow from the sinuses to the nose. C, Superior view of the normal nasofrontal duct. Adapted from Zide MF. Nasal and nasoorbital ethmoid fractures. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol. 2. Philadelphia (PA): JB Lippincott Company; 1992. p. 576–7.

The internal concave surface of the frontal bone forms the anterior cranial fossa that houses the brain. The floor of the frontal bone outlines the roof of the orbit. The convex outer table is bounded by the scalp and the frontalis, orbicularis, and procerus muscles. The osseous structures that abut the frontal bone are the lacrimal and ethmoid bones inferiorly, the sphenoid inferiorly and posteriorly, the parietal posteriorly and superiorly, the zygoma laterally, the nasal bones anteriorly, and the maxilla anteriorly and inferiorly. The ethmoid air cells and nasal apparatus are situated inferiorly.

The nasal part of the frontal bone extends inferiorly deep to the nasal bones and the frontal process of the maxilla, adding support to the NOE complex. The nasal bones and the maxilla make up the piriform rim. The articulation of the nasal bones forms a crest posteriorly and inferiorly; this crest articulates with the frontal bone, the perpendicular plate of the ethmoid (forming the upper third of the nasal septum), and the septal cartilage. The NOE region is supported structurally by a vertical buttress—the frontal process of the maxilla—and two horizontal buttresses: the supraorbital and infraorbital rims.³⁶

The medial walls of the orbit begin behind the frontal process of the maxilla. The thin lacrimal bone and a frail lamina papyracea in the anterior are weak and susceptible to fracture. Higher up, the frontoethmoid suture delineates the level of the cribriform plate and crista galli.

Neurovascular Structures

The arterial blood supply to the frontal sinus is from the supraorbital and anterior ethmoid arteries. Two foramina are present along the suture line: the anterior ethmoid foramen, through which course the nasociliary nerve and the anterior ethmoidal artery; and the posterior ethmoidal foramen, through which pass the vessel and nerve of the same name.

Further posterior along the medial orbital wall, the optic nerve exits through the body of the sphenoid bone, 3.5 to 5 mm behind the posterior ethmoidal foramen in a line parallel to the two foramina. The frontal bone is supplied by the supraorbital, anterior superficial temporal, anterior cerebral, and middle meningeal arteries.^{27,34,35} Venous drainage is transosseous through the anastomosis of vessels of the subcutaneous, orbital, and intracranial structures. The primary venous drainage is through the supratrochlear, supraorbital, superficial temporal, frontal diploic (veins of Breschet), superior ophthalmic, and superior sagittal sinuses.^{27,34} The relationship of the diploë to the anterior cranial fossae is important to understand because these structures can become a conduit for the spread of infection.

Interorbital Space

The nasofrontal suture is the continuation of the frontoethmoid suture and corresponds to the plane of the base of the skull or frontal sinus. The interorbital space is bounded laterally by the medial wall of the orbits. In the middle is the perpendicular plate of the ethmoid and nasal septum. The anterior wall is composed of the paired nasal bones, the frontal processes of the maxilla, and the nasal processes of the frontal bone.

The ethmoid air cells within the interorbital space occupy the upper half of the wall lateral to the nasal fossa. The dimensions of the anterior end of the ethmoid labyrinth are approximately 2.5 cm vertically and 1 cm transversely. The pyramid-shaped sinus measures 3.5 to 5 cm from front to back.

The ethmoid air cells drain into the middle meatus, as does the nasofrontal duct. The nasofrontal duct is located in the posterior medial floor of the frontal sinus at the junction of the ethmoid and nasal portions of the floor, and it courses through the anterior ethmoid in the middle meatus or just anterior to the middle

turbinate. The length of the duct may vary from a few millimeters to a centimeter or more (Figure 25-2).

Medial Canthal Tendon

The orbicularis oculi muscle has three portions: the orbital, the preseptal, and the pretarsal. The pretarsal portions of the upper and lower lids unite at the canthus to form the medial canthal tendon (MCT).

The MCT may be subdivided into a superficial portion and a deeper portion with the lacrimal sac between them. The superficial portion has two “legs” and inserts into the frontal process of the maxilla, providing support to the eyelids and maintaining the integrity of the palpebral fissure.^{36,37} The anterior leg attaches to the posterolateral surface of the nasal bones, and the superior leg inserts at the junction of the frontal process of the maxilla and the angular process of the frontal bone. The deeper portion (also known as Horner’s muscle or the pars lacrimalis) attaches to the posterior lacrimal crest.

NOE injuries may cause avulsion of the tendons from the bone or, more commonly, fractures of the bone that contains the attachment of tendons. This portion of the orbital rim is an important anatomic region with regard to reconstruction of NOE fractures.³⁶

Lacrimal Apparatus

The lacrimal drainage system is intimately related to the NOE region and can be damaged during trauma to or reconstruction of this area. The system removes any excess tears that accumulate after lubrication of the surface of the globe. The superior and inferior lacrimal canaliculi drain the lacrimal lake. The puncta of the canaliculi open just lateral to the lacrimal lake and are surrounded by Horner’s muscle. The orifice of the upper punctum faces downward and backward, and the orifice of the lower punctum faces upward and backward. The superior punctum is approximately 3 mm medial to the inferior

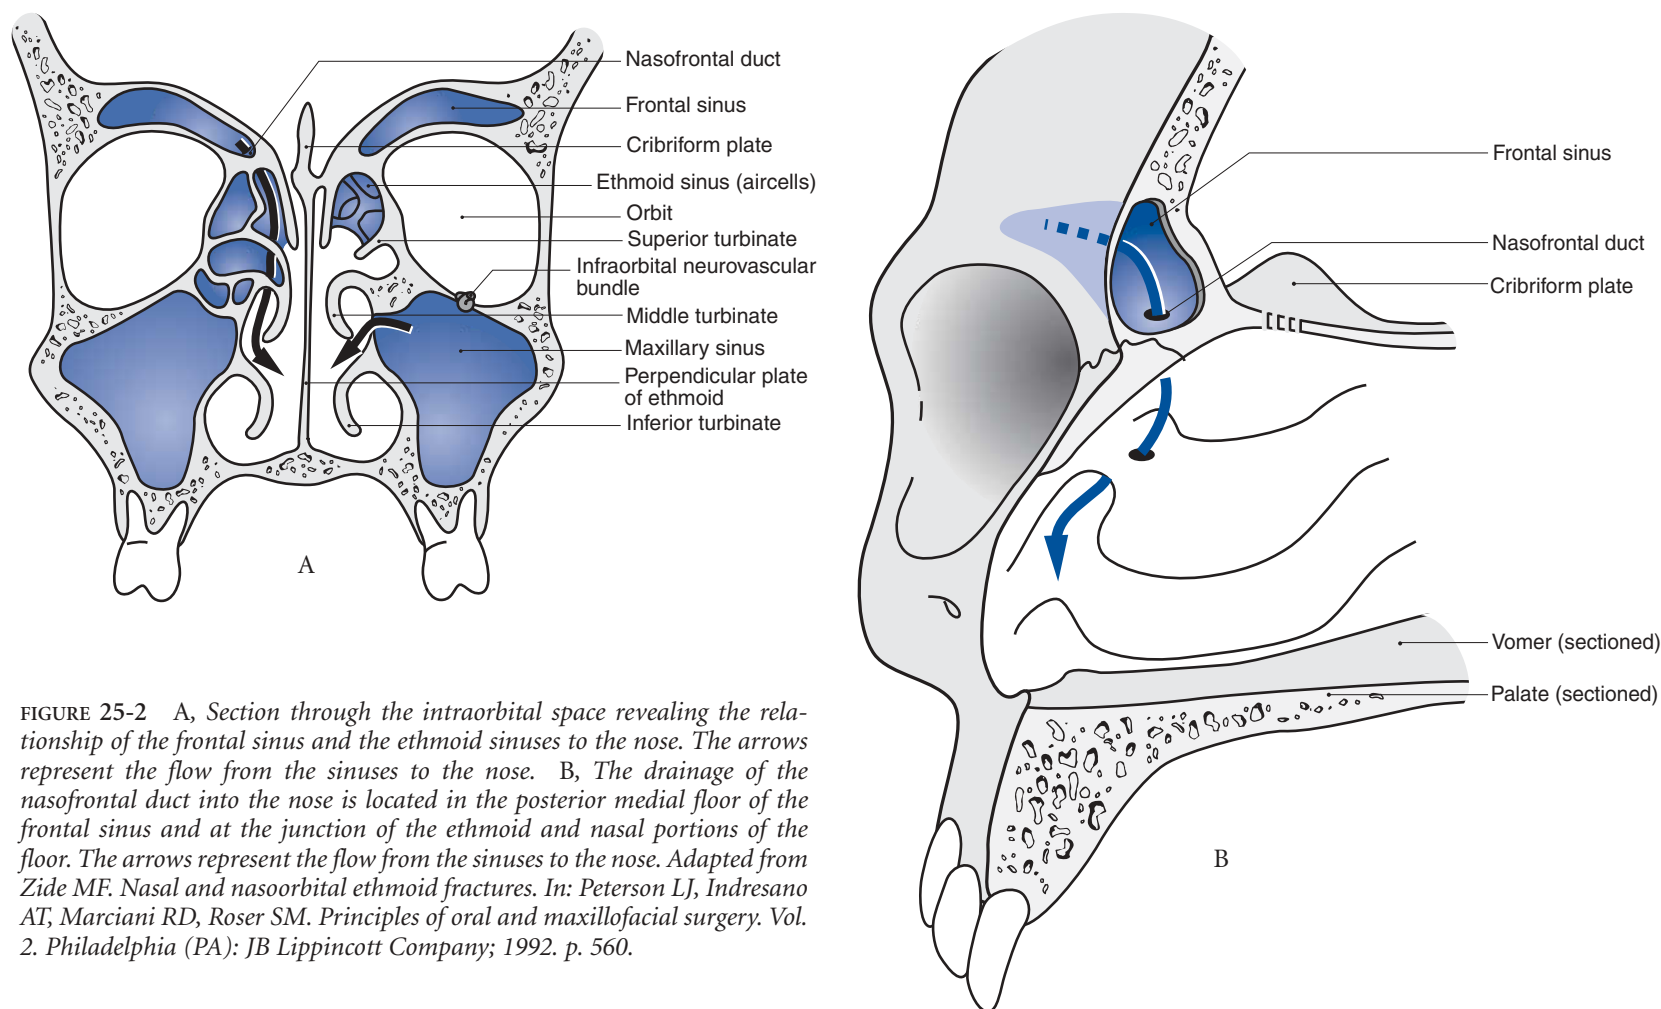

FIGURE 25-2 A, Section through the intraorbital space revealing the relationship of the frontal sinus and the ethmoid sinuses to the nose. The arrows represent the flow from the sinuses to the nose. B, The drainage of the nasofrontal duct into the nose is located in the posterior medial floor of the frontal sinus and at the junction of the ethmoid and nasal portions of the floor. The arrows represent the flow from the sinuses to the nose. Adapted from Zide MF. Nasal and nasoorbital ethmoid fractures. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 2. Philadelphia (PA): JB Lippincott Company; 1992. p. 560.

punctum. The two canaliculi pierce the lacrimal fascia and enter the lacrimal sac at or very near a common point. The canaliculi lie mostly behind the medial palpebral ligament and are surrounded by the pars lacrimalis.^{38,39} The lacrimal canaliculi are lined with nonkeratinized and non-mucin-producing stratified squamous epithelium. The epithelium is 75 to 150 μ thick and consists of a few layers of squamous cells, polyhedral cells, and a basal cell layer.³⁹

The lacrimal sac lies in a fossa on the anteromedial wall of the bony orbit. It is lined with pseudostratified columnar epithelium and is approximately 12 mm long.³⁹ The apex of the sac ends blindly in a superior fundus, and the sac continues inferiorly into the nasolacrimal duct,

which is housed in a bony canal. The duct empties into the inferior meatus in the nasal cavity.³⁸

Patient Evaluation

Clinical Findings

Periorbital ecchymosis and pain are the most common signs and symptoms associated with fractures of the frontal bone.^{5,40-44} When the bone bleeds and the periosteum is interrupted, leakage of blood into the adjacent facial planes results in periorbital ecchymosis. Through this same mechanism, subconjunctival hemorrhage may occur. If the nose and zygomas are unaffected, a finding of subconjunctival hemorrhage is sufficient for the diagnosis of frontal bone fracture.

Fractures of the NOE complex can produce the following signs: nasal deformity, edema and ecchymosis of the eyelids, subconjunctival hemorrhage, cerebrospinal fluid (CSF) leakage, hyposmia, traumatic telecanthus, increased canthal angles, and blindness (Figure 25-3).^{23,45}

Soft tissue lacerations in the region of the glabella and the supraorbital rims are also commonly found in association with frontal bone fractures and may be associated with anesthesia or paresthesia of the distribution of the supraorbital and supra-trochlear nerves.^{5,40-44} Depression of the bone with flatness and cosmetic deformity is noted if the patient is examined soon after injury. Examination of a patient with NOE fractures detects mobility of the nasal bones, traumatic telecanthus,

depression of the radix, a wide and flattened nasal dorsum, and an upturned nasal tip (Figure 25-4). From 1 hour to 5 days after injury, there may be enough edema to hide the contour depression. Palpation may reveal crepitation and tenderness over the fracture site.^{40–44}

Fractures involving the posterior table of the frontal sinus or the cribriform plate may cause CSF leakage.^{40–43,46} Confirmation of the presence of CSF can be made by collecting this fluid and comparing its concentrations of glucose and chloride with the patient's serum concentrations. Concentrations of chloride and glucose can be determined in as little as 0.1 mL of fluid. Chloride concentrations in the collected fluid that are greater than concentrations in serum and glucose concentrations less than those in serum indicate the presence of CSF. Collected fluid can also be tested for the presence of β_2 -transferrin; a positive result confirms the presence of CSF (Table 25-1).⁴⁷

FIGURE 25-4 Pre- (A) and postoperative (B) images of a patient with an NOE fracture showing a severely depressed radix.

FIGURE 25-3 Initial appearance of a patient with a frontal sinus fracture. Note the bilateral periorbital ecchymosis and forehead laceration.

The depression of bone fragments into the orbit may cause exophthalmos, proptosis, or ptosis. A depressed injury also causes restricted ocular movement if the superior rectus muscle, the superior oblique muscle, or the trochlea is damaged.^{43,44} Medial orbital wall fractures

associated with NOE fractures can also cause enophthalmos.

A thorough examination is important to distinguish between a nasal fracture and an unstable NOE fracture. The examiner should place the thumb and index finger over the medial canthus bilaterally. Mobility

Table 25-1 Normal Values of Constituents of CSF, Serum, and Nasal Secretions

Constituent	CSF	Serum	Nasal Secretions
Osmolarity	295 mOsm/L	295 mOsm/L	277 mOsm/L
Sodium	140 mEq/L	140 mEq/L	150 mEq/L
Potassium	2.5–3.5 mEq/L	3.3–4.8 mEq/L	12–41 mEq/L
Chloride	120–130 mEq/L	100–106 mEq/L	119–125 mEq/L
Glucose	58–90 mg/100 mL	80–120 mg/100 mL	14–32 mg/100 mL
Albumin	50–75%	55%	57%
Total protein	5–45 mg/dL	6.0–8.4 mg/dL	335–636 mg/dL
(% of total protein)			
Immunoglobulin G	3.5 mg/100 mL	1,140 mg/100 mL	51 mg/100 mL
β_2 -Transferrin (% of total transferrin)	15%	0%	0%

CSF = cerebrospinal fluid.

of these fragments may vary, but any movement implies instability and requires open reduction and stabilization.³⁶ A ruler or caliper should be used to measure the intercanthal distance. The normal distance is 28.6 mm to 33.0 mm for adult women; it is 28.9 mm to 34.5 mm for adult men. Increased widths suggest an NOE fracture. Two tests that can aid in the diagnosis of instability of the medial canthus are the “bowstring” test and the bimanual examination. The bowstring test involves pulling the lid laterally while palpating the tendon area to detect movement of fracture segments.^{48,49} The Furness test may also be performed by grasping the skin overlying the medial canthus with a small-tissue forceps (Figure 25-5). A lack of creasing or resistance by the underlying bone is indicative of an underlying fracture.⁵⁰ The bimanual examination requires placing an instrument (eg, a Kelly clamp) high into the nose, with its tip directly beneath the MCT. Gentle lifting with the contralateral finger palpates the canthal tendons and

allows an assessment of the instability of the tendon attachment and the necessity for open reduction.⁵¹

Imaging

Poor outcomes after the treatment of NOE fractures and frontal sinus fractures typically result from misdiagnosis, inadequate planning, lack of exposure, inadequate reduction or fixation of soft tissue or bone, stripping of the medial canthi, or loss of nasal contour with insufficient primary grafting.^{36,52} In the past, Waters’ projections, reverse Towne’s projections, lateral skull films, and laminar tomograms were used to visualize midface and upper-face fractures. It is clear that appropriate preoperative imaging can help to prevent misdiagnosis and can aid in proper treatment planning. Today computed tomography (CT) scans are the gold standard for imaging these fractures (Figure 25-6).^{5,10,36,52–56}

The plane of choice for frontal sinus imaging is the axial view, preferably with slice thicknesses of 1.0 or 1.5 mm.^{22,26,30} The

high degree of detail required for imaging NOE fractures necessitates axial and coronal views with slice thicknesses of 1.0 or 1.5 mm.^{25,36} Indeed, it has been shown that for severe fractures of the NOE region, two- and three-dimensional CT scans provide the most information about the medial orbital wall, the medial maxillary buttress, and the piriform aperture.^{36,57}

Patency of the Nasofrontal Duct

Although the newest CT scanners provide exceptional views and can often provide slices through the nasofrontal duct, evidence of their reliability in detecting obstruction of the ducts is scant.^{54,55} Duct obstruction should be suspected with fractures involving the medial supraorbital rim or the frontal bone with nasal ethmoidal component fractures, and it should always be considered when a CSF leak is present.¹² In these situations an open or intraoperative evaluation of patency is indicated. This evaluation is important because the condition of the nasofrontal duct has the most influence on the health of the frontal sinus (Figure 25-7).^{12,20,22,33,54,58–62}

Classification of NOE Fractures

As with all fractures, NOE fractures are classified as unilateral or bilateral, open or closed, and simple or comminuted. Three types of NOE fractures have been well described.^{25,36,38,63} A type I fracture maintains the attachment of the MCT to a large single nasoethmoidal fracture segment; repairing this type of fracture is straightforward. A type II fracture shows more comminution yet maintains the attachment of the medial canthus to a sizable bony segment. Type III fractures display severe comminution with possible avulsion of the MCT from its bony attachment (Figure 25-8).

Classification of Frontal Sinus Fractures

Traditional fracture classifications can be used with reference to frontal bone fractures

FIGURE 25-5 Illustrations of the bowstring (A) and bimanual examination (B) for possible NOE fractures. Adapted from Zide MF. Nasal and nasoorbital ethmoid fractures. In: Peterson LJ, Indresano AT, Marciani RD, and Roser SM. Principles of oral and maxillofacial surgery. Vol. 2. Philadelphia (PA): JB Lippincott Company; 1992. p. 562.

FIGURE 25-6 The detail of fracture anatomy is clearly superior in computed tomographic (CT) scans when compared with traditional radiography. A, Initial appearance of a patient with an NOE fracture. B, Axial CT scan showing the fracture. C and D, Axial and coronal CT scans of another patient illustrating detailed fracture anatomy.

(eg, open or closed). Numerous other classification schemes have been proposed in the surgical literature in an attempt to simplify surgical decision making. Although these schemes are well intended, some are so complex that they actually complicate decision making and are of no value. Consideration must always be given to the condition of the anterior table, the posterior table, and the nasofrontal ducts and to the presence of comorbid intracranial injury and concomitant craniomaxillofacial injuries.^{5,8,14,20,64} The simplest and most helpful classification schemes distinguish possible complications and treatments on the basis of types of fractures.

Isolated anterior table fractures should be treated so that cosmetic deformities can be prevented. Posterior table fractures, alone or in combination with anterior table fractures, should be treated so that neurologic sequelae, including meningitis and brain abscess, can be avoided. Combinations of fractures that compromise the nasofrontal duct should

be treated so that the development of mucocoeles and pyocoeles can be prevented. These fracture combinations include fractures of the anterior table and the posterior table, fractures of the anterior table and the NOE, and fractures of the anterior table and the medial superior orbital rim.

Treatment

Surgical Access

The coronal approach to surgery provides the greatest access to the frontal bone and sinus and produces the most desirable cosmetic results.^{5,10,22,61} Although lacerations may be considered as an approach to the fracture, their size and shape rarely provide enough access without undue and unsightly extension. Gullwing or spectacle incisions result in unattractive scars that are highly visible because of their prominence on the brow and the resulting reflection of light. These scars can be camouflaged only with wide-rimmed glasses. The “open sky” approach is equally deforming,

leaving an H-shaped scar over the brows and nasion.

Although the coronal approach has been well described,⁶⁵ the preparation required for a coronal incision varies. If a neurosurgical procedure is anticipated, the hair may be shaved and the skin degreased with alcohol and then prepared with an antimicrobial skin preparation agent, preferably povidone-iodine solution. If a neurosurgical procedure is not anticipated, the hair should be parted coronally from preauricular region to preauricular region. Water soluble lubricant is helpful in maintaining the part. The hair may then be braided in multiple pigtailed and gathered anteriorly and posteriorly on either side of the part. Local anesthetic with a vasoconstrictor is used to aid in hemostasis. Electrocautery should not be used for the initial incision because it may damage hair follicles. The incision is made to the depth of the loose aponeurotic layer. The flap is undermined along this plane and above the periosteum in an anterior direction. Raney clips are helpful in achieving hemostasis; however, hemorrhage may recur when they are removed, and electrocautery may need to be used carefully at the end of the procedure as the individual clips are removed. Again, care must be taken to avoid hair follicles to preserve scar camouflage.

The flap is elevated to within 2.0 cm of the fracture or within 3.0 cm of the supra-orbital rims. The pericranium is then

FIGURE 25-7 Intraoperative view of the floor of the frontal sinus with nasofrontal ducts.

FIGURE 25-8 Naso-orbitoethmoid fracture classification.

incised, and the reflection of the flap continues deep to the pericranium so that the branches of the facial nerve can be protected. Further reflection can be obtained with greater exposure by extension of the preauricular incision, galeal splitting (if a vascularized galeal flap is not anticipated), or release of the supraorbital nerve from its foramen or notch.

Osseous Recovery and Access

Recovery of bony fragments in comminuted fractures is best undertaken during the reflection of the coronal flap. Fragments of the anterior table should be released from the periosteum and removed one at a time. Some method of organizing the fragments should be used. For example, the fragments could be numbered and their positions recorded on a map. They should be arranged in the same order on a back table (Figure 25-9). If contaminated, segments of bone may be cleansed with copious irrigation, scrubbing, and even povidone-iodine solution, and then used for reconstruction as free grafts.⁶⁶ Once the anterior table has been removed, access should be adequate for sinus exploration, posterior

table inspection, and sinus floor (nasofrontal duct) evaluation.

If a more extensive neurosurgical procedure is anticipated, osseous recovery may be performed in concert with a craniotomy bone flap. Before small fragments are recovered, the osseous flap design should be mapped out on the frontal bone (with care taken to avoid the sagittal sinus). Bur holes are created at three or four corners of the frontal bone. The tenuous and adherent dura is released through the bur holes, and a craniotome is used to connect the bur holes. The dura is carefully reflected as the bone flap is removed. Recovery of the rest of the osseous fragments can then be completed.

A perimeter-marking technique can be used for removal of the anterior table that is unfractured.⁶⁷ The removal of the entire anterior table is important when obliteration of the sinus is anticipated because this procedure requires thorough removal of sinus mucosa. One side of a hemostat or pick-up instrument can be inserted into the sinus, and a small bur hole can be made at the tip of the superficial arm of the instrument. Fixation plates

can be adapted before the removal of the remaining anterior table segment.

Intraoperative Evaluation of the Nasofrontal Duct

After access has been obtained and osseous exploration and recovery have been performed, the condition of the frontal sinus floor and the nasofrontal ducts can be assessed by direct visualization (see Figure 25-7). The relative patency of the duct can then be evaluated by placing an

FIGURE 25-9 Comminuted frontal sinus segments arranged prior to reconstruction.

angiocatheter into the nasofrontal duct and introducing an appropriate fluid medium so that flow can be assessed. A 3.8 cm (1.5 inch) 18-gauge angiocatheter is the best instrument for this purpose. Patency of the nasofrontal duct can be confirmed by introducing normal saline and observing its emergence from beneath the medial turbinate or its collection in the posterior pharynx (Figure 25-10). Because of its dramatic hue, methylene blue dye has been offered as an appropriate fluid for evaluating patency. However, this blue dye can disrupt visualization of the surgical field because completely removing the dye is difficult during a surgical procedure (Figure 25-11). Fluorescein is an excellent alternative because it is clear, colorless, water soluble, and radiolucent.⁶⁸ However, its visualization sometimes requires using an ultraviolet light source and then dimming the operating room lights. Radiopaque dye has been suggested for use as a diagnostic

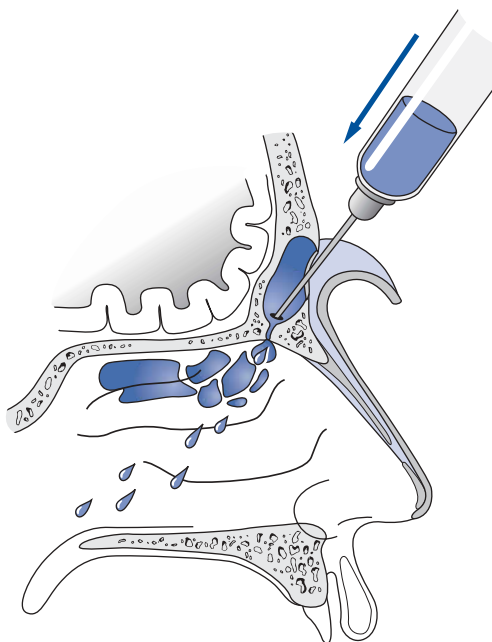

FIGURE 25-10 Technique of identifying a patent nasofrontal duct. Adapted from Zide MF. Nasal and naso-orbital ethmoid fractures. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. Principles of oral and maxillofacial surgery. Vol. 2. Philadelphia (PA): JB Lippincott Company; 1992. p. 582.

FIGURE 25-11 A and B, Intraoperative evaluation of nasofrontal duct patency by injection of methylene blue. In B, note the methylene blue coming from the patient's nostril. Reproduced with permission from Haug RH and Cunningham LL.⁶⁴

medium for nasofrontal duct fractures, but its visualization requires a C-arm fluoroscopy unit.⁶⁰ Moreover, any spilled radiopaque dye must be completely cleared before additional radiographs or computed tomographic images are obtained. Indigo carmine is another acceptable dye, but Congo red is neurotoxic.

Anterior Table Fractures

The thinnest area of the frontal bone is the region of the glabella, the anterior wall of the frontal sinus, and this region is highly susceptible to fracture. These fractures may seem straightforward but still deserve careful attention. Simple greenstick or nondisplaced anterior wall fractures do not require operative treatment.⁶⁹ Displaced anterior table fractures require open reduction. The surgeon should closely inspect the sinus floor, the posterior wall, and the patency of the nasofrontal duct. If the posterior wall and the floor are free of injury, the pieces of the anterior wall may be fixated with low-profile bone plates.^{64,66,70,71} Any void remaining in the anterior wall after reconstruction can be closed by placing titanium mesh, methylmethacrylate, or other

bone substitutes. The soft tissue injuries may then be repaired.

Posterior Table Fractures

Fractures to the posterior table of the frontal sinus are more concerning because of the proximity to the anterior cranial fossae (Figure 25-12). Posterior table fractures can be subclassified into three categories: nondisplaced, displaced, and displaced with gross neurologic injury. Each of the subclassifications is invariably associated with anterior wall penetration. Each is treated differently, and each requires neurosurgical consultation or joint management with a neurosurgeon. Antibiotic coverage is particularly important in preventing infection.¹⁶

FIGURE 25-12 CT scan demonstrating anterior and posterior table fractures of the frontal sinus.

The surgeon should check carefully for displacement of the fracture, CSF leak, entrapment of sinus membranes, and dural tears. If the injury is not substantial and the nasofrontal duct is patent, the anterior table is replaced and fixed and the soft tissue injuries are repaired. Comminution of the posterior table, penetrating injury, CSF leak with extensive dural damage, or frontal lobe damage requires frontal sinus cranialization: complete removal of the posterior table, thereby effectively increasing the size of the anterior cranial fossa.^{5,20,58,59,62,64} In one review of cases, as many as 16% of patients undergoing frontal sinus surgery required a cranialization procedure.⁵ In such a case the posterior table would be gently removed, either with a diamond bur or with rongeurs. Care should be taken in the area of the sagittal sinus to avoid severe bleeding. All irregularities of the sinus are smoothed with a bur. After bone removal the dura should be repaired with primary closure, a fascia or synthetic patch, or a galeal or pericranial flap.^{5,64}

The wound is closed in layers. Strict attention must be given to meticulous removal of all of the mucosal elements from the walls, cul-de-sacs, and septa of the sinus and from all bone fragments.⁷²⁻⁷⁴ Failure to remove such elements may result in a mucocele or pyocele. The mucosa is then reflected down into the nasofrontal duct, and the orifice is obstructed by local bone or muscle. The harvested fat is placed into the sinus and packed until the sinus is full. Finally, the outer table is reassembled and restored as would be done for a simple anterior wall fracture.

Orbital Roof and Supraorbital Bar Reconstruction

Once the posterior wall and the sinus floor have been explored, inspected, and evaluated for damage, the orbital roof and supraorbital bar may be reconstructed. After these procedures have been complet-

ed, a galeal flap should be reflected, the sinus obliterated, and the nasofrontal duct obstructed. The free osseous fragments that have been recovered, mapped, and arranged on a back table should be rigorously curetted for removal of any respiratory epithelium that could become entrapped between them during reconstruction. Every remnant of respiratory epithelium should be removed from every crevice and cul-de-sac so that the possibility of future mucocele formation is minimized. This procedure is followed with local osteotomy with a no. 8 round diamond bur and copious amounts of saline. The arranged bone fragments should be consolidated with titanium microscrews (1.0–1.3 mm) and with appropriate plates, mesh, or both.^{75,76} Mesh has an advantage in that it provides support and consolidation of the segments in three planes of space (Figure 25-13).^{75,76} Titanium mesh has been shown to be compatible with soft tissue, undergoing incorporation with indigenous cells.⁷⁷ Resorbable technology continues to show promise, even for frontal bone injury⁷⁸; however, the resorbable systems currently available are not as versatile as titanium mesh in their ability to be contoured or to stabilize small bone fragments. Before final placement of the consolidated titanium and bone segments, the sinus should be copiously irrigated and hemostasis achieved. Once this phase of the procedure has been completed, the nasofrontal ducts may be obstructed (if indicated), the sinus obliterated, the brain isolated with a galeal flap (if indicated), and, finally, the anterior table replaced.

Nasofrontal Duct Obstruction

Nasofrontal duct obstruction should not be confused with sinus obliteration. Sinus obliteration is the elimination of dead space by the introduction of another material. Duct obstruction is one of the methods of isolating the sinus (or brain) from nasal contamination, basically by plugging it with another material.

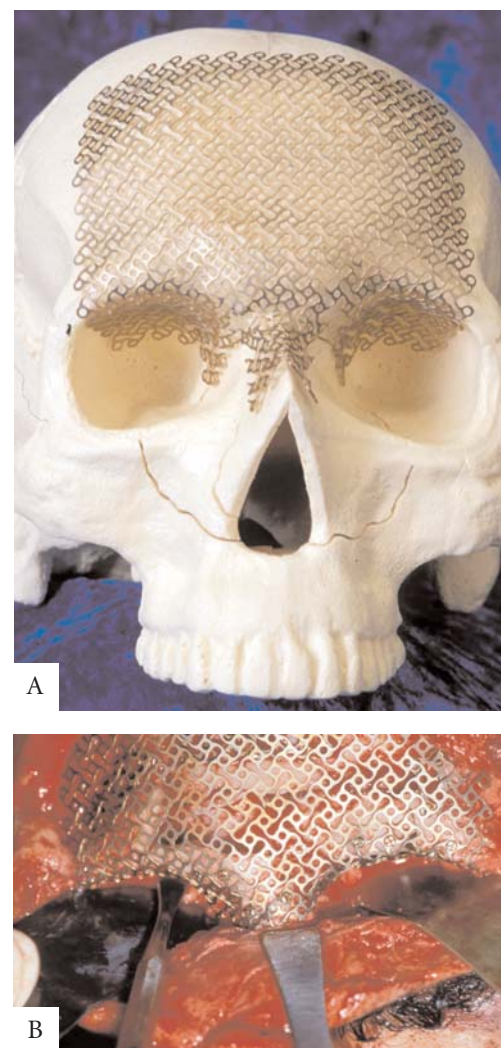

FIGURE 25-13 Reconstruction of the frontal bar and frontal sinus with titanium mesh. A, The mesh is adapted to a dried skull and then sterilized prior to surgery. B, Intraoperative view of reconstruction of the frontal bar and nasal dorsum with mesh.

As stated above, the condition of the nasofrontal duct is the most important factor in maintaining the health of the frontal sinus.^{12,20, 22,33,54,58-62} This duct permits the exit of mucin, seroma, or hematoma after injury. If the duct is injured and obstructed, sinusitis, meningitis, or osteomyelitis may develop. The condition of the duct should be considered in the evaluation of fractures of the NOE complex, the supraorbital rim, or the sinus floor. If the duct is not patent, thorough removal of every possible remnant of sinus mucosa is performed by curettage.^{20,58,68,73,74} This procedure is

followed by removal of additional mucosa from every cul-de-sac and crevice with a small (no. 8 or larger) diamond bur under copious amounts of irrigation and with the aid of magnification. Any remaining remnants of the nasofrontal duct mucosa are then inverted into the nose.

A number of materials can be used to obstruct the nasofrontal duct. Temporal fascia, temporal muscle, or both can be harvested from the adjacent temporal region through a bitemporal flap. Tensor fascia lata is another alternative, but it may produce morbidity at the second surgical site. Estimating the surface area to be covered is an important technical point. A suture package is a good template for measurement and recording. Because fascia shrinks, it is important to harvest approximately 20% more graft material than is indicated by the template. Bone graft material can be harvested from the sinus septum, the inner table, or elsewhere on the cranium.⁷⁹ Commercial tissue sealants prepared from human plasma and containing bovine-derived aprotinin are available. These sealants have been shown to be effective tissue adhesives and hemostatic agents.^{80–82} Autologous platelet gel and autologous fibrin glue have also been used for similar indications.^{83,84} In addition, a new fibrin sealant from the American Red Cross has been reported to show promise as a hemostatic agent without the addition of bovine aprotinin.⁸⁵

Whatever products are chosen, the organization and arrangement of the obstructive media are important. For example, a tissue sealant may be placed after inversion of the sinus mucosa. Fascia or muscle may then be introduced into the remnants of the duct to block passage of nasal contaminants, followed by inner-table cranium or remnants of septal bone from the sinus, followed by another layer of tissue sealant. Tissue sealants can be used effectively to seal off the sinus from the nasal cavity when they are applied layer by layer as described above.

Sinus Obliteration

Nasofrontal duct obstruction is necessary to seal off the frontal sinus from nasal contaminants. Sinus obliteration adds one more layer to the seal but also eliminates the “dead space” or air within the sinus that may permit fluids to accumulate, thus causing a seroma or a hematoma. Furthermore, after cranialization, sinus obliteration cushions and protects the brain. Historically, sinus obliteration has been accomplished in a number of ways, including inserting no substance or object (theoretically permitting bone fill after curettage) or hydroxylapatite, glass wool, bone, cartilage, muscle, absorbable gelatin sponge, absorbable knitted fabric, acrylic, or fat.^{16,73,74,86–92} The use of fat has been reported most frequently, and this method historically has provided the most desirable results.

Harvesting fat is simple and may be performed by liposuction or an open approach.⁸⁹ With the open approach the skin is first cleansed with an antimicrobial agent from below the umbilicus to above the escutcheon of the genitalia. A transverse semilunar incision is made within the “bikini” line, 5.0 cm superior to the symphysis pubis (Pfannenstiel’s incision); an incision 5.0 to 8.0 cm long is adequate. An alternative to this approach is a vertical incision from below the umbilicus to above the symphysis pubis. The incision is carried through skin and subcuticular tissue to the fat. The fat is grasped with an Allis clamp and retracted. Scissors are used to dissect the fat subcutaneously, moving laterally, inferiorly, superiorly, and caudally to the fascia overlying the abdominis rectus muscles, which are then connected, releasing the fat. Irrigation and meticulous attention to hemostasis are important before closure of the incision to avoid hematoma and infection (Figures 25-14 and 25-15).

NOE Reconstruction

Early surgical management is important in the reduction of NOE fractures.^{25,38,45} The

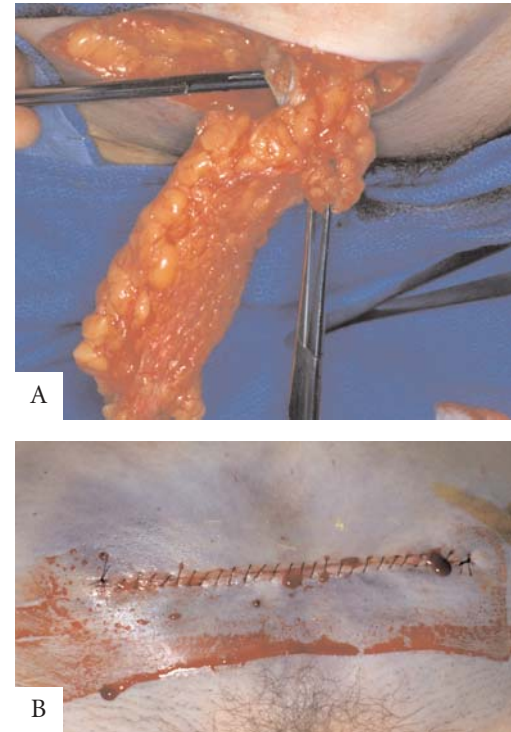

FIGURE 25-14 A, Abdominal fat graft harvest showing the amount of fat obtainable. B, Subsequent hematoma formation, which necessitated a return to the operating room for evacuation.

deformities that result from unrepaired NOE fractures are severe and difficult to correct, requiring NOE osteotomies and grafting, and satisfactory results are rarely achieved.

In addition to the coronal approach, complete exposure of the NOE area often necessitates lower eyelid incisions (transconjunctival or subciliary) and a maxillary vestibular incision.³⁶ These approaches aid in the treatment of displaced infraorbital rims and maxillary antrum or piriform rims.

Type I fractures are less difficult to treat and can at times be reduced transnasally and treated without fixation. More often, single-segment NOE fractures are reduced through a coronal incision and secured at the nasofrontal junction, the maxillary buttress, and the infraorbital rims.^{36,38}

Transnasal wiring is recommended for fractures graded as Markowitz type II or higher.²² Although we are truly in an era of rigid fixation (bone plates and screws),

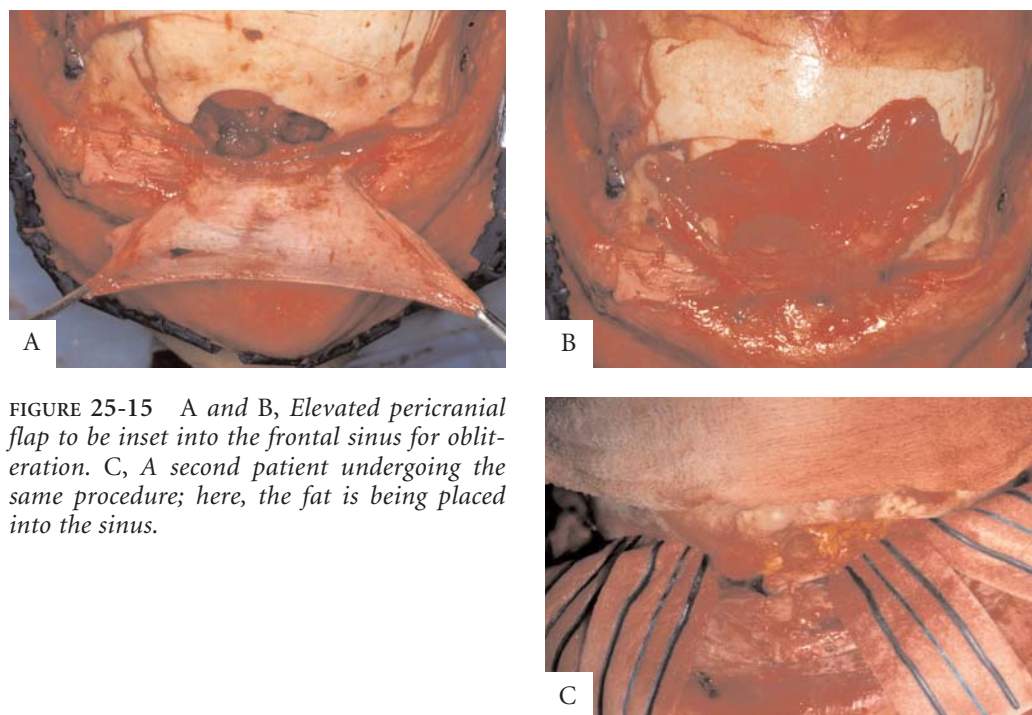

FIGURE 25-15 A and B, Elevated pericranial flap to be inset into the frontal sinus for obliteration. C, A second patient undergoing the same procedure; here, the fat is being placed into the sinus.

complete reduction of the NOE area and reattachment of the MCT, or replacement of a small bone segment, seem never to be adequate with microplates alone. For NOE fractures including avulsion of the MCT or in which the MCT is attached to a small bone segment, transnasal wiring should be considered. The point of fixation of the wires should be directed posterior and superior to the lacrimal fossa so that the medial canthal distance is decreased and widening of the nasal bones and blunting of the medial canthal area can be avoided.²² Wires must be passed through the medial orbital bone and the superior nasal septum or the perpendicular plate of the ethmoid. Their passage can be facilitated with the use of a spinal needle or a wire-passing awl. Drill holes can also be used to aid in wire passing. Some clinicians have advocated temporary removal of the nasal bone for identification of the “canthal bearing bone” and for facilitation of the passage of transnasal wires.^{22,36} The MCT and its bony segment can be incorporated into the transnasal wire fixation, or an avulsed MCT can be attached to the transnasal wire with sutures. Slight overcorrection of

the medial canthal distance is desired. In cases in which fracture comminution prevents adequate fixation of the MCT to a bone segment, stabilization with fixation to a calvarial bone graft has been advocated.³⁶ In cases in which sufficient medial orbital wall remains, placing a microplate and screw for attaching the MCT behind the lacrimal crest has been suggested.³⁸

Bone grafting may often be necessary in cases of severe comminution of the nasal bones or the medial orbital walls. Onlay of cranial bone grafts to maintain dorsal height and nasal tip projection can be performed through a coronal incision, and these grafts can be fixated rigidly or with wire.

Medical Therapy of the Sinus Postoperatively

Saline solution nasal spray can reduce symptoms of rhinosinusitis.⁹³ This therapy can prevent crusting of the nasolacrimal duct as well as the frontonasal duct and the ostia of the maxillary sinus. Because this treatment is inexpensive and involves little or no risk, it can be made a part of reasonable postoperative care regimens.

There have been no clinical trials related to post-traumatic medical treatment of the sinus. However, for patients in whom the frontal sinus has been left intact, there may be at least a temporary decrease in function of the mucociliary apparatus.^{94–96} In addition, the trauma of surgery causes edema in the sinus tissues. Mucolytics have been advocated for use in patients with rhinosinusitis to thin the mucus secretions and to improve clearance.⁹³ During the post-traumatic or postoperative period, the use of mucolytics such as guaifenesin may be beneficial.

Decongestants may also be considered in the immediate postoperative period. Decongestant medications (eg, pseudoephedrine or oxymetazoline hydrochloride) act by stimulating α -adrenergic receptors in the mucosa of the upper respiratory tract. This action causes vasoconstriction in the respiratory mucosa, thereby shrinking the mucosa and increasing the size of the airways or ducts.^{93,97,98} Topical agents have fewer systemic side effects but are known to have a rebound potential and should be used for no more than 3 days.

Because there is no consensus regarding the use of postoperative antibiotics, their use should be based on the individual patient and type of injury. The extent of soft tissue injury, presence of wound contamination, a concomitant CSF leak, and other associated injuries should all be considered. Current recommendations regarding the use of prophylactic antibiotics for head and neck injuries include a duration of therapy of no more than 24 hours.^{99,100} In cases of contamination by a foreign body, this treatment may be continued for 10 days. In the absence of gross contamination of the wound, a limited number of postoperative doses can be considered, or none at all. Antibiotics used to treat acute rhinosinusitis include amoxicillin, amoxicillin-clavulanate, azithromycin, cefpodoxime proxetil, cefprozil, cefuroxime axetil, clarithromycin, levofloxacin, loracarbef, and trimethoprim-sulfamethoxazole.⁹³ Penicillin is still the drug of choice for treating facial fractures.¹⁰¹

Complications

Complications of frontal bone injury vary in severity and may occur many years after the injury. The principal types of complications are those that occur directly at the time of injury, those of an infectious nature, and those that are chronic problems.

The most devastating complications are neurologic problems resulting from displacement or penetration of the frontal bones into the brain. These injuries can result in concussion, severe brain injury, or death. Displacement of the floor of the frontal bone can cause orbital damage. The most frequent ocular complication is diplopia. Damage to the superior oblique muscles or trochlea may result in limited range of motion of the globe. Severing of the supraorbital nerve by the injury or during reflection of the osteoplastic flap leaves a permanent anesthesia of the distribution of the forehead.¹⁰² Trauma to the floor of the frontal sinus or displacement of the medial supraorbital rim may cause a CSF leak. Generally, reduction of the fractures corrects this problem. If it is persistent, however, neurosurgical repair is indicated.

Infectious complications most frequently arise from occlusion of the nasofrontal duct or contamination of the sinus by penetrating foreign bodies. The most frequently encountered infection is meningitis.⁸⁸ If the nasofrontal duct is occluded, blood may accumulate in the sinus, creating an environment that is conducive to the growth of anaerobic bacteria.^{13,103} Frontal sinus abscess is spread by direct extension through small fractures of the frontal bone or through transosseous anastomotic vessels.⁵⁹ The result is brain abscess, meningitis, cavernous sinus thrombosis, or (if the abscess is long term) osteomyelitis.

Mucocele are the most common chronic problems.¹⁰⁴⁻¹⁰⁶ Respiratory mucosa trapped between fracture segments or left behind during obliteration procedures may continue to grow. This continued growth

may lead to the formation of mucoceles or pyoceles. The size of the growth determines how much damage occurs to adjacent bone and neurologic tissue. Frontal sinus imaging (CT or magnetic resonance imaging) should be ordered to detect a postoperative mucocele or pyocele. Imaging studies should be performed at 1, 2, and 5 years after surgery or whenever symptoms appear.¹⁰⁷ Complications can occur as late as up to 20 years postoperatively, and patients should be encouraged to have routine yearly follow-ups.⁵⁹

Pain and headache may be chronic and may persist without an identifiable cause.¹³ Cosmetic deformities such as contour deficits and irregularities stem from several causes. Bone loss at the time of injury may not be noticed for months. Osteomyelitis with subsequent débridement leaves voids in bone. Even if the fractures are properly treated at the time of injury, remodeling may leave irregularities.

Anosmia—the loss of the sense of smell—and hyposmia are known complications of NOE fractures and can occur in as many as 38% of patients with high central midface fractures.¹⁰⁸ In addition, 23% of patients with high midface fractures report a decreased sense of taste (hypogeusia).¹⁰⁸

Dacryocystorhinostomy

Dacryocystorhinostomy (DCR) is the repair of the lacrimal drainage system through the creation of a new “ostomy” or track from the lacrimal canaliculi to the nasal cavity. Techniques that have been described include open (external), endonasal, and soft tissue conjunctivorhinostomy.¹⁰⁹⁻¹¹¹

Perhaps the best-described technique is the open DCR. This procedure is performed through a 10 mm vertical incision placed 10 to 12 mm medial to the medial canthus of the affected eye. Blunt dissection is then used to approach the lacrimal crest. A periosteal incision is followed by careful dissection of the lacrimal sac away from the bony fossa, and an osteotomy is

placed posterior to the lacrimal crest. The deep surface of the bone in this region is lined with nasal mucosa, which should remain intact during the osteotomy. Placement of a lacrimal probe can facilitate visualization of the lacrimal sac. After the sac has been freed, it is incised on its medial surface, and superior and inferior releasing incisions are made on the superficial side of the sac (posterior flap). This procedure is followed by a vertical incision of the nasal mucosa and anterior releasing incisions (anterior flap). At this point Crawford tubes are used to intubate both the superior and the inferior canaliculi. When intubation is complete, the ends of the Crawford tubes are visible in the lacrimal sac and can be inserted through the lacrimal osteotomy and retrieved intranasally inferior to the middle turbinate. These ends are then cut to extend to the nasal vestibule and are sutured in place to the lateral nasal wall (Figure 25-16).^{39,110}

Closure is then begun with anastomosis of the lacrimal sac and the nasal mucosa. The anterior flap of the nasal mucosa is closed to the posterior flap of the lacrimal sac. Often this is technically challenging, and an alternative is to suture the anterior lacrimal sac flap to periosteum to maintain the opening between the lacrimal sac and the nasal mucosa. Care should be taken to avoid suturing the retained polymeric silicone tubing during flap closure. The remainder of the incision is closed in two layers. The tubing is left in place for 4 to 6 months, and patients should use saline nasal sprays to prevent crusting of the tubes (Figure 25-17).

The endonasal approach is conceptually the same procedure, except that the dissection is performed from inside of the nose with the aid of endoscopic instruments and a fiber-optic light, which are introduced into the sac through the canaliculi. The nasal mucosa is incised and reflected over an area transilluminated from above. The illuminated area is

FIGURE 25-16 A, Incision of lacrimal sac. B, Osteotomy, made with a round bur, through which the polymeric silicone tubes are placed. C, View of the polymeric silicone tubes exiting through the nasal mucosa into the nose. D, The lacrimal sac flap is shown being held in the forceps over the polymeric silicone tubing that exits into the nasal cavity.

most commonly seen beneath the middle turbinate, which may need to be displaced medially so that appropriate exposure can be obtained. The transilluminating light can be seen most readily through the lacrimal bone posterior to the frontal process of the maxilla. The frontal process can be removed with a Freer elevator or with a 2 mm Kerrison rongeur. The lacrimal sac is then gently lifted free from the lacrimal bone with a Freer elevator. The thin lacrimal bone overlying the sac is then removed. An opening is then made into the lacrimal sac, and the Crawford tubing is inserted as before. Polymeric silicone tubes are left in place for 1 month, and saline spray and lacrimal irrigation are recommended.¹¹¹

Correction of Post-traumatic Deformity

Six months to 1 year after the initial surgical correction, secondary deformities of the frontal bone may be addressed. Contour defects result from failure to fully elevate depressed fractures, from voids in bone lost at the time of the trauma, and from infection. A multiplicity of materials has been used to correct contour defects, including bone from the adjacent calvaria, ileum, or rib; cartilage; titanium or stainless steel; polymeric silicone, methylmethacrylate, hydroxylapatite granules, silver, a cobalt-chromium alloy, polytef, polyethylene terephthalate fiber, nylon, polyethylene, and aluminum.^{112,113} The

procedures for correcting such defects involve one-stage indirect prosthetic techniques, two-stage techniques, single-stage direct techniques, or computer-generated single-stage techniques.¹¹⁴⁻¹¹⁶ The one-stage indirect technique requires that an impression be taken of the defect through the skin. The impression negative is then filled with plaster to form a positive image on which an onlay prosthesis may be fabricated. Acrylic, polyethylene, tantalum, titanium, and cobalt-chromium prostheses may be fabricated with this technique. A full-thickness flap is then reflected, and the prosthesis is secured.

The single-stage direct technique requires that a full-thickness flap be reflected beyond the margins of the defect.

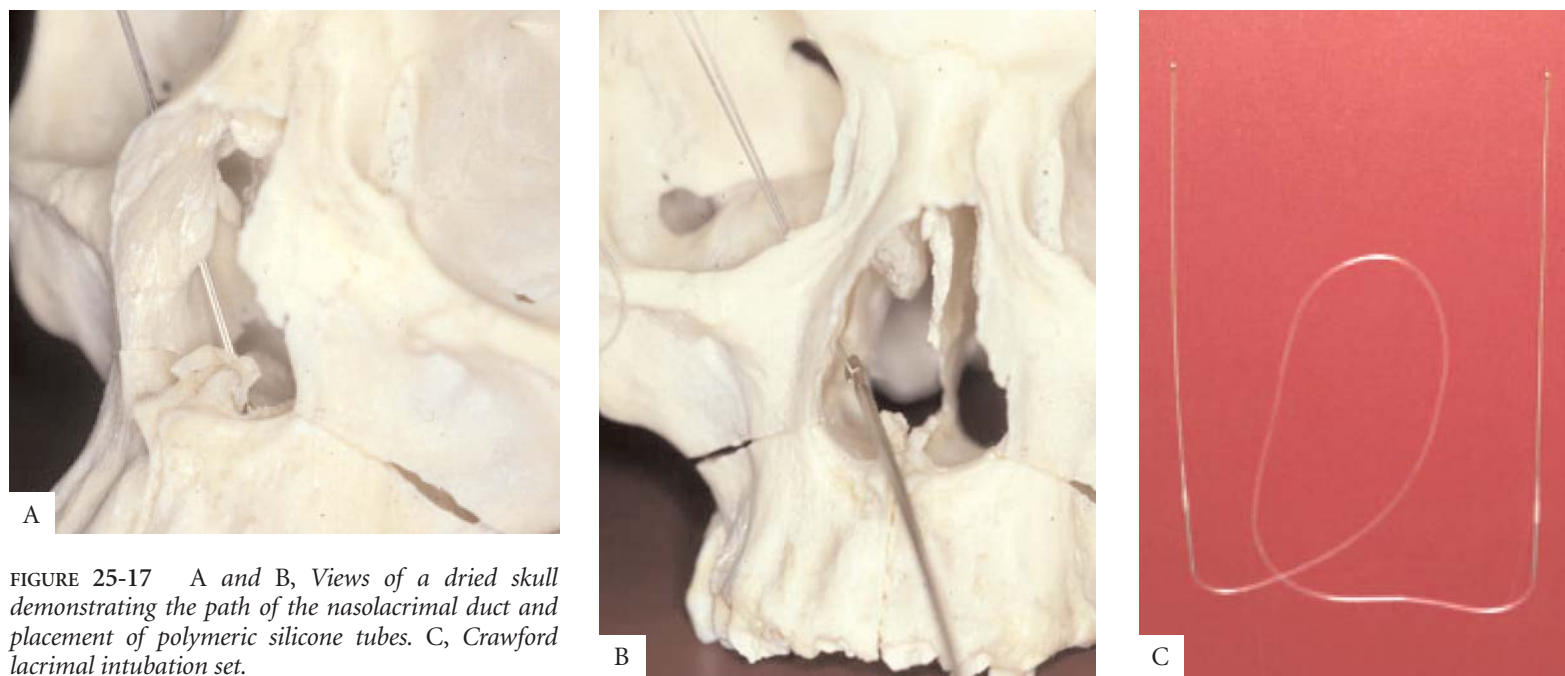

FIGURE 25-17 A and B, Views of a dried skull demonstrating the path of the nasolacrimal duct and placement of polymeric silicone tubes. C, Crawford lacrimal intubation set.

Onlay cartilage or bone grafts then may be secured if an autograft is desired. Otherwise, an acrylic resin may be used. The bone is moistened, and acrylic is mixed and placed on a glass or polytef slab and rolled to a uniform thickness. The acrylic is placed directly over the bone and covered with a sheet of separating foil. The full-thickness flap is replaced to ensure proper contour and then is again reflected. A copious amount of saline is used to irrigate the area so that the material does not cause thermal damage to the skull. The flap is then replaced and sutured.

Improvements in computer design and technology now enable the fabrication of prostheses for one-stage reconstructions. The patient undergoes a three-dimensional CT before the operative procedure is performed.¹¹⁴ A computer-assisted diagnosis/computer-assisted manufacturing (CAD/CAM) protocol is then used to create a model of the frontal bone and defect. A prosthesis may be created from polymeric silicone, acrylic, a cobalt-chromium alloy, or hydroxylapatite-coated metals. During the operative procedure, the prosthesis is inserted as described above.

Gunshot Injuries

Jon D. Holmes, DMD, MD

The greater the ignorance,
the greater the dogmatism.

—William Osler

Management of gunshot injuries to the face led in many ways to the development of modern maxillofacial surgery, and it remains a cornerstone of the specialty of oral and maxillofacial surgery. There is an aura that surrounds the management of these complex wounds that affects residents as well as experienced clinicians. The mystique that developed in the earliest accounts of management of gunshot wounds (GSWs) persists with the passing along of myths and dogma to subsequent generations of residents. Readers are encouraged to use the information in this chapter as a guide, to combine it with their own experience, and hopefully to continue the evolution in treatment of these unique wounds.

History

The introduction of Chinese gunpowder to Europe around the thirteenth century was quickly followed by the development of projectile weapons based on its explosive properties. The first recorded use of a cannon was by Edward III against the Scots in 1327, and small arms carried by one or two soldiers began appearing in the fourteenth century.¹ Early weapons that used modified arrows were replaced with more efficient stone and, ultimately, metallic projectiles. Improvements in pro-

jectiles and firearms led to increasing numbers of more devastating wounds. Surgeons accustomed to dealing with a variety of wounds from blunt, bladed, and pointed weapons were faced with blast and projectile injuries of a completely different nature. Contamination and devitalized tissues led to increasing numbers of infections, which surgeons of the day incorrectly attributed to the gunpowder itself, and to the anticipation of “laudable pus.” Subsequent advances in surgical knowledge went on to closely parallel the evolution of firearms. Knowledge gained on the battlefield by famed military surgeons such as Ambroise Paré (1510–1590) elevated the art of surgery to a learned profession.¹ Unfortunately, the battlefield has moved to the urban areas with increasing numbers of civilian gunshot injuries.

Demographics

GSWs are second only to motor vehicle accidents as a source of injury and death, and rank as the eighth leading cause of death in the United States.² Recently the number of firearm-related deaths and injuries in children and adolescents has declined.³ According to the National Center for Injury Prevention and Control, firearm-related deaths have shown a continual decline from approximately 15 per 100,000 in 1993 to approximately 11 per 100,000 in 1998.⁴ Because of past difficulties with surveillance, however, most

reports likely underestimate unintentional firearm-related deaths and injuries overall.^{5,6} Interestingly, Patton and Woodward reported that although GSW admissions decreased at the Henry Ford Hospital in Detroit by 45%, the number of patients who required operations actually increased by 17%. The number of gunshot victims dead on arrival remained steady. A possible explanation is that an increased number of patients are discharged from the emergency department after significant injury requiring admission has been ruled out; these patients are therefore not counted as admissions.⁷

The demographics of gunshot injuries are telling. Most victims are young males (< 38 yr). Suicides and assaults far outnumber unintentional and accidental shootings. Firearms are implicated in 58% of male suicides and 37% of female suicides. Importantly, the number of patients surviving and requiring treatment of gunshot injuries outnumber firearm fatalities by approximately 5:1.^{8,9}

Currently there are an estimated 135,000 GSWs treated annually in the United States. The incidence of firearm-related injury and death in the United States exceeds that of other developed countries.¹⁰ Although there appears to be a relationship between the rate of household firearm ownership and the homicide rate, most agree that other social factors are required to explain the number of firearm injuries in

the United States in comparison with other developed countries.⁹ Indeed, in countries in which firearm ownership is required for militia duty, firearm injuries are lower on a per-capita basis than in the United States. The majority of civilian firearm injuries are sustained from handguns (86%), followed by shotguns (8%) and rifles (5%). Approximately 12 to 14% of unintentional and assault gunshot injuries involve the head and neck, whereas 51% of self-inflicted gunshot injuries involve the head and neck.⁴ Clark and colleagues reported on their experience at the Maryland Shock Trauma Center and found that of 178 GSWs to the face, 40% involved the frontal bone and cranium, 9% involved the orbits, 14% involved the lower midface (maxilla), 13% involved the mandible, and 24% involved multiple sites. Shotgun injuries more commonly involved the mandible and midface.¹¹ Demetriades and colleagues reported on the extensive experience of the University of California at Los Angeles. Of 4,139 patients admitted with gunshot injuries over a 4-year period, 6% (247) had GSWs to the face. Thirty-eight percent of these had isolated wounds to the face, whereas the remaining 62% had associated injuries to other body areas. They reported that the mandible was the most commonly involved facial bone (54 cases), followed by the maxilla and zygoma (21 cases each). The orbits and nasal bones were involved in 18 and 15 cases, respectively. Thirty-six patients died following admission. All of the deaths were secondary to injuries to the chest, abdomen, or brain. There were no deaths associated with isolated facial injuries.¹²

Aside from the tragedy of firearm-related injuries and the emotional toll such injuries take on victims, their families, and communities, the financial burden to society of firearm-related injuries is significant. This is especially true with regard to the long-term rehabilitation and multiple reconstructive surgeries that many victims of facial GSWs require. Cook and colleagues reported approximately 115,000

firearm-related injuries in the United States yearly, with an annual cost of treating firearm injuries of approximately \$2.3 billion; of this, taxpayers pay \$1.1 billion. Although this cost represents only one-quarter of 1% of the US health care budget of \$950 billion, it is significant considering that the group most affected typically involves younger healthier patients that usually require very little medical care.¹³

Ballistics

Ballistics is the science of projectile motion. A prerequisite to understanding the injuries caused by various firearms is knowledge of the language of ballistics. The potential problems of a wound caused by a projectile can be better anticipated if one has some knowledge of the weapon and projectile type that caused the wound. For example, if the surgeon is aware that a patient suffered a high-energy wound caused by a high-power, high-velocity cartridge, he can better appreciate the potential for extensive areas of devitalized tissue that may declare later. In addition, an understanding of firearm nomenclature allows the surgeon some ability to predict the types of weapons that are commonly involved in various types of civilian gunshot injuries. For this reason, the clinician dealing with gunshot injuries should be conversant in the rudiments of ballistics, types of firearms, and projectiles.

Ballistic science seeks to explain the behavior of the projectile and is typically divided into three stages:

1. *Internal (or interior) ballistics* describes the forces that apply to a projectile from the time the propellant is ignited to the time the projectile leaves the barrel. An important consideration is barrel length. In general, longer barrels (rifles) allow the force of the propellant to act on the projectile longer and generate higher velocities than do shorter-barreled weapons. In addition, a longer barrel serves to stabilize the bullet over longer distances.
2. *External ballistics* refers to forces that act on the bullet in flight. The primary factors that govern external ballistics are the weight and shape of the bullet.
3. *Terminal ballistics* is the study of bullet behavior once it impacts the target and is primarily concerned with how much energy is transferred to the target material and the resultant damage. The science of terminal ballistics is most important to the surgeon and is the most common source of controversy when discussing ballistic wounding. Attempts to reproduce the interaction of bullets with living tissue by using various target media such as ballistic gel have led to many myths surrounding wounding and the “stopping power” of various bullets and weapons. Similarly, surgeons have passed on many myths of their own regarding GSWs and the firearms that cause them.

Energy and Wounding Power

Traditionally, kinetic energy has been used as the basis to explain wounds caused by a gunshot. Simple physics can be applied to the projectile using the following formula:

$$KE = mv^2$$

where *KE* is kinetic energy, *m* is the mass of the projectile, and *v* is the velocity of the projectile.

Wounding power is typically related to the amount of kinetic energy transferred to the target:

$$P = m(V_{\text{impact}} - V_{\text{exit}})^2$$

where *P* is power, *m* is mass of the projectile, and *V* is velocity.

Based on these formulas, the velocity of a projectile has traditionally been considered far more important than its mass in wounding power. Indeed, often guns are classified as low velocity (< 350 m/s), medium velocity (350–600 m/s), and high velocity (> 600 m/s). Considering a typically sized projectile, a velocity of approxi-

mately 50 m/s is required to penetrate the skin, and a velocity of around 65 m/s will fracture bone.¹⁴ See Table 26-1 for a comparison of commonly encountered pistol and rifle cartridges.

In general, there is an inverse relationship between a bullet's diameter (caliber) and velocity. Unfortunately, the realities of wounding are not as clear cut, and the emphasis on velocity and kinetic energy of the weapon as it relates to treatment strategies is excessive.¹⁵ In an excellent review, Fackler debunks many of the commonly held beliefs of ballistic injury, including the idolatry of velocity, the exaggeration of the effects of temporary cavitation and pressure, bullet tumbling, the exaggerated role of kinetic energy transfer, and, most importantly, the emphasis on extensive wound débridement.¹⁶ The heterogeneity of the human body, which is composed of tissues of varying densities and elasticities, does not allow formulas to explain all of the nuances of wounding caused by projectiles of different velocities, sizes, and weights. Practically, there is a balance between velocity, projectile mass, and projectile size that governs the

amount of energy transferred to the target and resultant tissue wounding. These factors govern the four components of projectile wounding: penetration, permanent cavity formation, temporary cavity formation, and fragmentation.

Penetration allows the projectile to transmit kinetic energy and destroy tissue. A bullet must penetrate to a sufficient depth to cause damage. Likewise, a projectile that over-penetrates or passes completely through nonvital tissue may result in little damage.

The permanent cavity describes the space that results from direct tissue disruption and destruction. It is a function of the penetration and size of the projectile. It is generally considered to be the most important factor in the wounding and stopping power of a particular cartridge and bullet.

The temporary cavity is produced as the projectile travels through the target tissue. Transfer of kinetic energy results in a stretching of elastic tissues. Although they may remain intact, some of these tissues may be irrecoverably damaged. Arteries may suffer pseudoaneurysm for-

mation and rupture, and nerves may fail to recover function.

Fragmentation, which may not be present in a GSW, refers to the projectile (certain projectiles are designed to fragment; see below) or secondary fragments such as clothing or bone that develop from being struck by the projectile.

Despite claims by many bullet manufacturers, fragmentation of the projectile does not reliably occur in most handgun wounds. Bullets specifically designed as fragmentation rounds typically suffer from low-penetration ability. High-velocity rifle rounds are known, however, for their devastating fragmentation.

The effects of the temporary cavity on wounding are often exaggerated in ballistic literature. Because most tissue has an elastic nature and ability to recover from stretching (certain tissues such as brain are exceptions), damage from temporary cavitation is not as important as many expound. The massive zones of necrotic tissue that were felt to develop from temporary cavitation do not exist in reality. The most important factors in projectile wounding remain penetration and the size of the permanent cavity. A very small projectile traveling at high velocity striking an area of low density (eg, fat) may impart far less damage than a larger projectile traveling at a lower velocity and striking an area of high density (eg, bone). The realities of stopping power further call into question many of the claims promulgated through ballistic literature as well as surgical practices. In reality, the power transferred to the victim is the same as what the recoil imparts on the shooter. Again, simple physics explains that the impact of a 9 mm pistol round (see below) is the same as that created by a 0.45 kg weight dropped from a height of 1.82 m or of a 4.53 kg weight dropped from a height of 1.82 cm. In more practical terms, the amount of energy delivered to a body by a bullet is approximately equivalent to that transmitted when one is hit with a baseball.¹⁷

Table 26-1 Comparison of Approximate Cartridge Velocities and Muzzle Energy*

Cartridge	Bullet Weight (grains) [†]	Velocity (ft./s)	Muzzle Energy (ft./lb.)
.22 LR	29	1,225	140
.32 auto	71	900	129
.380 auto (9 mm short)	95	955	190
.38 special	145	680	170
.357 magnum	110	1,565	535
9 mm	124	1,100	345
.45 auto	230	790	370
.44 magnum	240	1,420	741
.223 (NATO 5.56 × 45)	55	3,100	1,280
.308 (NATO 7.62 × 51)	110	3,000	2,650
.300 magnum	180	2,900	3,500
20-gauge shotgun	547	1,185	1,400
12-gauge shotgun	820	1,250	2,600

Adapted from Federal Ammunition Company high power ammunition handbook. Minneapolis; 1983.

*Velocities and muzzle energy can vary within different cartridges depending on the weight of bullet, powder type, and other variables such as barrel length.

[†]1 oz. = 437.5 grains.

It is important to understand that the science of wounding power is more than simple physics; it is a complex interplay of projectile and target tissue characteristics that makes each wound unique. For this reason, categorization of wounds based on projectile characteristics such as velocity, although useful, should not promote dogmatic management schemes but instead should serve as guides. Surgeons should be wary of strict categorization schemes and treatment algorithms based only on velocity or another bullet characteristic and should bear in mind Lindsey's statement, "I will keep treating the wound, not the weapon."¹⁵

Firearm Terminology

As with ballistics, some knowledge of firearms is necessary for surgeons managing GSWs. It is a prerequisite for communicating with law enforcement officers and other clinicians.

Firearms are generally classified as handguns, rifles, and shotguns. Handguns are also referred to as pistols and revolvers, depending on their mechanical actions. With few exceptions, most are low or medium velocity, typically < 600 m/s, and usually cause tissue damage along the bullet tract only. Rifles range from low to high velocities. Shotguns typically are smooth-bore weapons that fire shells filled with lead shot of various sizes. Some shotguns may be modified with rifled barrels to fire shells containing a solid lead projectile referred to as a *slug*. Although they are of low velocity, close-range shotgun injuries are devastating, especially with larger lead shot such as buckshot (see below).

Rifles and handguns are classified by caliber. The caliber of a weapon is the diameter of the muzzle bore, which is the same as the diameter of the projectile (bullet). *Cartridge* or *round* refers to the case containing the ignition system (primer), the propellant, and the projectile (bullet). Measurements for American firearms are typically in inches. For example, the .45 caliber pistol bullet is 0.45 in. (1.14 cm) in

diameter. Firearms of European origin, such as the 9 mm, have classically used the metric system. The American military round for the M-16 (military version of the AR-15) is usually the 223, which is 0.223 in. (0.57 cm) in diameter, whereas the Soviet AK-47 fires a 30-caliber projectile, or 7.62 × 39 (39 refers to the length of the case containing the propellant in millimeters; Figure 26-1).

Shotguns were originally designed to be used on small fast-moving game and typically fired small pellets that dispersed in flight to form a pattern. Typical muzzle velocities range from 335 to 427 m/s. They

are usually referred to by *gauge*, which is an English measurement that describes how many lead balls equaling 1 lb. (0.45 kg) would fit into a particular diameter of the barrel. For example, it would take 12 lead balls equal in diameter to the internal diameter of a 12-gauge shotgun barrel to make 1 lb. A 12-gauge shotgun has an internal barrel diameter of 1.85 cm, whereas a 28-gauge shotgun has an internal barrel diameter of 1.41 cm. It is clear that the higher the gauge, the smaller the diameter of the barrel (Figure 26-2A). There are some exceptions to this classification scheme. For example, a 410 shotgun has a

barrel whose internal diameter is 0.410 in. (1.04 cm). In general, the lower the gauge, the more powder and shot the shell can contain.

Shot is also classified by size. Commonly encountered shot sizes range from 8 shot (0.23 cm), with approximately 500 pellets in a 12-gauge shell, to number 00 buckshot (0.83 cm), with 9 to 15 pellets in a 12-gauge shell. Shells come in different lengths within the same gauge as well. For example, a 12-gauge shell may be a 2¼ in. (6.99 cm) or 3 in. (7.62 cm) shell. Longer shells hold a larger charge of powder and shot, which can be used for larger game or game at further distances. As a general rule, longer-barreled shotguns and those with a full choke (a constriction of the end of the barrel) keep the pellets in a tighter pattern over longer distances. Finally, some shotguns may be modified with rifled barrels to fire shells containing a solid lead projectile referred to as a slug. Shot is usually selected based on the size of game. *Buckshot* refers to larger pellets meant for large game or human targets; it is particularly devastating because its impact is similar to multiple low- to medium-velocity handgun wounds, depending on the range.¹⁸ It is also important to note the

different makeup of a shotgun shell (see Figure 26-2A). The pellets are typically separated from the propellant by wadding that helps to contain and transfer the power of the charge to the pellets. This partition can be made of felt or plastic and may be found embedded in close-range wounds (Figure 26-2B).

Most handguns and rifles have barrels with internal grooves referred to as *rifling* that impart a spin to the bullet. This keeps the projectile stable in flight over longer distances. In early firearms that were loaded from the muzzle (muzzleloaders), the tight fit between the bullet and the barrel that resulted from rifling significantly slowed loading. For this reason, most early military weapons were smoothbore. Sacri-

fices in long-range accuracy were a trade-off for rapid rates of fire. This obstacle was overcome in 1847 by Captain Minié, who developed a projectile with a hollow conical base that loaded easily but expanded for a tight fit when the propellant enlarged behind it (Figure 26-3). Ultimately, breech-loading weapons, in which a self-contained round enclosing the ignition system (primer), propellant, and projectile was loaded from the beginning of the barrel instead of the end, overcame these difficulties. The development of rifling, however, allowed high-velocity projectiles that would remain stable in flight over long distances. Eventually, all projectiles become unstable in flight because the center of gravity lies well behind the center of

FIGURE 26-3 Left, Early round projectile and Minié ball with expanding base. Right, Modern full-jacketed and soft point rounds with “boat tail” to improve flight characteristics.

resistance (the bullet tip) causing them to take on various motions during flight.

Oscillation around the long axis of the bullet is referred to as *yaw*. Rifling seeks to stabilize yaw but imparts its own motion, referred to as *precession* (circular yawing), around the center of gravity, creating a decreasing spiral and nutation, which is a rotational movement in small circles.¹⁹ These motions occur during flight through air. Bullets may be modified in an attempt to decrease these motions in flight; an example is a “boat tail” bullet, intended to be stable over longer distances. Upon encountering a denser substance such as tissue, the projectile immediately starts tumbling. Increased tumbling causes more tissue wounding because it presents a larger surface area. Bullets have undergone a variety of modifications in an attempt to control these motions and increase wounding and stopping power.

The simplest and earliest projectile was a stone or lead ball (see Figure 26-3). Over time the projectile evolved to the conical-shaped Minié ball. The lead conical bullet remains in use. Modifications are made based on intended use. In general, military rounds are restricted by the Hague convention (1899) to the full-metal jacket. Fragmentation rounds have been outlawed, although some countries continue to use flechette rounds (designed to fire small metal spikes or fragments). Simple lead bullets referred to as *wadcutter*s are inexpensive and often used as target rounds. Jacketed bullets with exposed lead tips (soft points) are designed to expand on impact for maximum tissue destruction (maximum permanent cavity) and are typically designed for hunting. A variety of modifications have been made to handgun bullets in an attempt to make up for their lack of velocity and to increase wounding (Figure 26-4). Because of their low velocity, handgun bullets have difficulty expanding reliably in tissue. Attempts to overcome this have centered on the creation of bullets with various

FIGURE 26-4 Full-jacketed bullet compared with various hollow-point rounds designed to aid the expansion of lower-velocity bullets.

open ends, so-called hollow points (see Figure 26-4). Some of these are partially covered with a metal jacket in attempt to control expansion. As noted earlier, despite manufacturers’ claims to the contrary, reliable expansion is difficult to obtain in low-velocity rounds. Some manufacturers have created +P ammunition, which contains different gunpowder to obtain a higher velocity. Also, some bullets are designed to explode on impact by incorporating an explosive into a hollow cavity in the bullet (devastator rounds).

The ignition of most cartridges is accomplished by a firing pin striking a primer. Some cartridges use a primer built into the case and are referred to as *rimfire* because the firing pin strikes the edge of the cartridge rim to discharge the propellant.

Mention should be made of other projectiles that have been associated with injury. Modern airguns can achieve velocities sufficient to cause tissue damage. The proliferation of paint-ball guns has led to an increase in the number of ophthalmologic injuries.²⁰ Finally, unorthodox bullets such as wooden, rubber, and “bean bag” projectiles are being used increasingly in crowd-control situations. Although meant to be nonlethal methods of deterrence, these rounds can cause significant tissue damage and even death. They are frequently associated with facial fractures.²¹

Classification Schemes

Classification of traumatic injuries is helpful in guiding treatment and, more importantly, tracking outcomes for various treatment modalities. A number of trauma scoring systems and classifications for various injuries have been developed and validated. Similarly, attempts have been made to classify GSWs to assist the surgeon in selecting appropriate management strategies. Many of these classification schemes were developed on the battlefield. Dissimilarities between civilian and military gunshot injuries, such as ammunition, wounding potential of military weapons, and treatment objectives, make these classification schemes of little use in the urban trauma center, which most commonly deals with low- to medium-velocity handgun injuries.^{22,23}

Trauma systems have attempted to incorporate gunshot injuries into existing classification and trauma scoring systems. Unfortunately, current schemes have not proven beneficial in guiding treatment and judging outcomes to develop ideal approaches. Attempts to distinguish GSWs as low or high velocity have suffered from the shortcomings noted above. In addition, velocity is less critical than bullet type, mass, distance to target, and specific vital organs involved because most civilian

injuries are caused by low- or medium-velocity weapons.

One of the earliest and simplest classification schemes classifies GSWs as non-penetrating (grazing or blast wound), penetrating (bullet does not exit), perforating (in and out), and avulsive. The International Committee of the Red Cross introduced the armed conflict classification system to improve information gathering and communication regarding war wounds. Because of the diversity of battlefield weaponry, by necessity the system ignores weapon type and instead concentrates on wound severity in terms of tissue damage and anatomic structures involved.^{22,23} Gugala and Lindsey suggested a civilian gunshot injury classification scheme. It takes into account energy (high or low), involvement of vital structures (neural and vascular), wound type (non-penetrating, penetrating, perforating), fracture (intra-articular and extra-articular), and contamination. Primarily used in orthopedics, its usefulness in gunshot injuries to the head and neck is limited.²³

Shotgun Wounds

Because of their unique ballistic profile, shotgun injuries are often classified based on the distance to the target. Shotgun pellets have significant aerodynamic resistance and give up substantial amounts of kinetic energy during flight. In type I shotgun injuries (< 5 m), the pellets strike the target as a single mass, resulting in massive kinetic energy transfer, tissue avulsion, and a high mortality rate (85–90%). Patients that survive suicide attempts with shotguns typically survive because, in an attempt to reach the trigger with the muzzle under the chin or in the mouth, the head is hyperextended, which causes the pellets to create devastating injuries to the face but avoid the cranium. Fragments of paper or plastic wadding may be found in the wound. Type II injuries (5–12 m) usually result in much less tissue destruction. At these distances there is significant dispersal of the pellets

and loss of energy. Penetration may occur through deep fascia, but fractures are rare. Ocular injuries can occur as well as embolization of lead pellets, but mortality is less (15–20%). At distances > 12 m (type III), usually only the skin is penetrated and mortality is rare (0–5%).^{24,25} Because specific information on shooting distances is not often available to the clinician, a system was suggested that evaluated the maximum distance of pellet scatter. Type I injuries had > 25 cm of pellet scatter. Type II injuries had 10 to 25 cm of scatter. Type III injuries had < 10 cm of scatter and would roughly correspond to a type I injury in the classification of Sherman and Parrish.²⁴ This classification scheme was developed and applied to abdominal shotgun wounds in an attempt to guide therapy.²⁶ Again, the difficulty lies in applying this scheme, or any scheme, universally to GSWs involving different anatomic sites and weapon types.

It should be noted that rifle and shotgun injuries, although rare in assaults, are frequently encountered in attempted suicide patients. A characteristic wound profile is seen because of the head position assumed when the patient places the barrel of the weapon in the mouth or under the chin and subsequently hyperextends to reach the trigger. Characteristic powder burns are seen at the entrance wound (Figure 26-5). The face frequently takes the full effect of the blast, whereas lethal intracranial involvement is avoided.²⁷ If a high-energy weapon such as a shotgun or rifle is used, the injury can be devastating with significant tissue loss.

Although classification schemes can serve useful purposes in research as well as clinical practice, strict adherence to treatment algorithms based on wound classification can lead to mismanagement. Importantly, information regarding types of firearm and other details of the shooting are frequently not available, and clinical assessment of the wound remains the most reliable method for determining treatment approaches.

FIGURE 26-5 Submental entrance wound with powder burns characteristic of a suicide attempt by placing a gun under the chin.

Management

General Principles

On admission victims of gunshot injuries are best managed by standard advanced trauma life support (ATLS) protocols. Even seemingly innocuous wounds deserve attention, given the erratic nature of the wounds. Specific attention must be given to the possibility of multiple injuries; it is imperative to thoroughly inspect the patient for multiple entrance and exit wounds. Visually disturbing but nonlife-threatening facial gunshot injuries can distract medical personnel from other more subtle lethal injuries such as a penetrating thoracic wound that entered through the back. Ophthalmologic and neurosurgical consultations are obtained when indicated. Approximately 17% of patients with a GSW to the face have associated brain injuries, and 8% have associated C-spine injuries.^{12,28} Eye injuries are present in approximately 13% (Figure 26-6).²⁸ Certain considerations for gunshot injuries should be emphasized.

Airway

Loss of the airway is the single most likely cause of death in an isolated GSW to the face. When confronted with a patient with a facial GSW, surgeons should have a low

FIGURE 26-6 *Perforated globe with shotgun pellet.*

threshold for establishing a definitive airway through intubation or a surgical airway if intubation is not possible. Intubation either in the field or the emergency department is required in 25 to 36% of patients. Wounds involving the mandible have the highest rate of intubation (37–53%), followed by those of the mid-face (18–36%).^{28–31} Excluding patients that require airway control for associated brain injuries, Demetriades and colleagues found that 17.4% of patients required urgent airway control for facial injuries.¹² Gunshot injuries to the neck may result in tracheal damage and require an emergent

surgical airway (cricothyroidotomy). Intubation with fiber-optic assistance is possible, but paralytics should be avoided owing to the risk of expanding hematomas or massive edema. Cricothyroidotomy or an awake tracheostomy is more appropriate in this setting. The need to convert an intubated airway to a tracheostomy depends on several factors. Tracheostomy can make repair of injuries involving the mandible and midface easier. Patients who will require multiple return trips to the operating room for wound débridements and “second looks” will benefit from the decreased risk of multiple intubations. Delayed swelling can be anticipated with trauma to the upper aerodigestive tract including the tongue (Figure 26-7A); this may influence the decision to proceed with tracheostomy. Associated tracheal injuries are another indication for tracheostomy (Figure 26-7B). Lastly, multiple system injuries with anticipated long-term ventilation is an indication for early tracheostomy. Most experienced surgeons would agree that it is rare to regret having performed a tracheostomy, but tragic to regret not performing one.

Hemorrhage Control

Life-threatening hemorrhage is unusual in civilian gunshot injuries. Low-velocity

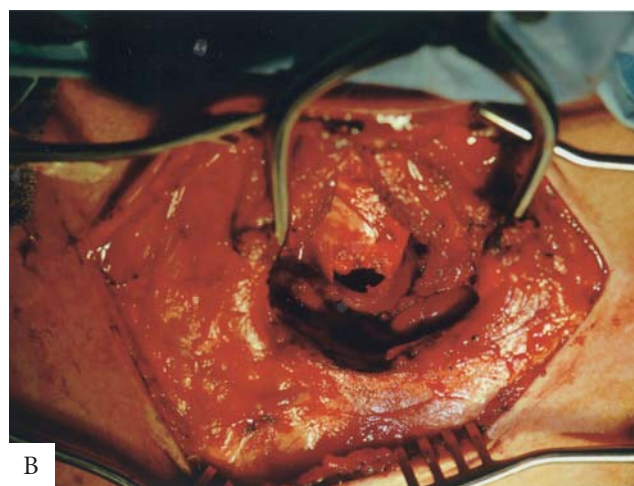

FIGURE 26-8 *Blind clamping in the emergency department management of a facial gunshot wound.*

handgun injuries typically do not involve the great vessels. Demetriades and colleagues in Los Angeles reported only 7.5% of patients with isolated gunshot wounds to the face to be in shock upon admission (systolic blood pressure < 90 mm Hg). In their report 70 patients (28.3% of the total) required angiography, and 10 of these required embolization.¹² Overall the literature reports angiography in 17 to 63% of patients with a GSW to the face, with positive findings in 15 to 51%. Indications for angiography include expanding hematoma and bleeding that persists despite local measures.^{29,32,33} The most commonly involved vessels in these cases were the maxillary and facial arteries. Gunshot injuries associated with high-velocity weapons or fractures, however, can result in significant blood loss. Initial attempts to control hemorrhage in the emergency department center on direct pressure and packing. Blind clamping should be avoided because of the attendant risk of damage to other structures (Figure 26-8). Standard methods for epistaxis control such as Foley catheters or specially designed balloon catheters will control most midface bleed-

A

B

FIGURE 26-9 Nasal packing with anterior and posterior balloon catheters.

ing (Figure 26-9). In cases of mandible fractures, temporary reduction of the fracture may be required. Penetrating injuries can require that the surgeon make difficult choices. Injuries at the skull base may benefit from angiography and embolization (see “Penetrating Neck Injuries,” below). Unfortunately, the time necessary to mobilize the angiography suite often makes this an impossible choice for the unstable trauma patient in the middle of the night. For this reason, control of life-threatening hemorrhage is typically best performed in the operating room. Ligation of multiple vessels is required. “Tying off” the carotid is usually ineffectual and dangerous; an attempt should be made to control specific vessels. Lacerations of the internal jugular artery are best controlled with ligation or repair (Figure 26-10). Packing and reduction of fractures should be performed to control bleeding from the midface if possible. There is possibility of late pseudoaneurysm formation and delayed hemorrhage, and selective angiography should be performed as indicated. Additionally, the possibility of bullet or fragment embolization should be considered.

Penetrating Neck Injuries

Gunshot wounds involving the face may be associated with an entrance or exit wound in the neck, which is divided into three zones originally described by Monson and colleagues from Cook County Hospital³⁴:

- Zone I is most commonly defined as the area from the clavicles to the cricoid cartilage. It contains the inferior aspect of the trachea and esophagus along with the major vessels of the thoracic inlet: the common carotid arteries, thyrocervical trunk, internal jugular veins, brachiocephalic trunk,
- Zone II represents the area from the cricoid cartilage to the angle of the mandible. It contains the common carotid arteries, internal and external carotid arteries, internal jugular veins, larynx, hypopharynx, and cra-

subclavian arteries and veins, thoracic duct, thyroid gland, and spinal cord. Risk of injury to the great vessels is common in this area, and, consequently, injuries to zone I carry a high mortality rate (approximately 12%). Some authors place the junction of zones I and II at the cricoid cartilage, whereas others define it as being at the top of the clavicles.

- Zone II represents the area from the cricoid cartilage to the angle of the mandible. It contains the common carotid arteries, internal and external carotid arteries, internal jugular veins, larynx, hypopharynx, and cra-

FIGURE 26-10 A, Gunshot wound to zone II associated with a mandible fracture. B, Plain film demonstrating the bullet in zone II. C, Computed tomographic angiography failing to demonstrate tamponaded laceration in internal jugular vein but showing subcutaneous air and edema of neck injury. D, Lacerated internal jugular vein (clamped) found on neck exploration.

nial nerves X, XI, and XII. It is the largest area and therefore the most commonly involved zone in penetrating neck trauma.

- Zone III spans the region from the skull base to the angle of the mandible. It contains the carotid arteries, the internal jugular veins, and the pharynx along with multiple cranial nerves exiting the skull base. It should be appreciated that gunshot wounds that involve mandibular fractures are accompanied by injuries to zone III.

Van As and colleagues reported on 116 patients shot in the neck in South Africa. Of these, 70 suffered a direct hit to the neck; in 46 patients the bullet traversed the face or chest first. Of the 116 patients 85 suffered some vascular injury, although most were minor branches, 61 had some injury to the airway, and 32 had an injury to the pharynx or esophagus.³⁵ Many patients had more than one injury. Management strategies for penetrating neck injuries are typically based on the zone(s) involved.^{36,37} Gunshot wounds to the head and neck frequently involve projectiles that traverse or involve more than one zone. For this reason, surgeons may have to modify management plans based on the situation at hand. Although a complete discussion of penetrating neck trauma is beyond the scope of this chapter, general principles should be understood by surgeons managing facial gunshot injuries.

Initially the patient's stability from an airway and hemodynamic status guides the decision-making for penetrating neck injuries (Figure 26-11). In the stable patient, a complete examination is part of the secondary survey of ATLS. Signs of tracheal injury, such as subcutaneous emphysema, stridor, hoarseness, dysphonia, or hemoptysis require urgent intervention. Hard signs of vascular injury, such as expanding hematoma, and pulse or neurologic deficit, also signal the need for urgent

management. In the absence of urgent management needs, the surgeon must rule out occult injuries based on the zones involved.

Injuries to zone I can be associated with significant bleeding because of the large vessels in this area. This is especially true with regard to injuries caused by high-energy weapons. Although serving to protect the vessels, the clavicles are a hindrance to the application of direct pressure to the area and to rapid surgical exposure. In the stable patient most surgeons advocate routine angiography and an evaluation of the esophagus via rigid esophagoscopy or a barium swallow. The choice between barium swallow and esophagoscopy varies according to the surgeon's preference as both are reasonably accurate at diagnosing injury (90% and 86%, respectively). In addition, there is some controversy regarding the appropriate contrast media. Although meglumine diatrizoate causes less inflammatory response than does barium when it extravasates into tissues owing to an esophageal perforation, it results in a severe chemical pneumonitis if aspirated. For this reason, barium should be used if there is any impairment to the gag and cough reflexes; if there is a leak, early operative intervention allows it to be washed out during surgery. Penetrating injuries to the left neck, and rarely to the right, can result in a chyle leak (Figure 26-12). The surgeon should take care to exclude this at the initial exploration, if possible, and to repair it by oversewing the duct with local tissues. It is useful to have the anesthesiologist apply positive pressure and to place the patient in Trendelenburg's position. Delayed management is much more difficult after the tissues have been exposed to chyle. Conservative management with a diet of medium-chain triglycerides, which are not carried by the gut lymphatics, and drainage should be attempted initially if the leak presents in the postoperative setting. Exploration is indicated for leaks of > 400 to 500 cc/d for a week.

Penetrating injuries to zone II are the most common and are most amenable to surgical exploration, if warranted. For asymptomatic patients, computed tomographic angiography is becoming an important tool for screening and can assist in determining whether operative exploration is warranted. Patients can undergo serial examinations over 24 hours if the angiography results are negative. Computed tomographic angiography is faster and less invasive than angiography but is of lower specificity. It should also be noted that injuries that have "tamponaded" themselves can be missed on either (see Figure 26-10C). Some surgeons recommend the use of a barium swallow or rigid esophagoscopy, whereas others recommend observation only if the index of suspicion for injury is low, as with wounds from low-energy guns. If patients have associated mandible fractures, the neck can be explored while the mandible fractures are exposed for fixation.

Imaging is required in zone III injuries if the patient is stable. Diagnosis of vascular injuries at the skull base typically requires angiography, which can also allow intervention if indicated. Injuries to zone III are rarely amenable to surgical intervention.

Overall, angiography remains the gold standard for exploration of vascular injuries of the neck. In Van As and colleagues' report, 89 patients underwent angiography for GSWs to the neck; results were positive in 12 patients, with most lesions occurring in the common carotid followed by the internal and external carotids (3 cases each), the vertebral artery (2 cases), and the subclavian artery (1 case).³⁵ Currently ultrasonography is gaining popularity as a rapid noninvasive technique for the evaluation of a variety of traumatic injuries in the emergency department. Ginzburg and colleagues evaluated the usefulness of duplex ultrasonography to evaluate vascular injuries in a double-blind study using angiography as a control. They reported a 100% true-negative rate, 100% sensitivity, and

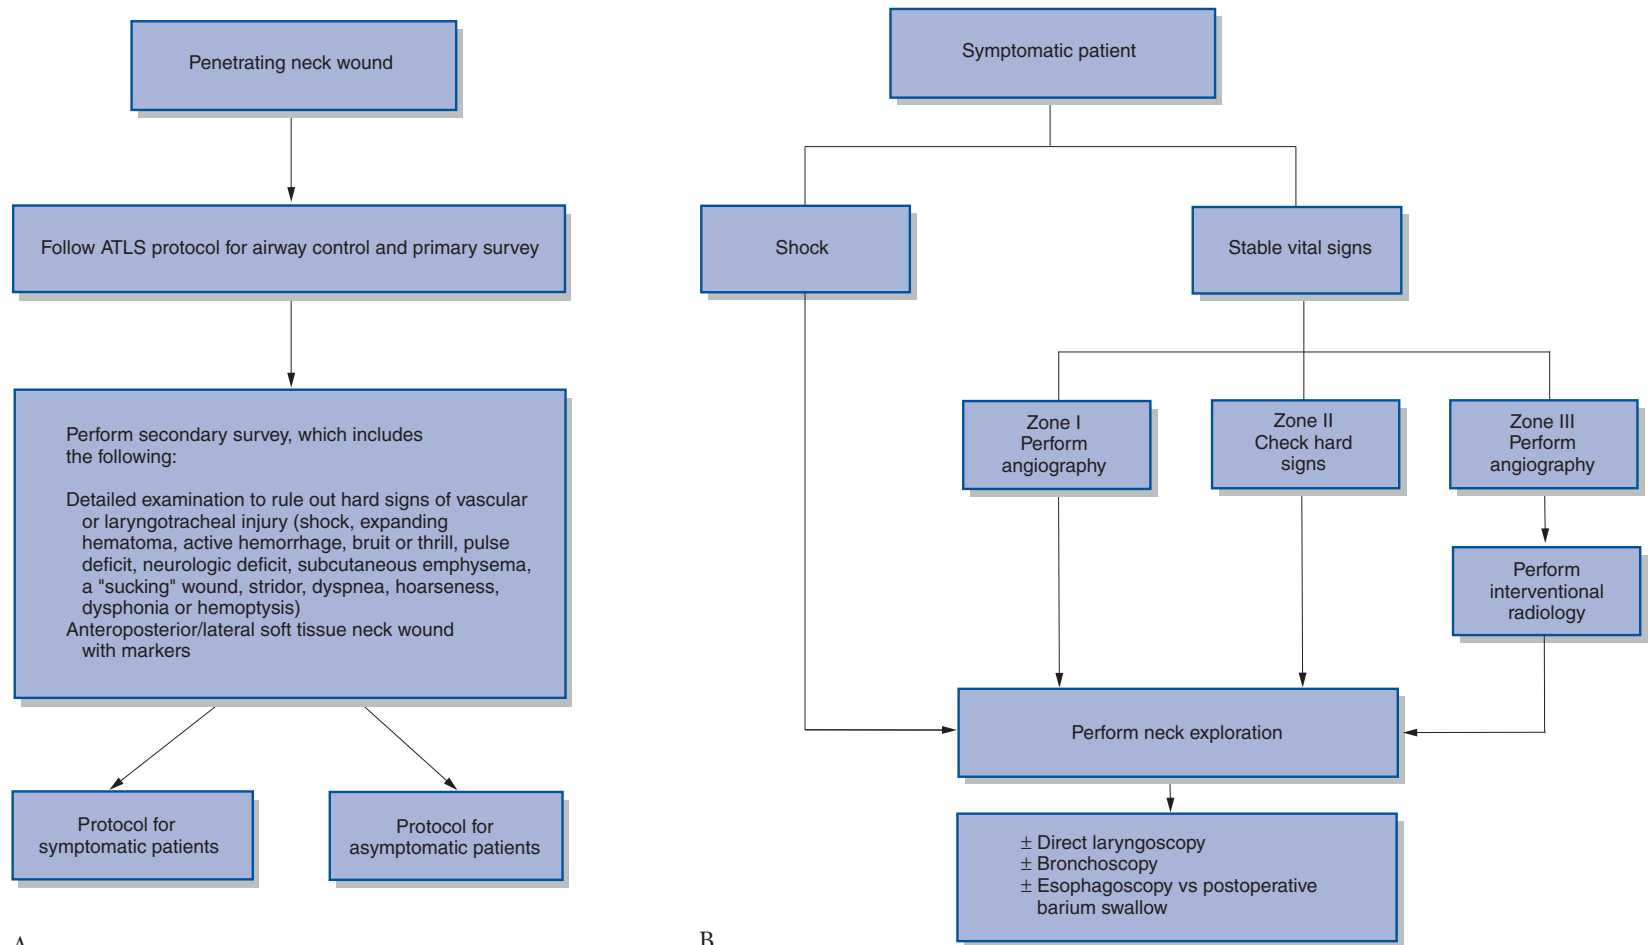

FIGURE 26-11 A, Initial decision tree for penetrating neck trauma. B, Management of the symptomatic patient with a penetrating neck wound. ATLS = advanced trauma life support.

85% specificity in detection of arterial injury. Ultrasonography will most likely continue to grow in popularity as a screening tool because of its cost and the speed at which it can be performed.³⁸ Further improvements in noninvasive vascular evaluation techniques, such as helical computed tomographic angiography and ultrasonography, will reduce the number of patients undergoing traditional angiography and improve patient selection for nonoperative management.

Nutrition

The majority of civilian gunshot wounds affect young healthy males. Nutritional status becomes an issue only in patients whose injuries preclude oral alimentation for an extended period (> 4 or 5 d). Feeding via nasogastric intubation allows

bypass of the oral cavity and improved hygiene in the early days following injury. Consideration should be given to percutaneous endoscopic gastrostomy if long-term bypass of the oral cavity is necessary, the patient will be unable to eat, or the patient has a preexisting nutritional deficit.

Imaging

Following the ATLS protocol, standard C-spine and chest radiographs should be obtained. These can be valuable for visualizing the bullet fragments and in gaining some insight into the path of the bullet (see Figure 26-10B). It is important to recall, however, that projectiles rarely follow a straight path once they enter tissue.

The ability to obtain accurate three-dimensional images in a rapid fashion has been one of the most important advances

in dealing with gunshot injuries to the face. Spiral computed tomography combined with three-dimensional reconstructions allows the surgeon an unparalleled view of

FIGURE 26-12 Chyle leak following penetrating injury to zone I of neck oversewn with nonabsorbable suture and covered with a flap from the sternocleidomastoid muscle.

FIGURE 26-13 Three-dimensional computed tomography scan demonstrating fragmentation of the mandible resulting from a gunshot wound. (Courtesy of James R. Koehler, MD, Birmingham, AL)

the extent of damage to the maxillofacial skeleton, which lies beneath the skin (Figures 26-13 and 26-14). Although it does not accurately demonstrate the amount of soft tissue damage, clinical inspection combined with three-dimensional imaging allows an accurate assessment. As discussed

previously, the importance of temporary cavitation and emphasis on the amount of devitalized tissue distant from the primary wound has probably been overstated in the past. Computed tomographic angiography can also be useful in certain situations for evaluating vascular damage, especially in cases of penetrating neck injuries. It should be remembered, however, that angiography remains the gold standard to evaluate the vasculature. Also, angiography allows the ability to intervene with embolization of active bleeding vessels that are difficult to approach surgically (see “Penetrating Neck Injuries” above). Patients who are not sufficiently stable for imaging should be stabilized in the operating room, and definitive repair should be deferred until appropriate imaging can be obtained.

Operative Procedure

Paralleling the evolution of firearms has been development in the management of gunshot injuries to the head and neck. The earliest surgeons dealing with gunshot

injuries blamed complications on gunpowder that would later be ascribed to contamination and infections. The mystique that surrounded gunshot injuries persists in some ways to modern times in surgical dogma that is passed down. During World War I, high-energy close-range gunshot and shrapnel wounds to the face necessitated the development of maxillofacial surgery. Kazanjian and Converse described their approach to gunshot wounds as three phases consisting of initial débridement and suturing, immobilization of bony fragments with splints and ligatures, and, finally, reconstruction following healing of the soft tissue.³⁹ Many of the principles developed at that time persist today, with surgeons advocating a phased approach with delayed closure of wounds, débridement of tissue, and secondary reconstruction.⁴⁰ Many surgeons still advocate closed reduction and division of care into early (first 10 d), intermediate (10–60 d), and late (> 60 d) phases.²⁸ The different nature of civilian gunshot wounds and improved management techniques have led to a reappraisal of staged approaches, and current management principles should more properly be considered a continuum that is based on the wound and patient profile.^{11,41,42} The successful application of rigid fixation principles to blunt traumatic injuries resulted in incorporation of these techniques to gunshot injuries. Early surgeons understood the importance of immobilization on the healing of GSWs but lacked the ability to truly immobilize bony structures of the face. The development of rigid fixation techniques and their application to GSWs was an important advance. Early concerns regarding placement of hardware into contaminated sites proved unfounded. By allowing the early stabilization of bone segments, percolation of contaminated oral fluids was prevented, primary bone healing was made possible, and the effects of scar contracture were minimized. This has led most surgeons to advocate early definitive repair of the majority of civilian gunshot

FIGURE 26-14 A, High-velocity entrance wound of the right cheek. B, High-velocity exit wound of left cheek. C, Three-dimensional computed tomography scan demonstrating extensive bony comminution associated with a high-velocity gunshot wound. (Courtesy of James R. Koehler, MD, Birmingham, AL)

wounds, which generally are inflicted with low-velocity weapons.

An operative plan for a gunshot injury to the face is best formulated after characterization of the wound as low or high energy (Figures 26-15 and 26-16). The surgeon facing a gunshot injury should consider the concept introduced by Manson for evaluation of four components: soft tissue injury, bone injury, soft tissues loss (true avulsion), and bone loss.⁴³ After evaluation of the wound, a decision is made regarding early definitive repair versus the need for delayed repair. The majority of civilian gunshot wounds resulting from assaults can be managed with early definitive repair because these injuries usually result in injury to the soft tissue and bone but rarely loss of these tissues. Impressive soft tissue injuries are usually not avulsive, and most can be closed primarily (see Figure 26-15). Extensive débridement of soft tissue is not indicated. Wound debris should be removed, and wounds should be lavaged with normal saline. Antibiotic solutions such as saline and bacitracin (50,000 U/L) have not been shown to be more effective than normal saline but are still popular. A pulsating irrigator is useful to mechanically agitate debris from the tissue. Obvious devitalized and loose teeth should be removed. Fractures are reduced and fixed rigidly. Otherwise, teeth should be maintained if possi-

ble to aid in restoration of occlusion and proper jaw relations. Drains are often indicated; whether closed suction or Penrose is used depends on the wound. Pressure dressings can also be used to minimize dead space. In cases of true soft tissue avulsion, a decision must be made regarding whether primary flaps or grafting is indicated. In wounds that are relatively clean, local flaps and skin grafts may be appropriate. In grossly contaminated wounds, delayed closure or grafting may be necessary. Closing mucosa to skin can be a useful technique, but many cases can be managed with dressing changes and incorporation of an early flap procedure. Free tissue transfer, although useful, should be delayed until the initial phase of wound healing, when its accompanying vascular spasm and attendant hypercoagulable state has decreased.

In wounds with extensive soft and hard tissue damage and true loss of soft and hard tissue, an approach using early stabilization of bone fragments with maxillomandibular fixation, external fixation, or internal fixation with reconstruction plates combined with conservative management of soft tissue is indicated. In this era of rigid internal fixation, the utility of maxillomandibular fixation should not be overlooked.^{12,28} In addition, external fixation devices are still useful in select cases. Second-look operations with conservative

wound washouts and débridement of only obviously dead tissue, which have gained popularity in orthopedics, have great utility in injuries to the maxillofacial skeleton. Second débridements should be performed 24 to 48 hours after the initial surgery. This allows for the maintenance of tissue considered “borderline,” which can be excised if it truly becomes devitalized. Skin grafts can be used as permanent or temporary replacement for missing tissue to reduce deformity from scar contrac-

FIGURE 26-16 Extensive wound resulting from a high-velocity weapon.

ture. Once the soft tissues have stabilized, a decision can be made regarding early replacement of lost tissues with free tissue transfer or delayed reconstruction. In general, earlier repair leads to improved outcomes with less scar contracture and resultant deformity. Bone grafts at the time of initial surgery may be indicated in the midface (see below). Again, management strategies should be considered a continuum that is modified as necessary rather than strict distinct stages.

Contamination

It should be remembered that projectiles from firearms are not sterile. This fact is well known to those who have dipped their bullets in feces prior to assassination attempts but lost on clinicians who have taught that gunshot wounds are indeed sterile. The heat generated by the discharge of the propellant as well as the friction between the bullet and barrel is not sufficient to sterilize the bullet.^{44,45} Contamination can occur from the bullet and also from skin flora and foreign bodies (clothing) carried into the wound. Historically, streptococcal bacteremia was the most important cause of death on the battlefield in the preantibiotic era.⁴⁶ Wounds in which the bullet traverses the aerodigestive tract or paranasal sinuses are at particular risk. Devitalized tissue and vascular congestion leads to an ideal environment for bacterial growth. Prophylactic coverage with broad-spectrum antibiotics, typically a second-generation cephalosporin, and tetanus prophylaxis, when indicated, should be initiated in all gunshot wounds. Extensive surgical débridement is rarely indicated in wounds consistent with low-velocity projectiles to prevent infection.

Removal of projectiles, a well-worn tradition in Hollywood, is less commonly indicated in reality. The need for the removal of bullets must be balanced against the real risk of increasing damage. Lead toxicity is a rare complication that does not typically justify the routine

removal of bullet fragments.⁴⁷ Removal of intra-articular bullet fragments should be considered when the increased risk of lead toxicity is associated with fragments within joint spaces and the potential for long-term deterioration of the joint.⁴⁸ Finally, consideration may be given to the removal of brass- or copper-jacketed bullets that are in close proximity to central or major peripheral nerves because of potential neurotoxicity.^{49,50}

It is important to remember that bullet fragments are potential evidence and an appropriate chain of custody is required. Most hospitals have a protocol in place to ensure that this chain is unbroken from the time they are retrieved to when they are logged in as evidence. This usually involves a police officer or other designee taking direct possession of the bullet or fragments in the operating room or nearby. Documentation of injuries with photographs can aid in reconstructing the events leading to the injury and recording where fragments were retrieved. Since some assaults have injury patterns similar to suicides, it is important to consider this chain of custody because subsequent investigations may reveal that an apparent suicide was actually an assault.⁵¹

Specialized Structures

Facial Nerve

Damage to the facial nerve is present in only 3 to 6% of civilian GSWs to the face.^{12,28} This is most likely because low-energy weapons are involved in most of these cases. However, such damage is not uncommon in injuries inflicted by higher-velocity firearms. Careful documentation at the earliest possible opportunity is important. If a functioning nerve becomes nonfunctional secondary to swelling, the surgeon can be reasonably confident that function will return. Obvious transection of the nerve requires repair. In heavily contaminated wounds, repair should be delayed for 48 to 72 hours, given the pos-

sibility that grafts will be required to span damaged segments. Beyond 72 hours distal branches of the facial nerve will not respond to a nerve stimulator, making their identification difficult. If possible, tagging the branches with suture at the initial surgery is invaluable. Extensive damage to the proximal nerve may require a temporal bone dissection to identify a viable proximal nerve for grafting. Injuries distal to a line dropped vertically from the lateral canthus (zone of arborization) do not typically require repair because of the multiple interconnections distal to this line and the reasonable expectation of return of function, even if the nerve is temporarily nonfunctioning (see Figure 26-15).

Salivary Ducts

Transected salivary ducts may be repaired or ligated depending on the amount of damage. The parotid duct can be repaired over an intravenous catheter or polymeric silicone tubing, which is then sutured to the buccal mucosa. It is best to avoid bringing the tubing out of the mouth because of the tendency for it to be dislodged. In injuries that penetrate the parotid-masseteric fascia, there is a potential for development of a sialocele or fistula. These typically resolve with drainage and pressure dressings. Aspiration may be required multiple times, and, rarely, anti-sialagogues may be indicated. In addition, removal of any associated foreign bodies may be necessary to resolve the fistula and hasten healing. Dermal grafts can be used at the time of repair (Figure 26-17).

Controversies: Delayed versus Early Management and Closed versus Open Fracture Management

Proponents exist both for closed management of fractures with delayed reconstruction as well as aggressive early management with open reduction of fractures and replacement of missing tissue as soon as

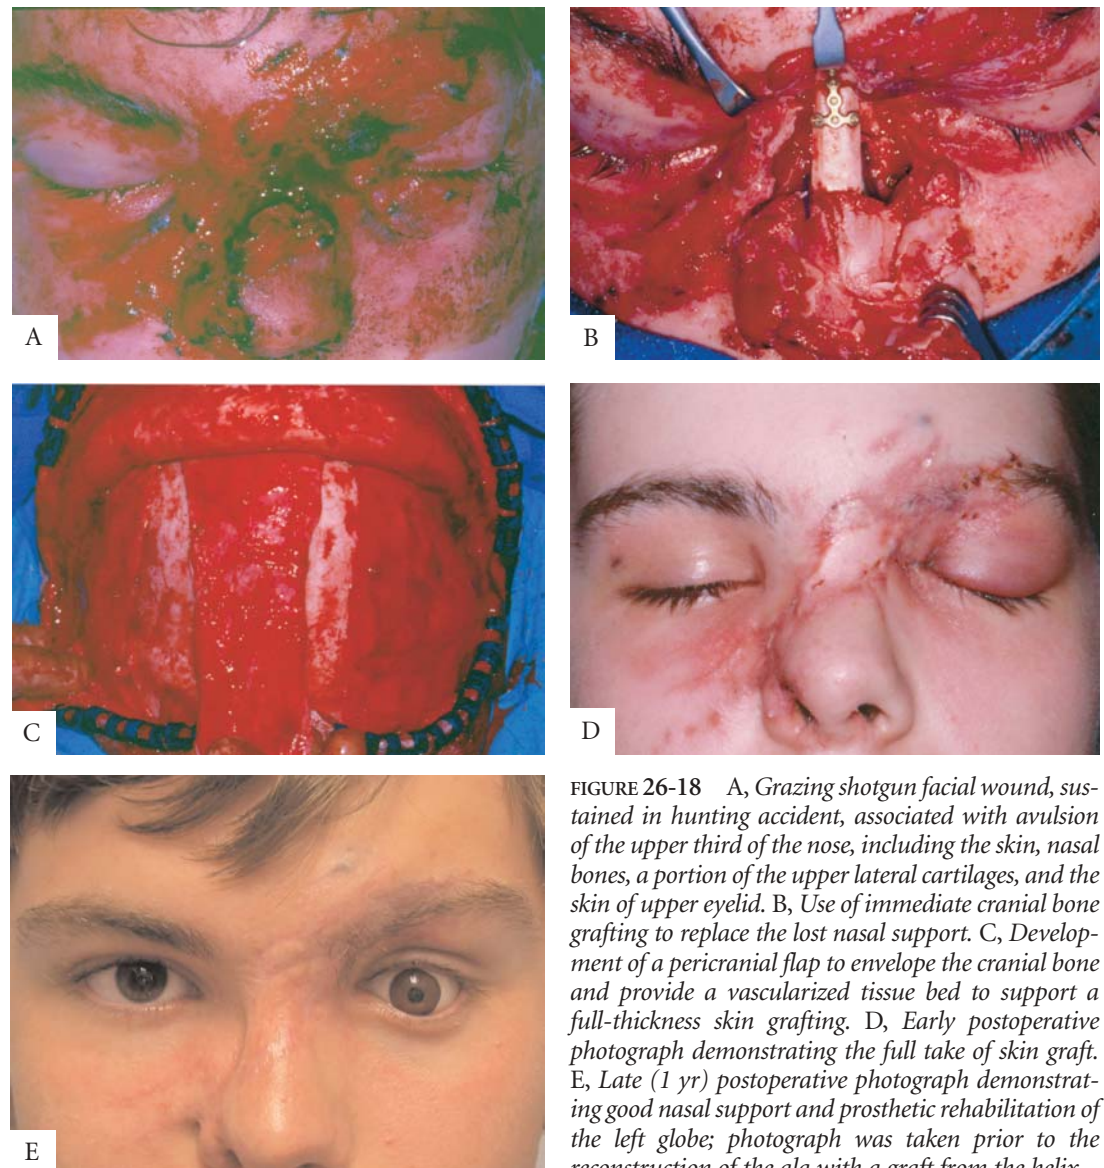

FIGURE 26-17 A, Salivary-cutaneous fistula associated with a retained bullet fragment. B, The bullet was removed and a dermal graft was placed.

possible. Both groups point to failures and shortcomings of the other to justify their approach. Advocates of delayed repair point to a higher incidence of infection and to benefits of closed treatment, whereas those advocating more aggressive management report improved functional and esthetic outcomes.^{52,53} Since neither approach is likely to ever be subjected to a randomized trial measuring outcomes, surgeons must base their treatment decisions on a critical review of the literature and their own experience. As with most arguments in surgical science, the truth most likely lies somewhere in the middle. Certainly the advantages of aggressive early management are appealing (Figure 26-18). Early return to function and decreased numbers of revision surgeries are laudable goals. Currently techniques involving open reduction and fixation of fractures resulting from GSWs seem to be gaining in popularity, and patients are less likely to be treated with closed reduction. Given that most of these injuries are low energy, this is acceptable. The main disadvantage of open reduction is infection, which primarily affects the mandible. The reported rate of infection with open reduction and fixation of mandible fractures resulting from a gunshot is around 16 to 17%.⁵⁴ However, rigid fixation can frequently be maintained in the event of wound problems and still serves to stabilize mandibular segments. Surgeons should avoid the application of a set protocol to every GSW situation and

should instead rely on a careful appraisal of the wound and decide on the amount of early repair that is indicated.

Bone Grafting

Bone grafts are frequently required in the management of GSWs to the face, whether for replacement of true loss of bone (avulsive injuries) or in cases in which comminuted and misplaced fragments need to be replaced or reinforced. Reconstruction with bone grafts gained popularity in World War I, and much of what we know about the healing of free bone grafts was learned following their introduction for late reconstruction of gunshot injuries in wartime. Iliac bone grafts were popular for late reconstruction. Surgical dogma was against early or

FIGURE 26-18 A, Grazing shotgun facial wound, sustained in hunting accident, associated with avulsion of the upper third of the nose, including the skin, nasal bones, a portion of the upper lateral cartilages, and the skin of upper eyelid. B, Use of immediate cranial bone grafting to replace the lost nasal support. C, Development of a pericranial flap to envelope the cranial bone and provide a vascularized tissue bed to support a full-thickness skin grafting. D, Early postoperative photograph demonstrating the full take of skin graft. E, Late (1 yr) postoperative photograph demonstrating good nasal support and prosthetic rehabilitation of the left globe; photograph was taken prior to the reconstruction of the ala with a graft from the helix.

primary bone grafting and stipulated waiting until soft tissue healing had occurred. More recently the use of bone grafts in the early setting has gained popularity. Gruss and colleagues have published extensively on their success with early bone grafting to stabilize and support soft tissues, and to decrease scar contracture and distortion.⁵⁵ The use of cranial bone in blunt injuries was extended to include GSWs with some success. Currently many surgeons advocate the use of primary bone grafting in the midface. Some surgeons also advocate immediate bone grafting of mandible defects.⁵⁶ Most agree, however, that delayed grafting of discontinuity defects of the mandible is still indicated because of the high risk of exposure and loss of bone grafts in this site, and that immediate grafting in the mandible should be avoided.^{11,52} Clark and colleagues reported a 35% incidence of wound complications in patients undergoing immediate reconstruction of significantly comminuted mandible fractures resulting from GSWs. Conversely, primary bone grafting was uniformly successful in the cranium and midface.¹¹ Rigid fixation maintains the mandibular segments. Even if the titanium plate becomes exposed, wound care will allow it to be maintained until definitive reconstruction.^{43,55} In summary, primary bone grafting in the early phase of gunshot wound management can be useful, but it should be limited to the upper and midface. Maintenance of mandibular segments with rigid reconstruction plates combined with delayed grafting or free flap reconstruction offers a predictable result, and in most cases primary grafting of the mandible is not indicated.

Late Reconstruction

Delayed bone reconstructions frequently suffer from a scarred hypovascular environment that does not support the graft. In addition, there is typically a deficiency in soft tissue that becomes more pro-

nounced when wounds are opened. In these cases vascularized tissue transfer offers the ability to import soft tissue and/or bone into the site. As noted previously, free tissue transfer is usually delayed until after the acute setting to decrease the incidence of flap loss secondary to clotting of the vascular pedicle. Preoperative angiography often is beneficial to identify appropriate vessels in the neck. Vascularized bone grafts can support osseointegrated implants to complete the reconstruction. Anthony and colleagues reported on the use of the fibula in patients in whom previous reconstructive attempts for gunshot injuries had failed.⁵⁷ Both cases involved secondary reconstructions. Some surgeons have advocated delayed reconstruction in gunshot wounds that resulted from suicide attempts because of the potential for repeat suicide attempts, arguing that there is a high rate of recidivism and that patients should be stabilized psychologically for some period of time prior to undertaking an extensive (and expensive) reconstructive effort. However, Cusick and colleagues found an incidence of only 8% confirmed mortality in the follow-up of 91 patients who had attempted suicide.⁵⁸ All were patients who had long-standing chronic mental illness. De Leo and colleagues found a higher rate in an elderly European population. In a 1-year follow-up, they found 24% had attempted suicide again, with approximately half being successful in their second attempt.⁵⁹ With modern techniques, however, primary reconstruction has become more attractive in most patients who have self-inflicted gunshot wounds.^{1,60} It should be noted, however, that some authors still recommend delayed reconstructive efforts. Siberchicot and colleagues reviewed 165 patients with self-inflicted gunshot injuries between 1982 and 1996 and suggested that delayed definitive reconstruction was more likely to achieve satisfactory results in appearance and function.⁵³

Conclusions

The development of firearms heralded a new era in surgery as well as warfare. Evolution of more efficient weapons continues to force surgeons to improve techniques. Similarly, improvement in the management of GSWs to the face has paralleled the advancement of oral and maxillofacial surgery. Advances by Varaztad Kazanjian, the “miracle man of the Western front” during World War I, continued through the wars of the twentieth century. Improvements in casualty management and triage in the Korean and Vietnam conflicts led to increased survival of those with devastating facial injuries. Techniques and skills developed by oral and maxillofacial surgeons in the management of these injuries translated directly to other areas such as bone grafting, and promoted the growth and expanding scope of the specialty. These efforts are continued today in urban trauma centers dealing with gunshot injuries to the face. Improvements in imaging and fixation techniques have resulted in an evolution in management, with an emphasis on earlier repair and a focus on improvement in quality of life.

Pediatric Craniomaxillofacial Fracture Management

Jeffrey C. Posnick, DMD, MD

Bernard J. Costello, DMD, MD

Paul S. Tiwana, DDS, MD, MS

Historic Perspectives

The management of craniomaxillofacial trauma, and the treatment of facial fractures in children in particular, has evolved gradually. A review of the historic landmarks in its treatment is important for understanding what has yet to be accomplished.

At the turn of the century Rene Le Fort was the first to document a tendency for the occurrence of specific patterns of midface fractures after direct facial trauma.¹ Within a few years thousands of combined soft and hard tissue facial injuries resulted from the trench warfare of World War I and required urgent treatment and secondary reconstruction. Two physicians in particular, V.H. Kazanjian and H. Gillies, stand out for their work during this period.^{2,3} During and after World War I and again during World War II, these men laid the foundation for what we now know as craniomaxillofacial surgery. Rowe and Killey, Dingman and Natvig, and others refined the basic principles laid down by their mentors, set out to educate their peers, and brought these treatment principles to the civilian population after the two world wars.^{4,5} At the same time, the use of antibiotics and improved airway and metabolic management of the trauma patient increased survival rates.⁶

The extensive surgical procedures that were often required to improve the quality of life of the multiply traumatized patient also became a reality.

Knowledge of the successful repair of traumatic facial injuries brought hope to people with congenital facial deformities. Gillies and Harrison pioneered the elective (extracranial) total midface advancement (Le Fort III osteotomy) for Crouzon syndrome.³ In 1967 Tessier described a cranial base approach to the management of skeletal deformities associated with Crouzon syndrome and Apert syndrome. His landmark presentation and publications were the beginning of modern craniofacial surgery. In 1968, Hans Luhr, a young maxillofacial surgeon, proposed that miniature (metal) bone plates and screws could be constructed and used effectively to fixate a mandibular fracture together for improved healing.⁷ Despite his enthusiasm these concepts of internal fixation for the craniomaxillofacial skeleton were not put into wide practice until the mid-1980s.

The concept of a hospital-based civilian trauma service that functioned 24 hours a day, 7 days a week, coupled with immediate “in-the-field” emergency recon-

struction of the trauma patient followed by rapid transport to the trauma center, was pioneered by R.A. Cowley with the development of the University of Maryland’s shock trauma center.⁸ This concept of accurate and rapid verification of injuries by the trauma surgeon, combined with well-trained and immediately available surgical subspecialists, hospital support staff, and technology, led to remarkable patient recoveries in otherwise hopeless situations.

The importance of managing the facial injuries of the multiple-trauma patient became evident early in the trauma center’s experience. Following the basic philosophy of total patient rehabilitation, Gruss and colleagues in Canada and Manson and colleagues in the United States developed new concepts for the management of craniomaxillofacial trauma.^{9–13} Their basic approach incorporated the early accurate preoperative diagnosis of all skeletal injuries by clinical examination with verification using computed tomography (CT) scanning techniques, wide (direct) surgical exposure of all fractures for open reduction of displaced and mobile segments, use of stable internal fixation techniques (plates and screws), and primary autogenous bone

grafting to replace missing or irreversibly damaged skeletal units. The rapid dissemination of their concepts and basic clinical approach to everyday surgical practice around the world is a tribute to Gruss and Manson, who remain dedicated to the highest standards of clinical care, research, and education.

Children with facial injuries have not benefited equally from this rapid refinement in the management of facial trauma in adults. In 1943 Waldron and colleagues were the first to bring to the maxillofacial surgeon's attention the often unique facial injuries in the traumatized child.¹⁴ MacLennan, and then Rowe, wrote about the rarity of facial fractures in children and suggested a basic approach with a philosophy toward conservatism.^{15,16} Other published articles have also tended toward conservatism, with only limited incorporation of the principles described earlier by Gruss and Manson.¹⁷⁻³⁹ Only recently have the distinct advantages of accurate primary repair and the stable fixation of facial fractures been applied to the rehabilitation of injuries in children.⁴⁰⁻⁴⁷ Also, resorbable materials have been made available as a fixation option for pediatric craniomaxillofacial fracture management.

Special Considerations in Children

The general principles for resuscitating multiply injured patients follow the advanced trauma life-support principles created by the American College of Surgeons.⁴⁸ This systematic approach to trauma in adult patients has been modified for the management of trauma in the child, taking into account several critical differences:

- Children frequently swallow air when they are injured or frightened, resulting in gastric dilatation. This may be a source of confusion when evaluating the patient to rule out an acute abdomen.
- Abdominal girth and the volume of the peritoneal cavity in infants and young children are relatively small. Significant intra-abdominal bleeding results in a rapid change in girth.
- Children may maintain a normal or borderline blood pressure level despite significant fluid loss and then decompensate rapidly.
- Children have a larger body surface area-to-overall mass ratio than adults and are therefore more prone to hypothermia.

Children are generally injured in low-velocity accidents secondary to falls from low heights, playground equipment, or riding toys. Most commonly they arrive at the emergency room in a state of hemodynamic stability. With regard to the frequency of organs injured, the kidney is the solid organ that is the most frequently injured, followed by the spleen, liver, and pancreas. Hollow viscus perforations are much less common compared with adult injury patterns. In contrast nonaccidental trauma is more insidious and devastating. The pattern of organs injured, especially in the toddler, is the reverse of that seen in accidental trauma. With child abuse the history is often vague and inconsistent.^{49,50} A history of prior injuries and hollow viscus perforation is common.

Airway management in children with facial trauma has undergone significant change. With the widespread use of soft endotracheal tubes in the 1960s, the number of tracheostomies carried out for perioperative airway management decreased.^{51,52} Use of fiberoptic laryngoscopy has further decreased the incidence of tracheostomy for acute airway management in the pediatric trauma patient. Kaban and Posnick and colleagues reported no tracheostomies for airway management in their series con-

sisting of 262 and 137 pediatric facial trauma patients, respectively.^{30,53} Also cervical spine injuries are exceedingly rare.^{30,53,54}

Anatomic Considerations

Maxillofacial injuries are much less common in younger children than in adolescents and adults. This lower incidence of facial trauma in infants and young children is a result of socioenvironmental, general physical, and craniomaxillofacial anatomic factors.^{55,56}

Before the age of 5 years most children live a relatively protected existence, with close adult supervision, strict limitations on their physical environment, and constant safeguards to limit injury. Although falls from limited heights are frequent the momentum gained by the child's small body is of a low velocity. These low-impact forces can usually be absorbed by their well-padded skin, elastic skeleton, and cartilaginous growth centers.

After the age of 5 to 7 years, rapid progression of neuromotor development results in a general desire for independent activity, more frequent social interactions with other children, and a wider range of activities outside of the house, with less stringent parental and adult supervision. These factors result in increased opportunity for direct facial trauma. Additionally, increasing numbers of automobiles on the road and participation in pedestrian activities in public areas result in competition for space with motorized vehicles.

Ongoing craniomaxillofacial growth results in a changing anatomy (Figure 27-1).⁵⁷ For the first several years of life the cranium follows the rapid pace of brain growth and results in a relatively large and prominent forehead. The ocular globes and orbits also develop rapidly early in life and join the forehead in their relative prominence early in life. This early period of life is marked by a lack of paranasal sinus and dental development, resulting in limited vertical height, horizontal projection, and transverse width of

FIGURE 27-1 Oblique view of dry skulls of various ages. Ages of skulls (left to right) are approximately 6 months, 11 years, and 20 years. Reproduced with permission from Posnick JC.¹³²

the maxillomandibular regions early in childhood. These factors result in a high skull-to-face ratio, leaving the frontal and upper orbital regions more exposed to trauma while the lower face remains relatively protected.

The mandible defines the lower border of the facial skeleton. Its evolving anatomy throughout growth and development significantly affects the pattern of injuries that occur in the lower face throughout childhood. During infancy and early childhood, the condylar process of the mandible has a well-vascularized marrow space with a thick and short neck. The condylar injuries seen involve compression, whereas neck fractures are more rare. This is in contrast with the condylar process's tall and cortical characteristics later in childhood and adolescence, which leave it vulnerable to neck fractures. The mandible and maxilla continue to grow throughout childhood, maintaining a high cancellous-to-cortical-bone ratio and resulting in greater elasticity of the jaws, with more greenstick and nondisplaced fractures than are seen in adulthood. During the first few years of life the developing permanent tooth buds are small, and the tooth-to-bone ratio of the jaws is relatively low. In the mixed dentition phase (6 to 12 years) a higher tooth-to-bone ratio weakens the mandible in specific locations and encourages fracture through the developing tooth crypts when trauma occurs. After 5 years of age the paranasal

sinuses develop gradually, resulting in areas of skeletal weakness, which results in ease of separation of the midface from the base of the skull when facial trauma occurs. Another factor in children is the highly osteogenic periosteum, which results in early healing of a fracture with more extensive remodeling after bone union has occurred.

Prevention

The increased use of age- and weight-specific protective restraints, lower speed limits, more strict alcohol abuse laws, and use of air bags have greatly diminished the incidence of motor vehicle-related trauma.^{58,59} For the infant and young child (less than 100 lb) release of the automobile's air bag may in itself cause trauma and even death (suffocation). The recognition that conventional lap belts do not properly restrain or protect infants and young children is a relatively recent finding. Special harness restraints, marketed since 1967, are required for children weighing less than 44 lb to prevent forward movement, to support the head, and to distribute the force of injury over a larger surface area. Current recommendations state that children weighing less than 100 lb or younger than 12 years should not be placed in an air bag-equipped seat. Infants should face the rear of the vehicle until they are at least 1 year of age. Vehicle safety belts are not to be used until the shoulder belt can be positioned across the chest

with the lap belt low and snug across the thighs. Larger children may use booster seats, which have been shown to be protective in many motor vehicle crashes.⁵⁸ A booster seat is used until the standard shoulder and lap belts fit appropriately. Public acceptance, with mandatory laws, has progressively increased their use. Adults have a particular obligation to ensure that children riding in their automobiles are properly restrained in devices that are appropriate for their size and age.

Popular multispeed bicycles, dirt bikes, and off-road vehicles placed in the hands of untrained or unprotected children and adolescents have contributed to an increasing number of maxillofacial injuries in these users. Demas and Braun reviewed the injuries of all-terrain vehicle accident victims at a major pediatric trauma center and found that 37% of these patients sustained facial injuries.⁶⁰ Participation in everyday sport activities is another source of pediatric facial fractures. Proper helmets, mouth protectors, and face guards are not always mandatory equipment, even in many organized contact sport leagues.

The awareness and recognition of child abuse and parental and family violence as a cause of facial trauma is another consideration that must not be overlooked by the pediatric or general dentist, pediatrician, and emergency room or trauma physician.⁶¹

Diagnostic Studies

When facial trauma is suspected in the child, either by history or physical examination, radiographic documentation is mandatory. For the isolated mandible fracture the panoramic tomogram provides an excellent image of the entire mandible. However, for many patients with significant mechanisms of trauma, unclear history, or other factors, CT scanning provides the necessary information to make a complete diagnosis of any facial fractures. CT scanning has for the most

part supplanted standard radiography as the preferred method of imaging pediatric facial trauma.^{62,63} Multiple CT scan planar views (coronal, axial, sagittal) performed with spiral scanning through all of the facial structures of interest, with three-dimensional reformation of the CT scan data, confirm the location and extent of skeletal, soft tissue, and visceral injuries (ie, brain or eye trauma). The patient is placed in the CT gantry and when necessary given sedation or, occasionally, general anesthesia. The radiation doses required for imaging are generally much lower than that for standard tomograms and have more limited scatter. Spiral and multislice techniques have reduced the dose of radiation significantly when compared with older CT methods.⁶⁴ These techniques also allow for reformatted images in other planes (eg, coronal views) that are of excellent quality. This is helpful in patients who have been immobilized in a cervical collar. For isolated mandibular injury the panoramic tomogram still gives the best overall perspective of dentoalveolar and condylar head (of the mandible) anatomy and injuries and can be taken with a cervical collar in place.

Epidemiology and General Treatment Concepts

The patterns of facial injury in the pediatric population are considerably different than those for adults. Understanding these differences in injury presentation helps the surgeon during the evaluation and treatment phases. The objectives of the study previously published by Posnick and colleagues were to record the pattern of facial injuries treated over a 4-year period at a pediatric tertiary trauma unit and to document the treatment provided and any complications that occurred (Tables 27-1–27-4).⁵³ The information gained from this study remains pertinent because it illustrates the common injury patterns seen in pediatric facial trauma at a major referral center for acute treatment.

All patients with acute facial fractures evaluated at a single tertiary care pediatric hospital over a 4-year period and treated by the author (J.C.P.) were enrolled in the study.⁵³ The mechanism of injury, location and pattern of facial fractures, and extent of associated soft tissue injuries were evaluated. For each fracture the method of reduction, the type of fixation, and the need for primary bone grafts were recorded. Patients were placed into two groups: (1) those requiring acute care who received their primary treatment and evaluation at a single hospital, by Posnick; and (2) those treated for secondary (or residual) deformity, who were referred to Posnick for management at varying times after their injuries. All perioperative complications were catalogued. Follow-up of the patient group ranged from 1 to 5.5 years at the close of the study.

Fracture patterns were classified according to their complexity. Group 1 included all isolated fractures limited to one bone, group 2 included all multiple fractures occurring in a single bone, and

group 3 included multiple fractures occurring in multiple anatomic regions within the facial skeleton. Because of the hospital's entrance restrictions the oldest child in this population was 18 years.

The facial trauma population consisted of 137 patients (318 fractures) seen over a 4-year period.⁵³ Most of the patients (42%) were between 6 and 12 years of age, and the total population averaged 10.2 years of age. Boys (63%) outnumbered girls (37%) in the study (see Table 27-2). Of the 137 patients, 81 were treated for acute fractures (171 fractures) and 56 were evaluated for reconstruction of secondary deformities resulting from the initial fractures (147 fractures). Of the 171 acute fractures, 121 were treated surgically.

Fifty percent of the patients were injured in traffic accidents, followed in frequency by falls and injuries related to sports and altercations (see Table 27-1). Causal mechanisms appeared to be distributed similarly between sexes, except for a slightly higher number of males with fractures attributable to an altercation or

to recreational vehicle accidents. The likelihood of high-velocity injuries increased with age (10% in the 1- to 2-year age group, increasing to 55% in the 6- to 12-year age group). Falls as a cause declined with age (55% in the 1- to 2-year age group, dropping to 8% in the 13+ year age group). The number of facial fractures tended to increase in the summer months; 45% of all fractures occurred between the months of May and August.

Of the 137 children with facial fractures, 66 (48%) sustained isolated fractures (group 1), 27 (20%) had multiple fractures in a single bone (group 2), and 44 (32%) had multiple fractures in multiple sites within the craniofacial skeleton (group 3). Children younger than 3 years were more likely to sustain only single fractures (see Tables 27-2 and 27-3). The children experienced one or more fractures in the following craniofacial regions: mandibular (55%), orbital (30%), dentoalveolar (23%), midface (17%), nasal (15%), zygoma (14%), and cranium (12%). Fracture pattern profiles were similar in both the acute care and secondary treatment groups. Midface (20 of 23) and zygoma (18 of 21) fractures were more likely to occur in children older than 6 years of age (see Table 27-2).

The distribution of fractures by anatomic region and degree of complexity is presented in Table 27-3. Similar anatomic patterns were seen in both the acute and secondary cases. Most of the fractures occurred as part of a complex injury pattern, with the exception of mandibular fractures, which occurred as isolated fractures with nearly equal frequency.

Eighty-one patients with acute injuries were seen for evaluation during the period of the study. These patients sustained 175 fractures, requiring 121 operative interventions. Injuries occurring at high velocity, such as traffic-related events (74%), more frequently required interventions than those occurring at low velocity, such as falls (51%). Boys did not require

significantly more operations than girls. Necessity for operative intervention increased significantly with the increasing complexity of facial fractures (group 1 to group 3) but not with age.

Open or closed reduction techniques were used with approximately the same frequency. When closed reduction was used, most patients (93%) underwent reduction and stabilization of the fracture with maxillo-mandibular fixation (eg, Erich arch bars, skeletal suspension wires, Stout wires). An external fixation device was used for only one patient. Only four fractures were reduced and not stabilized. Thirteen fractures (20%) were opened and explored without any form of fixation. Most of these were orbital floor fractures with associated bone-grafting procedures. Of the fractures treated by open reduction, 35 (55%) were managed with only one form of fixation to stabilize the reduction and 14 (21%) with multiple forms. Use of plates (miniplates or

microplates) and screws accounted for 82% (40 of 49) of the internal fixation methods used. Although age was not a factor in the choice of plate-and-screw fixation, review of the data indicated that this method was not used on any patient younger than 3 years (only three of the children in our population were younger than 3 years). Plates and screws were used most often in the mandible (40%) and orbits (26%). Bone grafts (21) were used for fractures of the orbit (16), cranial vault (2), mandible (2), and nose (1). The preferred donor sites included cranium (10), anterior maxillary wall (4), and hip (2).

Complications in treating pediatric facial trauma are rare if good principles are adhered to and precise surgical execution is achieved. This is due, at least in part, to the excellent healing capabilities of most children. Nonunion is very rare due to the excellent healing potential of pediatric bone. Malunion may occur but is

usually due to inadequate reduction. In Posnick and colleagues study no deaths, tooth loss, or injuries to the eye or brain were directly attributable to any operative procedure. Two patients developed soft tissue infections that responded to treatment by incision, drainage, and administration of antibiotics. Another developed a small area of alopecia after a coronal flap procedure. One patient, in whom a fracture extended through a tooth root, developed a periapical tooth abscess. This condition was treated with extraction and systemic antibiotic therapy. One miniplate was removed 1 year later because it was palpable and visible below thin forehead skin.

Of the 137 patients in this series, 77 (56%) had associated soft tissue injuries. These included lacerations to the scalp (31%), and injuries to the ear (20%), chin (13%), tongue (8%), forehead (6%), and eyelid (6%). Thirty-three percent in the facial fracture group had injuries to other organ systems. Associated head injuries accounted for 42% of this group, followed by damage to the extremities (24%), eyes (22%), thorax (10%), and abdomen (2%). None of our patients sustained injuries to the cervical spine. As expected, the more complex the facial injury, the greater the likelihood of associated injury ($p = .03$); 19% of group 1, 26% of group 2, and 36% of group 3 patients had an associated injury. Six percent required emergency endotracheal intubation when first evaluated; no emergency tracheostomies were required.

Patterns of Pediatric Facial Fracture Injury and Methods of Management

Anterior Cranial Vault and Supraorbital Ridge Fractures

Fractures of the forehead and upper orbital regions, combined with brain injury and dural tears with cerebrospinal fluid (CSF) leakage, constitute a frequent pattern of injury in infants and in children younger than 5 years when major anterior craniofa-

cial trauma occurs (Figure 27-2).⁵³ Isolated cranial vault fractures (18 of 318 fractures, 6%) occurred infrequently in this series. When they did occur, the anterior cranial vault was the most common location (13), followed by the posterior vault (4) and frontal sinus (1). Complete evaluation using CT scanning of the brain, eyes, and craniofacial skeleton, combined with neurosurgical, ophthalmologic, and craniofacial assessment, should be performed to evaluate the injuries completely. A combined neurosurgical and craniofacial reconstructive procedure is necessary for repair of the injured brain, dura, and skeleton. A coronal (skin) incision provides the best exposure of the fractured regions and surrounding normal structures. Once the brain and dural injuries have been managed by the neurosurgeon, reduction and stable fixation (microplates and screws) of all fractures are completed by the craniofacial surgeon. When massive comminution exists, bony defects are present, or complete orbital roof reconstruction is required, then autogenous cranial bone is harvested and used. In a normally developing child the skull will mature into three clinically reliable layers (outer table, medullary cavity, inner table) between the ages of 2 and 5 years. In these instances the bone of the cranial vault is suitable for splitting, yielding bone for grafting. These techniques and a team approach to the early diagnosis and management of combined injuries are cost effective and result in a rapid facial rehabilitation for the injured child.

Naso-orbitoethmoid and Frontal Sinus Fractures

The prevalence of naso-orbitoethmoid fractures closely follows the development of the paranasal sinuses. They are rarely seen in children younger than 5 years, but they become progressively more common in adolescents and adults (Figure 27-3). Rowe reviewed his series of pediatric fractures and found that injuries to the middle

third of the face made up only 0.5% of all pediatric fractures.¹⁶ Kaban and colleagues reported no midface fractures in 109 pediatric facial fracture patients from 1965 to 1975.³¹ During the next 10 years, with another 184 fractures, they reported only 5 midface fractures, all Le Fort III level injuries. Posnick and colleagues reported that midface injuries seen at a major pediatric trauma center during a 4-year period made up 17% of a series of 318 fractures in 137 patients.⁵³ Kaban associated this increased prevalence of midface injuries with the increase in survival of persons involved in serious motor vehicle accidents, which may result in more extensive facial injuries in the survivors.⁶⁵ When displaced naso-orbitoethmoid fractures do occur in children, we have adopted the same open reduction and internal fixation (ORIF) techniques generally accepted for adult-type injuries. Stable internal fixation techniques (micro- and miniplates and screws) and primary autogenous cranial bone grafts when indicated, result in the anatomic healing required to achieve satisfactory rehabilitation of the child with facial injury.^{28,33,66-74}

As in the adult, when the medial canthal ligament is displaced, it usually remains attached to a bone fragment. The medial canthal ligament and bone fragment are repositioned and fixed without the need for a direct medial canthopexy. Formal medial canthopexies often contribute to an unnatural appearance and should be avoided if possible. Often the bony fragment(s) can be repositioned with the aid of microplates and screws with or without the use of a transnasal wire.

Frontal sinus injuries in children are approached in a similar way to those in their adult counterparts.^{75,76} Anterior frontal sinus wall fractures are anatomically reconstructed and stabilized to prevent contour deformity. When the fracture components are severely comminuted, autogenous cranial bone grafts can be used to replace the entire unit. Depending on the

FIGURE 27-2 A 16-year-old girl sustained frontal and upper orbital trauma when she hit her forehead on the dashboard in a motor vehicle accident. Initially the cerebrospinal fluid (CSF) leak was repaired through a local scalp laceration; minimal attention was given to her frontal and orbital fractures. Ongoing CSF leak with meningitis and loss of the frontal bone flap occurred, after which she was referred to Posnick and colleagues, and a delayed combined neurosurgical/craniofacial approach was carried out. extent of frontal sinus development and injury, the mucous membranes may require débridement with maintenance of a patent frontonasal duct or, in cases of fractures of the ducts, sinus obliteration with sealing of

the duct. If the posterior frontal sinus wall is injured, neurosurgical consultation helps determine whether cranialization of the sinus through an intracranial approach is required.⁷⁷ Since CSF leaks are common

with dural tears in these injuries, it is often helpful to place bone, fibrin glue, and a pericranial flap in the defect to prevent CSF leaking. A double-ring sign is seen on filter paper when CSF is present within nasal

FIGURE 27-2 (CONTINUED) I, Intraoperative view of fronto-orbital reconstruction with split cranial grafts and plate/screw fixation. fluid. Alternatively, β_2 -transferrin can be measured within the nasal fluid to determine if nasal leaking is indeed CSF. Endoscopic techniques with imaging guidance can be used to effectively repair persistent leaking that may occur postoperatively.

Le Fort (Midface) Fractures

The prevalence of Le Fort midface fractures increases rapidly once aeration of the maxillary and ethmoid sinus cells has occurred. The rapid development of the sinuses takes place between 6 and 12 years of age. Consequently maxillary fractures in children do not follow the patterns seen in adults. Displaced midface fractures should be treated with ORIF techniques similar to those used in adults.^{13,78} This is necessary to achieve and maintain anatomic restoration. Closed reduction techniques may be preferred in specific clinical situations to avoid injury to the

unerupted permanent dentition, but the dental injuries are generally the result of the trauma event rather than of reduction and fixation techniques that have been carried out by an experienced surgeon familiar with the dentition.

In Posnick and colleagues study 23 patients sustained 31 fractures in the midfacial region. These included nasofrontoethmoid fractures (13 of 31, 42%), Le Fort I (8 of 31, 26%), Le Fort II (5 of 31, 16%), and Le Fort III (5 of 31, 16%). Midfacial fractures generally occurred as part of a complex facial fracture pattern; only 2 of 31 (6%) occurred in isolation. Although few acute midfacial fractures occurred, the majority (9 of 12) required surgery (Figure 27-4). Unstable or displaced fractures were treated with open reduction and internal fixation. The surgical goals in such cases are to restore midface projection, facial width, and orbital volume, and to normalize occlusal

relationships. Seven of nine midfacial fractures were stabilized with plates and screws.

A circumvestibular intraoral mucosal incision provides ideal exposure of maxillary fractures through the zygomatic buttress, anterior maxillary wall, and piriform nasal aperture regions. When additional access to the zygomatic arch, frontozygomatic suture, supraorbital ridge, and frontonasal junction is required, a coronal (skin) incision is also used. If specific exploration of the infraorbital rims, orbital floors, and lower aspects of the medial orbital walls is required, a subciliary, lower lid, or transconjunctival incision is added. Palatal incisions are to be avoided, and preservation of the gingiva is important to the child's periodontal health. As in the case of adults the restoration of normal anatomic position of the midfacial skeleton generally requires open reduction, stable fixation (miniplates and microplates and screws) and may rarely require autogenous cranial bone grafts or the placement of alloplastic materials.

Zygomatic Complex Fractures

A zygomatic complex fracture describes a fracture through the frontozygomatic suture, zygomatic arch, infraorbital rim, and zygomatic buttress. Fracture through the orbital floor and lateral orbital wall completes the quadripod injury. The extent of displacement of the zygomatic complex fracture is best clarified through CT scanning in the axial and coronal planes and defines the extent of surgery necessary to restore and maintain preinjury anatomy. The child's presenting physical findings are similar to those seen in the adult. They generally include periorbital ecchymosis; paresthesia over the zygomatic arch, lateral nose, cheek, upper lip, and anterior maxillary teeth; and subconjunctival hemorrhage.⁷⁹ Ophthalmologic consultation is essential to determine baseline ocular globe and extraocular muscle injury and dysfunction. Since the base of the lateral orbit is made up of the zygomatic bone,

FIGURE 27-3 A 5-year-old girl who was in a motor vehicle accident sustained orbitonasal, ethmoid, and frontal bone fractures with associated brain and dural injury with cerebrospinal fluid leak. She required a combined neurosurgical/craniofacial procedure. A, Frontal view 6 days after surgery. B, Frontal view 2 years after (single-stage) reconstruction. C, Oblique view 6 days after surgery. fractures within the orbital floor frequently require management in conjunction with repositioning of the zygoma. Some injuries require reconstruction of the orbital floor with autogenous bone or synthetic materials. Of the eight acute zygoma fractures observed in Posnick and colleagues' study, three were minimally displaced and managed without surgery. The five displaced

fractures were comminuted injuries that were treated with open reduction and internal fixation. Three of these fractures were stabilized with plates and screws.

Most zygomatic complex fractures can be approached and reduced using multiple approaches such as maxillary vestibular, lower eyelid, and brow incisions. If a badly comminuted zygomatic arch is associated

with a displaced zygomatic complex fracture, a coronal (scalp) incision may be used with intraoral and subciliary (or lower lid or transconjunctival) incisions to expose, explore, reduce, graft, and internally fix all fractured regions.⁷⁸ With a minimally displaced or incomplete fractured zygoma, more limited treatment is used to achieve adequate fracture reduction. This can be

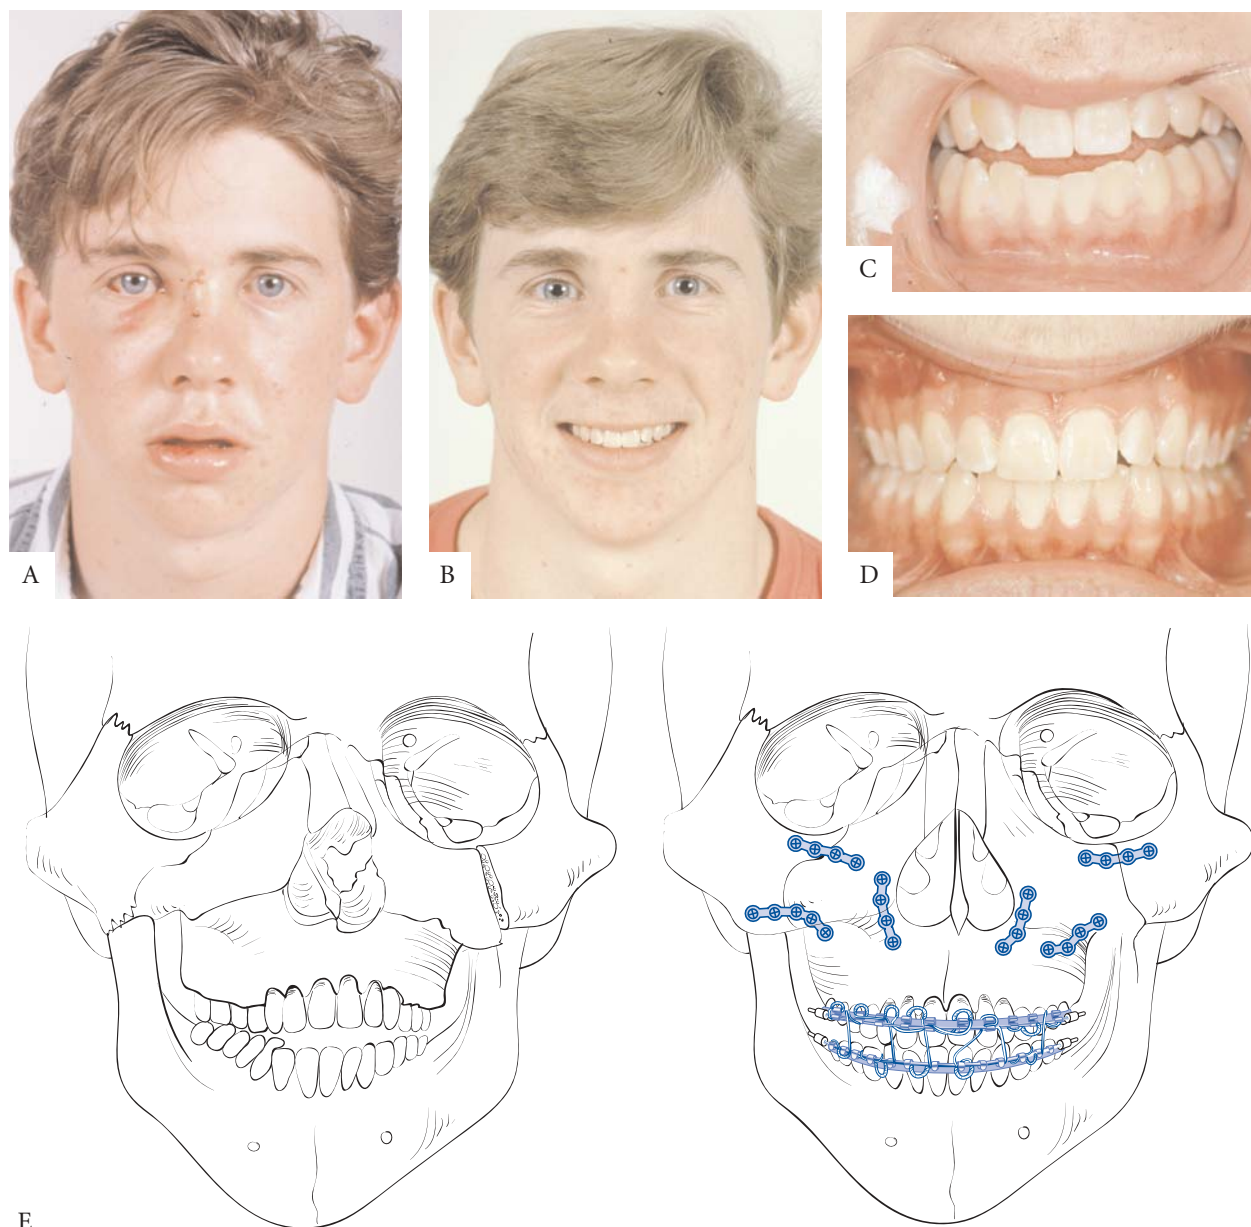

FIGURE 27-4 A 14-year-old boy sustained combined Le Fort I and II fractures with bilateral orbital blow-out fractures when he was accidentally kicked in the face while playing competitive soccer. done through a Gillies' approach within the temporal scalp, an eyebrow incision, or a Keene approach from an intraoral vestibular incision.

Blow-Out and Blow-In Fractures of the Orbit

Blow-in and blow-out fractures of one or more orbital walls and/or floor may be associated with more complex fractures

(eg, anterior cranial vault/upper orbital, naso-orbitoethmoid, Le Fort midface, or zygomatic complex fractures) or may occur as isolated injuries.⁸⁰⁻⁸³ The key to thorough evaluation is complete clinical, ophthalmologic, and CT scan assessments.⁸⁴ A thin-sliced axial and coronal CT scan is completed to visualize all four orbital walls and/or floors to ensure that the presence and extent of all blow-in or

blow-out fractures are recognized. The ophthalmologic assessment may require pupillary dilatation and slit-lamp evaluation in the ophthalmologic suite.

Orbital fractures are common in children and were frequent in Posnick and colleagues' study; 41 patients sustained 73 separate fractures of the orbit. The distribution of fractures within the orbit included the floor (23 of 73, 32%), medial wall

FIGURE 27-4 (CONTINUED) F, Computed tomography (CT) scan demonstrating nasofrontal bone separation and comminuted medial orbital walls. G, Three-dimensional CT views demonstrate Le Fort II fracture with nasofrontal separation and location of the infraorbital rim and maxillary fractures. H, CT scans demonstrating the morphology of the midface after reconstruction. A–D, F–H reproduced with permission, E adapted from Posnick JC.¹³²

(14 of 73, 19%), and orbital roof (13 of 73, 18%). Only 7 of these orbital fractures were sustained as isolated injuries. Of the acute fracture group, 21% of the fractures were orbital fractures. These were treated both surgically (59%) and nonsurgically (41%) (see Table 27-4). Most of the orbital injuries that were managed operatively were minimally displaced floor fractures. Thirty-two percent of orbital fractures were managed by exploration, reduction, and grafting with autogenous material but without graft fixation (Figure 27-5). Plate-and-screw fixation was used in six orbital rim fractures and three roof fractures. With the collaboration of a neurosurgeon, displaced roof fractures (blow-in fractures) were routinely treated with open reduction via an intracranial approach. The roof was reconstructed with contoured calvarial bone grafts fixed with plates and screws.

Once a clinically and radiographically significant orbital wall and/or floor injury is

recognized, early exploration and repositioning of the soft tissues back into the orbit with simultaneous reconstruction of injured orbital walls and/or floor to appropriate dimensions and overall intraorbital volume is carried out.^{80,85} Because the complications of extraocular muscle entrapment, diplopia, and enophthalmos are difficult to treat later, early evaluation of patients at high risk, followed by prompt surgical intervention, is encouraged. Orbital wall and/or floor fractures heal rapidly in children and result in a higher incidence of scar cicatrization of the herniated orbital soft tissues than in adults.

Nasal Fractures

Nasal fractures are also common in the pediatric population. Of the few acute nasal fractures that occurred in the author's series (12 of 171, 7%), 58% were minimally displaced and did not require surgery, and 33% were treated by closed means. Only one fracture required open reduction. Many isolated nasal fractures were treated

on an outpatient basis. The nasal fractures seen by Posnick and colleagues in this study were generally associated with other facial fractures and were therefore not representative of nasal fractures seen in general at the hospital (emergency department).

Development of the nasal septum is thought to be a major factor in midface growth. In theory, trauma to the nasal region early in childhood will negatively impact on midface growth.⁸⁶ Although the nose is the most frequently fractured part of the face in a child, extensive midface growth retardation after trauma has only rarely been documented.⁸⁶

Nasal injuries are often recognized but then ignored as unimportant. Two serious pitfalls in treating nasal fractures in children are (1) failure to recognize adjacent bony injuries extending outside the nose and (2) septal hematoma after nasal trauma (which may in theory result in septal necrosis and perforation). Diagnosis of nasal and septal fractures is usually based

FIGURE 27-5 A 4-year-old boy sustained an isolated blow-out fracture of the left orbital floor with entrapment of the inferior rectus muscle through the floor defect. He underwent explorative surgery with repositioning of the orbital contents back into the orbit. Reconstruction of the orbital floor defect was with a split cranial graft taken from the temporoparietal region. A, Frontal view with eyes in upward gaze demonstrating left inferior rectus entrapment. B, Close-up view early after reconstruction demonstrating improved upward gaze ability. C, Comparison of two-dimensional coronal sliced computed tomography scans through the midorbits before (left) and after (right) reconstruction. Reproduced with permission from Posnick JC.¹³²

on clinical examination. Radiographic confirmation can be made with CT scans or plain films of the nose, but these are usually not necessary for clinically apparent and isolated nasal septal fractures. Displaced nasal bone and nasal septal fractures should be reduced and stabilized with splints in a similar manner as is done in adults. This should be completed within several days of the injury, as children heal more quickly than adults, making repositioning of the small nasal bone fragments more difficult with time.

Mandibular Fractures

The lower jaw of a child represents an evolving anatomy that affects the pattern of fractures seen at varied ages (Figures 27-6 and 27-7). Mandibular fracture patterns are affected by the fact that the child's jaws are filled with teeth at various stages of development at different

ages.^{15,18,40-46,64,87-91} Injury to the developing bone and tooth buds may result from the trauma of the fracture, the surgical technique, or complications of treatment (eg, nonunion, malunion, infection).⁴⁷

In Posnick and colleagues' study mandibular fracture sites included the condyle (59 of 107, 55%), parasymphysis (29 of 107, 27%), body (10 of 107, 9%), and angle (9 of 107, 8%). Thirty-nine percent of all fractures in the study were of the mandible. Of those treated, 18 of 28 (64%) were treated with closed reduction, most of which were condylar process fractures with an element of malocclusion. Only two condylar process fractures were opened. Both were low subcondylar mandibular neck fractures associated with other injuries in the mandible. Minimally displaced body and angle fractures with a satisfactory occlusal relationship were frequently treated with maxillomandibular fixation. Displaced or comminuted fractures

were treated with open reduction and internal fixation, and this treatment was used most frequently for parasymphyseal injuries (53%) and angle fractures (24%) (see Table 27-4).

A surgeon familiar with the evolving dentition is able to apply arch stabilization and maxillomandibular fixation, when indicated, in dentulous children of all ages. Obstacles to the usual application of surgical arch bars are overcome with the use of skeletal fixation: circum-mandibular, circumzygomatic, infraorbital, anterior nasal spine, and piriform aperture wires are used for additional support. When internal fixation techniques are required, careful application of microplate or miniplate and screw fixation, generally with unicortical screws strategically placed along the thick cortical inferior border combined with arch bar stabilization, is often the least traumatic and most stable option. Knowledge of the location of developing teeth allows the surgeon to place internal fixation as needed, with minimal trauma.

The general principles of treating mandibular fractures are the same in children and adults: anatomic reduction is combined with stabilization adequate to maintain it until bone union has occurred. With the exception of mandibular condyle fractures, we frequently find that the judicious use of ORIF is preferable to the closed reduction and immobilization techniques with splints when treating fractures in the deciduous and mixed dentition. Some surgeons believe that minor degrees of malunion may be self-correcting in children or at least amenable to orthodontic alignment. This margin of safety should not be used as an excuse for inadequate treatment.

Mandibular Condyle and Subcondyle Fractures Injury to the mandibular condylar process may affect jaw growth and temporomandibular joint (TMJ) function.^{18,31,33,92-109} The mandible is the final facial bone to complete normal growth, and injury to the condylar growth center before skeletal maturity may lead to growth retardation on the

FIGURE 27-6 Illustration of three skulls of various ages (A, 2 years; B, 6 years; C, 12 years). Different methods of achieving arch bar stabilization at different ages including circum-mandibular, circumzygomatic, infraorbital, and piriform aperture wires. Adapted from Posnick JC.¹³⁵

ipsilateral side, resulting in facial asymmetry and malocclusion.

Once a mandibular condylar fracture occurs, a degree of TMJ degenerative changes or growth restriction is a likely scenario despite the treatment option selected. Condylar injuries represent a wide spectrum of fractures, dislocations, and compression injuries. They may be intracapsular or extracapsular, displaced or nondisplaced, comminuted or noncomminuted, open or closed, located low or high in the condylar neck, medial or lateral pole fractures, and isolated injuries or associated with more complex facial fractures.

The treatment of a fracture of the mandibular condyle remains controversial.^{110–124} Most authors and clinicians continue to advocate a nonoperative approach, whereas a few prefer the use of open reduction techniques. The frequency of less than ideal results seen with varied treatments given for similar injuries is a reflection of the irreversible injury that may occur to

the highly differentiated and specialized TMJ structure. Despite a great deal of surgeon interest and experience over the years with open reduction techniques, its proponents have not been able to convincingly demonstrate a lower incidence of growth disturbance, TMJ ankylosis, internal derangement of the TMJ, loss of posterior facial height, or malocclusion in their patients. Although endoscopic techniques have been reported, a detailed analysis of outcomes is lacking and the benefits remain to be seen.¹²⁵

Open reduction of a condyle fracture may be warranted in a child in some instances.^{122–124} Indications may include the following:

- Displacement into the middle cranial fossa
- Unacceptable occlusion after a closed technique trial has failed
- Avulsion of the condyle from the capsule

- Bilateral fractures of the condyles with comminuted midface fractures

We continue to advocate a nonoperative approach for most condylar and subcondylar fractures in young children. A short period of partial immobilization with elastics is generally useful for patient comfort, to encourage soft tissue healing, and to limit the conversion of a greenstick or minimally displaced fracture into a complete or fully displaced one. Ten to 14 days of use of firm elastics is generally enough to accomplish these goals and still allow early increased range of motion to limit the likelihood of the development of TMJ fibrosis or ankylosis. Instituting a regimen of physical therapy for several months is important to avoid TMJ fibrosis or ankylosis.

When a condyle fracture occurs and the use of firm elastics needs to be limited to reduce the incidence of TMJ sequelae, the fixation technique selected for additional simultaneous maxillary and mandibular

FIGURE 27-7 An 11-year-old boy sustained multiple facial trauma in a waterskiing accident. The injuries included a left intracapsular condyle fracture, a right low condylar neck fracture, a right parasymphiseal fracture, dentoalveolar injuries, and multiple facial lacerations. A, Frontal view before fracture reduction. B, Full-face view 2 years after reconstruction, with facial symmetry and good facial nerve function. C, Oblique view 2 years after reconstruction. D, Demonstration of 40 mm of vertical opening 2 years after reconstruction. E, Occlusal view 2 years after reconstruction. F, Illustration of fractures before and after reduction and fixation. G, Intraoral view of displaced right parasymphiseal fracture. (CONTINUED ON NEXT PAGE)

fractures should be carefully considered. The common occurrence of a combined parasymphiseal and condylar fracture will warrant a more stable form of parasymphiseal fracture fixation (miniplates and screws) so that early active mandibular range of motion with TMJ function can occur. Instituting a liquid diet for a limited

time period even after firm elastic use may be helpful in preventing displacement of parasymphysis or body fractures. When a mandibular angle fracture occurs in the presence of a condyle fracture, the combined forces may be significant enough to cause displacement unless ORIF at the angle fracture is carried out.

The advantages of continuous passive motion (CPM) for the healing of injured joint surfaces have been well documented in experimental animals.¹²⁶⁻¹²⁸ Salter and colleagues concluded that chondrogenesis in the healing of full-thickness defects in the rabbit femur occurs through differentiation of the pluripotential cells of the subchondral

FIGURE 27-7 (CONTINUED) H, Intraoral view of reduced and plate/screw stabilized right parasymphiseal fracture. I, Computed tomography (CT) scans demonstrating left intracapsular condyle fracture and right condylar neck fracture. J, CT scans demonstrating right parasymphiseal fracture. bone to chondrocytes as a result of the stimulation provided by CPM of the joint.^{126,127} They documented improved healing of intra-articular fractures with the use of CPM compared with immobilization.¹²⁸ The use of CPM in the treatment of TMJ disorders and for the early management of acute TMJ injuries seems to have promise but has not been used often. Conversely the use of extended periods of immobilization of the acutely injured TMJ appears to be counterproductive. A regimen of physical therapy for the TMJ after an initial phase of immobilization is recommended for optimal rehabilitation. Also, functional appliances have been used in an attempt to reestablish vertical height to foreshortened fracture sites in the early injury phase. Although case series have shown good results, no outcome data are available that show a clear advantage to using this technique.¹⁰⁴ Since growth distur-

bance is a concern with these injuries, long-term follow-up is necessary to evaluate the possible development of asymmetry.

Parasymphiseal Fractures When marginal reduction and fixation techniques are used for parasymphiseal or symphyseal fractures, a small dentoalveolar gap often occurs between the two teeth adjacent to the fracture site. Using open reduction techniques with stable (miniplate and screw) fixation at the inferior border, combined with reduction and stabilization at the dentition with an arch bar, gives a more reliable bony union of the injury without displacement. Plating at the tension-band zone is not recommended in the mixed dentition.

Body Fractures Body fractures of the mandible usually have favorable “muscle

pull” vectors on the segments, which encourage reduction rather than displacement. In these situations closed reduction techniques with maxillomandibular fixation generally suffice. Alternatively the skilled surgeon can place inferior border plates and screws with the aid of a transcutaneous trocar and intraoral incision. When extended maxillomandibular fixation must be avoided (eg, associated condyle fracture or severe trauma), more stable forms of internal fixation (plates and screws) are indicated.

Dentoalveolar Injuries Anterior maxillary and mandibular teeth and their supporting alveolar structures often bear the brunt of lower face injuries, and as a result dentoalveolar injuries are very common in the pediatric population.^{43,111,129–131} The teeth may be concussed, subluxed,

partially or totally avulsed, or intruded. In Posnick and colleagues' study dentoalveolar fractures were evenly distributed between the mandible and the maxilla. Thirty-two children sustained 44 fractures, 8 of which were isolated. Teeth that are loosened should be returned to their normal position in the tooth socket and alveolar segments reduced to their preinjury position. The reduced teeth and alveolar segments should be immobilized until healing occurs. Isolated dentoalveolar injuries may be adequately reduced under local anesthesia and then stabilized with the application of acid-etch bonding techniques and a braided wire. Arch bars can be helpful in select cases but often will extrude the teeth. The selected splinting techniques must meet certain criteria, including easy fabrication, maintenance of only passive forces on the teeth, lack of irritation to the soft tissues, maintenance of normal occlusion, allowance of good oral hygiene, access for subsequent endodontic treatment, and easy removal. Longitudinal reassessment with a pediatric or general dentist is important because ankylosis of primary teeth may prevent the normal eruption of permanent teeth.

Resorbable Fixation Materials

Titanium alloy plates and screws are the standard for craniomaxillofacial fixation. The use of plate and screw titanium fixation in the craniomaxillofacial skeleton has consistently resulted in low complication rates and excellent biocompatibility. However, controversy associated with their use in growing bones has led to the development of resorbable fixation materials. Issues of biocompatibility, strength, bulk, inflammatory response, and predictable resorption rates continue to be discussed. Most resorbable plate and screw fixations use isomer configurations of alpha-hydroxy polylactic and polyglycolic acids.

Possible advantages of resorbable fixation include the following:

- Degradation of the material by the citric acid cycle into CO₂ and H₂O
- No interference with imaging (CT, magnetic resonance imaging, standard radiographs)
- No effect on postoperative radiation treatment
- The possibility of integrating substances such as antibiotics within the fixation material

Possible disadvantages of resorbable fixation include the following:

- Less mechanical strength when compared with titanium alloys of similar sizes
- "Memory" of the material, which may distort reduction of fracture
- Increased reactivity during the degradation phase
- Increased operative working time

Summary

The pattern of craniomaxillofacial fractures seen in children and adolescents varies with evolving skeletal anatomy and socioenvironmental factors. Facial fractures in children may go unrecognized as a result of limited communication, incomplete radiographic examination, or the late presentation of the patient by the family. Recognition of the differences between children and their adult counterparts is important in facial rehabilitation. Consideration should be given to open reduction of the fractures, primary autogenous cranial bone grafting, and the use of stable forms of fracture fixation (miniplates and microplates and screws). Late sequelae of pediatric fractures occur even when appropriate and prompt treatment is instituted. The effects of the trauma event as well as the surgical intervention or lack of treatment on growth and development may be contributing factors. Long-term follow-up by appropriate practitioners is mandatory to monitor these events.

Management of Panfacial Fractures

Patrick J. Louis, DDS, MD

Management of patients with multiple displaced and comminuted fractures can be extremely challenging not only for those who are inexperienced but also for experienced surgeons. Improper diagnosis, treatment planning, and sequencing produce inadequate results and can lengthen procedure time. However, with the availability of detailed imaging,¹⁻³ ridged fixation,⁴⁻⁶ bone grafting techniques,⁷⁻⁹ and proper sequencing,^{4,10,11} outcomes can be optimized.

All facets of facial form and function are important, and one should strive to preserve them. The importance of proper occlusion cannot be underestimated since acute changes in the way teeth come together can be readily detected by the individual.¹² Such alterations can result in myofascial or temporomandibular joint pain.¹³ Reestablishing the patency of the nasal cavity is important in the prevention of nasal obstruction and potential problems such as sinusitis and obstructive sleep apnea.^{14,15} It is also required to establish the proper quality of speech.¹⁶ Small changes in orbital volume can result in enophthalmos and/or diplopia.^{17,18} The reestablishment of facial height, width, and projection is important for the prevention of facial deformities and for the psychological and social well-being of the individual.¹⁹⁻²¹ No one of these factors can be considered more important than the other; together they constitute the face and its associated functions.

In this chapter, discussion is presented on some of the historic perspectives, etiology, anatomic considerations, imaging, bone grafting, soft tissue resuspension, sequencing of treatment, and complications as they relate to the management of panfacial fractures.

Historic Perspective

Panfacial fractures are defined as those involving the upper, middle, and lower thirds of the face.⁴ These complex injuries are fractures that involve the frontal bones, zygomaticomaxillary complex, nasoorbitoethmoid region, maxilla, and mandible. Complex facial injuries such as these are generally the result of high-velocity trauma.²² Prior to the advent of rigid fixation techniques,²³⁻²⁵ these fractures were treated with wire fixation and head frames.²⁶⁻²⁸ With these techniques it was difficult to establish and maintain the three-dimensional stability of the facial skeleton.

There have been several important advances in the management of maxillofacial trauma that have resulted in improved outcomes. These include the development of high-resolution computed tomography, rigid fixation techniques, soft tissue resuspension, and primary bone grafting. All of these have made a significant impact on the diagnosis and treatment of panfacial injuries; each is discussed later in this chapter.

Etiology

Panfacial fractures result from motor vehicle collisions, assault, sports-related accidents, industrial accidents, and gunshot wounds.^{22,29-32} Since gunshot wounds are addressed in Chapter 26, and because there is usually associated soft tissue damage causing them to generally require different principles of management, they are not discussed in this chapter.

Anatomic Considerations

Facial Buttresses

Many authors have described the buttresses of the face both in vertical and horizontal planes.^{10,32-34} The vertical buttresses include the nasomaxillary, zygomaticomaxillary, and pterygomaxillary buttresses (Figure 28-1). The nasomaxillary buttress includes the maxillary process of the frontal bone and the frontal process of the maxilla, extending lateral to the piriform rim. The zygomaticomaxillary buttress is composed of the zygomatic process of the frontal bone, lateral orbital rim, lateral zygomatic body, and zygomatic process of the maxilla. The pterygomaxillary buttress includes the pterygoid plates of the sphenoid and maxillary tuberosities. Usually the nasomaxillary and zygomaticomaxillary buttresses are reconstructed, but the pterygomaxillary buttress is not because of inaccessibility. The condyle and posterior mandibular

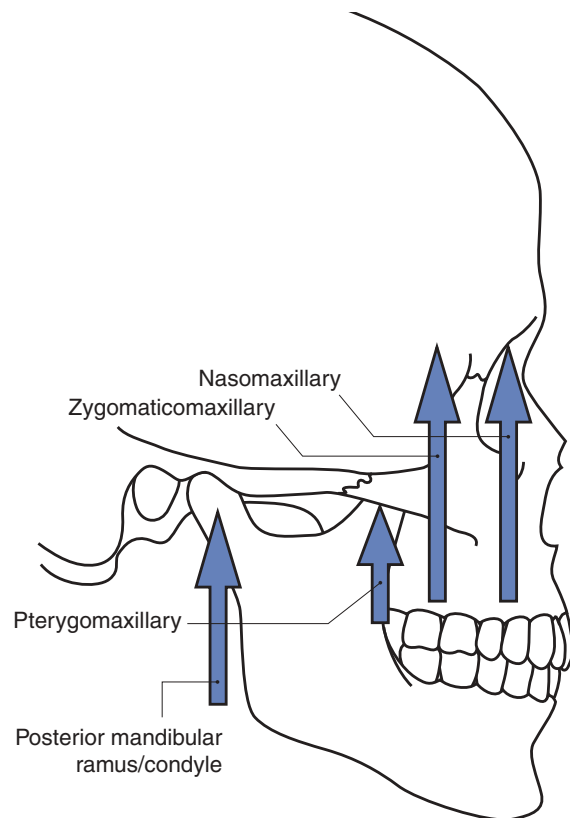

FIGURE 28-1 Vertical buttresses of the face.

FIGURE 28-2 The horizontal buttresses of the face.

ramus make up yet another buttress establishing posterior facial height.

The horizontal buttresses are also described as *anterior posterior buttresses*.¹⁰ These include the frontal, zygomatic, maxillary, and mandibular buttresses (Figure 28-2). The frontal buttress is composed of the supraorbital rims and the glabellar region. The zygomatic buttress consists of the zygomatic arch, zygomatic body, and infraorbital rim. The maxillary and mandibular buttresses are composed of the basal bone of the maxilla and mandible arches.

None of these buttresses exists in a vacuum. Together they give the facial skeleton its structural integrity. The bone is generally thicker over these described areas to neutralize the forces of mastication or impact. With the proper reduction of these buttresses, we are able to reconstruct the height, width, and projection of the face.

Key Landmarks

When there are multiple facial fractures involving the upper, middle, and lower face, reconstruction should be approached as a puzzle. Known landmarks and anatomy can be used to reconstruct more precisely those areas that have been damaged. Some key landmarks that may help in establishing the proper positioning of the facial skeleton include the dental arches, mandible, sphenozygomatic suture, maxillary buttress, and intercanthal region.

Dental Arches

When one or both of the dental arches are intact, they can be used as guides. For example, if the patient has suffered a Le Fort fracture but no midpalatal split, the maxilla, as an intact arch, can be used to set the mandibular arch and establish proper width. Particularly problematic is the situation in which there is a mid-

palatal split and the mandible is also fractured along the tooth-bearing region, with associated condyle fractures. This can easily lead to widening of the entire facial complex if these segments are not properly reduced. One approach to this problem is to reestablish the maxillary width by exposing the palatal fracture, then reducing and fixating the region (Figure 28-3).³⁴⁻³⁷ This approach works well if there is a solitary midpalatal fracture without comminution or avulsion. A second approach is to obtain impressions for fabrication of dental models. Simulated surgery can then be performed on the upper and lower casts and a surgical splint fabricated (Figure 28-4).^{38,39} This is by no means a foolproof method when both the upper and lower arches are fractured. The more severe the injury (ie, multiple segments), the more difficult it is to establish a preinjury occlusion. If the patient has dental models of his preinjury occlusion

FIGURE 28-3 Reduction and fixation of a palatal fracture using a miniplate.

from previous orthodontic or prosthetic rehabilitation, these can provide invaluable clues to establishing the proper arch form. A third option is to reconstruct the mandible since this is generally a robust bone that can undergo anatomic reduction if attention is paid to detail.

The Mandible

Anatomic reduction at the symphysis and/or body can be achieved with an extraoral exposure of the fracture. Such exposure allows for direct visualization

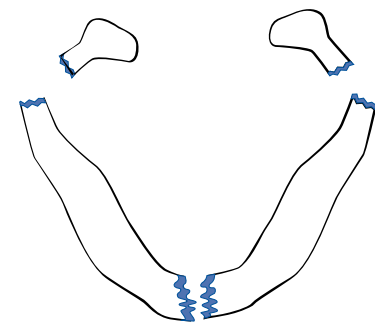

of the inferior border and, to a lesser degree, the lingual cortex. The reduction of both the buccal and lingual cortical surfaces prior to fixation yields better results (Figure 28-5).^{40,41} When bilateral subcondylar fractures are present, they must be treated to establish the posterior facial height and facial width. When bilateral subcondylar fractures are present and there is an associated fracture along the symphysis and/or body region, the mandible may undergo splaying, with a resultant increase in facial width. The lateral pterygoid muscle attachment at the pterygoid fovea, as well as the lateral capsular ligament of the temporomandibular joint, acts to prevent extremes of movement laterally. The mandibular condyle can be reconstituted to the mandibular ramus to help establish facial height and width.

Sphenozygomatic Suture

The sphenozygomatic suture, along the internal surface of the lateral orbital wall, has been shown in cadaver studies to be a key landmark for both the reduction and fixation of the zygomaticomaxillary complex.⁴²⁻⁴⁴ If other aspects of the facial skeleton are ignored, use of this suture alone can result in errors; however, if the

orbital roof and superior lateral orbit are intact, this suture can be an important landmark for the proper positioning of the zygoma and zygomatic arch. The sphenozygomatic suture is usually exposed along the internal surface of the lateral orbital wall (Figure 28-6).

Once reduced, a small plate is placed across this fracture for fixation. Since the

FIGURE 28-4 Dental models from one patient: postorthodontic models (A), post-trauma models (B). Model surgery has been performed on these casts using the postorthodontic models as a guide (C).

FIGURE 28-6 Reduction and fixation of the sphenozygomatic suture.

orbital roof and superior lateral orbit are rarely fractured, they are usually accurate landmarks. Likewise, the zygomatic buttress is important in establishing the proper position of the zygoma and/or maxilla. Once the zygoma is in the proper place, the location of the maxilla can be verified. This broad area of surface contact aids in the reduction and fixation process. If there is significant bone loss in this region, consideration should be given to primary grafting to reestablish this buttress.

Intercanthal Region

The intercanthal region may also be used to reestablish midfacial width since the intercanthal distance is fairly constant in the adult facial skeleton.⁴⁵ Restoration of the proper intercanthal distance via reduction of the naso-orbitoethmoid complex can help to determine facial width (Figure 28-7).¹⁰ This depends mainly on the fracture type. If there is minimal or no comminution in the region, proper reduction can aid in reestablishment of facial form. Unfortunately, many times this area is severely comminuted and is of little help. Establishing the proper intercanthal distance through measurement is usually performed in cases with severe comminution.

FIGURE 28-7 A, Clinical photograph of patient who has a naso-orbitoethmoid fracture with an intercanthal distance of 43 mm. B, Intraoperative photograph showing exposure of the naso-orbitoethmoid fracture.

Imaging

Imaging of the facial skeleton has gone through a gradual evolution in the area of facial trauma. Plain film radiography and

linear tomography were the gold standard until the advent of computed tomography (CT).⁴⁶⁻⁴⁹ CT has improved our ability to image the facial skeleton and obtain details not possible with plain films (Figure 28-8).¹ It allows the clinicians to determine not only the location of fractures but also the degree and direction of displaced segments.^{2,3} Since the introduction of CT, it has undergone an evolution both in the quality of the images and its application. In a previous article authors reported on “sophisticated CT,” in which 5 mm cuts through the facial skeleton were presented.² It is now a routine practice at the University of Alabama at Birmingham to obtain 0.75 mm axial cuts with coronal reconstructions. This allows for three-dimensional reconstruction (Figure 28-9), if needed, and decreases the number of repeat scans.^{50,51} The scans are loaded onto the hospital information system and can be viewed on computers throughout the medical center and at remote locations. This decreases costs by avoiding the production of multiple hard copies, and it improves efficiency.

With current CT technology, the maxillofacial trauma surgeon can evaluate the fracture pattern by viewing individual cuts or the three-dimensional reconstructions.³ This allows the surgeon to view necessary

FIGURE 28-8 Computed tomography showing midfacial fractures and a left condylar head fracture on the axial view (A), and a left condylar head fracture on the coronal view (B).

FIGURE 28-9 A and B, Three-dimensional computed tomography images of patient with extensive midface injuries. Note the detail and quality of the images.

details or the overall injury pattern. By manipulating the image windows on a monitor, the surgeon can view hard and soft tissue details. Soft tissue details that can be viewed on CT are not readily apparent on plain films. These include intracranial injuries, injuries to the globe, presence and location of foreign bodies, extraocular muscle entrapment, soft tissue avulsion, displaced teeth, and the airway. If a cervical spine injury is suspected, it may be imaged at the time of cranial and maxillofacial imaging.

The combination of physical examination and current CT imaging allows a clear treatment plan to be generated. This helps greatly with sequencing at the time of surgery.

Surgical Approaches

Approaches to the facial skeleton in panfacial trauma should permit wide exposure of the fracture to allow for anatomic reduction. The location and extent of exposure are dependent on fracture severity and combination. The following describes which fractures can be accessed through the various surgical approaches (Figure 28-10):

- Bicoronal flap procedure: frontal sinus, naso-orbitoethmoid (superior aspect), medial canthal tendon, supra-orbital rim, orbital roof, superior aspect of the medial and lateral orbital wall, zygomatic arch, and mandibular condyle (with preauricular extension)
- Subciliary and transconjunctival incision with lateral canthotomy: infra-orbital rim, medial and lateral orbital wall, and orbital floor. The transconjunctival incision with lateral canthotomy does allow access to the frontozygomatic suture. This requires detachment of the lateral canthal tendon and incision through the orbicularis oculi muscle and periosteum deep to the lateral periorbital skin. The subciliary approach may allow better access to the lateral nasal region
- Upper eyelid crease incision: superior and lateral regions of the orbit. It is generally used to expose the frontozygomatic suture. This incision is not needed when the bicoronal incision is used
- Perinasal incisions: naso-orbitoethmoid region, medial canthal tendon, and nasolacrimal sac. These incisions are generally avoided because of the

potential for significant scarring. This incision is not needed when the bicoronal incision is used

- Maxillary vestibular incision: maxilla and zygomaticomaxillary buttress
- Mandibular vestibular incision: mandible from the ramus to the symphysis. This approach is not usually recommended for comminuted fractures
- Cervical incisions: mandible, except for when there is a high condylar neck fracture. The approach is generally indicated when anatomic reduction is crucial. It allows the surgeon to visualize the reduction of the lingual cortex. It is also indicated for comminuted and complicated fractures such as a fracture of the atrophic edentulous mandible

Bone Grafting and Soft Tissue Resuspension

Two procedures have improved outcomes in the management of panfacial trauma:

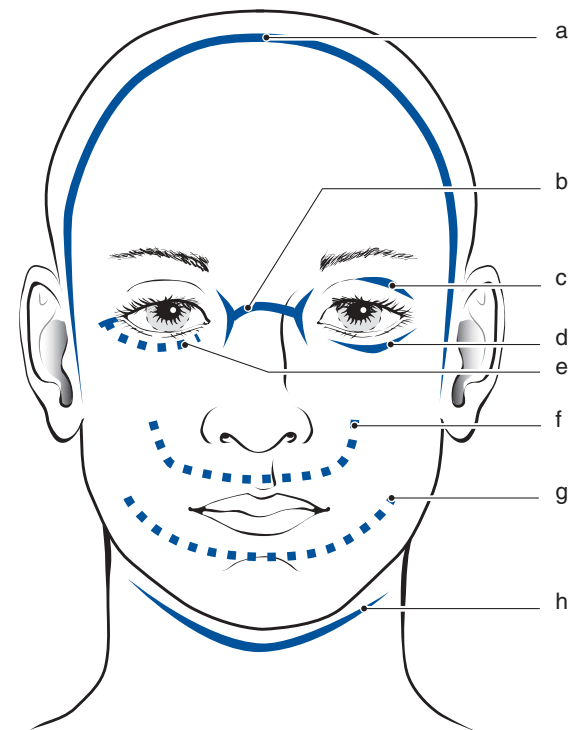

FIGURE 28-10 Surgical approaches to the facial skeleton: bicoronal with preauricular extension (a), paranasal (b), superior tarsal crease (c), subciliary (d), transconjunctival with lateral canthotomy (e), maxillary vestibule (f), mandibular vestibule (g), cervical crease (h).

primary bone grafting and resuspension of the soft tissue after extensive exposure of the facial skeleton.⁷⁻⁹ As previously discussed, the facial buttresses are areas that can serve as guides in the reduction of the facial skeleton and provide stabilization of fractures. With high-velocity trauma, comminution and loss of bony segments can occur in the buttress and “nonbuttress” areas of the face. When these defects are significant, the surgeon may consider the use of bone grafting to prevent soft tissue collapse and to allow for structural support of the facial skeleton. Previous articles have reported on primary bone grafting with few complications.⁷⁻⁹ Even when the bone graft becomes exposed, secondary wound healing generally occurs. Common areas that may require primary bone grafting include the frontal bone, nasal dorsum, orbital floor, medial orbital wall, and zygomaticomaxillary buttress.

There are many potential sources of bone for a graft, but calvarial bone may be the best. Access is often achieved through a bicoronal flap that has already been created during the management of the fractures. These grafts have been shown to resist resorption better than endochondral bone.⁸ Rigid fixation of these grafts has been shown to decrease resorption (Figure 28-11).⁸

Soft tissue resuspension after surgical access to facial fractures is important for

FIGURE 28-11 Primary bone graft rigidly fixed into position to reconstruct the anterior maxillary sinus wall including the nasomaxillary and zygomaticomaxillary buttress. (Courtesy of James Koehler, DDS, MD.)

long-term facial esthetics.^{42,52,53} Resuspension may be especially beneficial in the midface region. For repair of midface fractures, the region is usually exposed transorally and from a periorbital approach.⁵² The soft tissue attachment over the midface is customarily completely stripped. This frequently results in sagging of the soft tissue, with reattachment at a more inferior position. Manson and colleagues stated that there are two steps to placing the soft tissue back into proper position after exposure of the facial skeleton: reattachment of the periosteum or fascia to the skeleton, and closure of the periosteum, muscle fascia, and skin where incisions have been made.⁴² The periosteum is inflexible and limits soft tissue lengthening and migration. Its reattachment is usually accomplished by drilling holes in key locations to fix the periosteum to the bone. Areas where periosteal closure should be obtained include the frontozygomatic suture, infraorbital rim, deep temporal fascia, and muscular layers of maxillary and mandibular incisions.^{32,42,52,54} Areas where periosteal reattachment should be obtained include the malar eminence and infraorbital rim, temporal fascia over the zygomatic arch, medial and lateral canthi, and mentalis muscle.⁴²

Sequence of Treatment

Airway Management

How to maintain the airway is a crucial decision in the management of panfacial fractures. There are several options that are dictated by the fracture pattern and extent of other injuries. When there are extensive head injuries and prolonged intubation is anticipated, tracheostomy should be considered.⁵⁵⁻⁵⁷ Likewise, tracheostomy is an appropriate option to facilitate the management of multiple facial fractures.^{10,56,57} In many cases there are extensive injuries to the naso-orbitoethmoid region, making nasal intubation difficult and hazardous.^{58,59} With nasal intubation, access to

the frontal sinus and naso-orbitoethmoid region is hindered.

Oral intubation may be an option when maxillomandibular fixation is either not possible or not indicated. When prolonged intubation is not anticipated, options include submental intubation^{60,61} or passing the tube behind the dentition, if space permits. If an extraoral approach is indicated to manage a mandibular body/angle fracture or a symphysis fracture, submental intubation may hinder access.

Fracture Management

Much has been written about the proper sequencing of treatment for panfacial fractures.^{10,28,42,52,62} Sequences such as “bottom up and inside out” or “top down and outside in” have been used to describe two of the classic approaches for the management of panfacial fractures. To my knowledge there have been no randomized studies to ascertain whether one approach is superior to the other. The bottom up and inside out approach predates the use of rigid fixation but it is still a valid approach. It establishes the mandible as a foundation for setting the rest of the face and includes open reduction and internal fixation of subcondylar fractures, as well as the remainder of the mandible. The occlusion is set by placing the patient in maxillomandibular fixation; then, the maxilla should be in the proper position. Realignment of the zygomatic buttresses follows in this sequence; however, fixation at this point may lead to inaccuracies in upper midface position. Instead, a break in the sequence is usually preferred here. The zygomaticomaxillary complex is reduced and fixated first. This allows for a more accurate repositioning of the upper midface before fixation at the zygomatic buttress. The maxilla is now fixated along the zygomaticomaxillary buttress. Last, the naso-orbitoethmoid fracture is reduced and stabilized (Figure 28-12).⁶²

The opposite approach, top down and outside in, starts at the zygomatic region. The sphenozygomatic suture is reduced

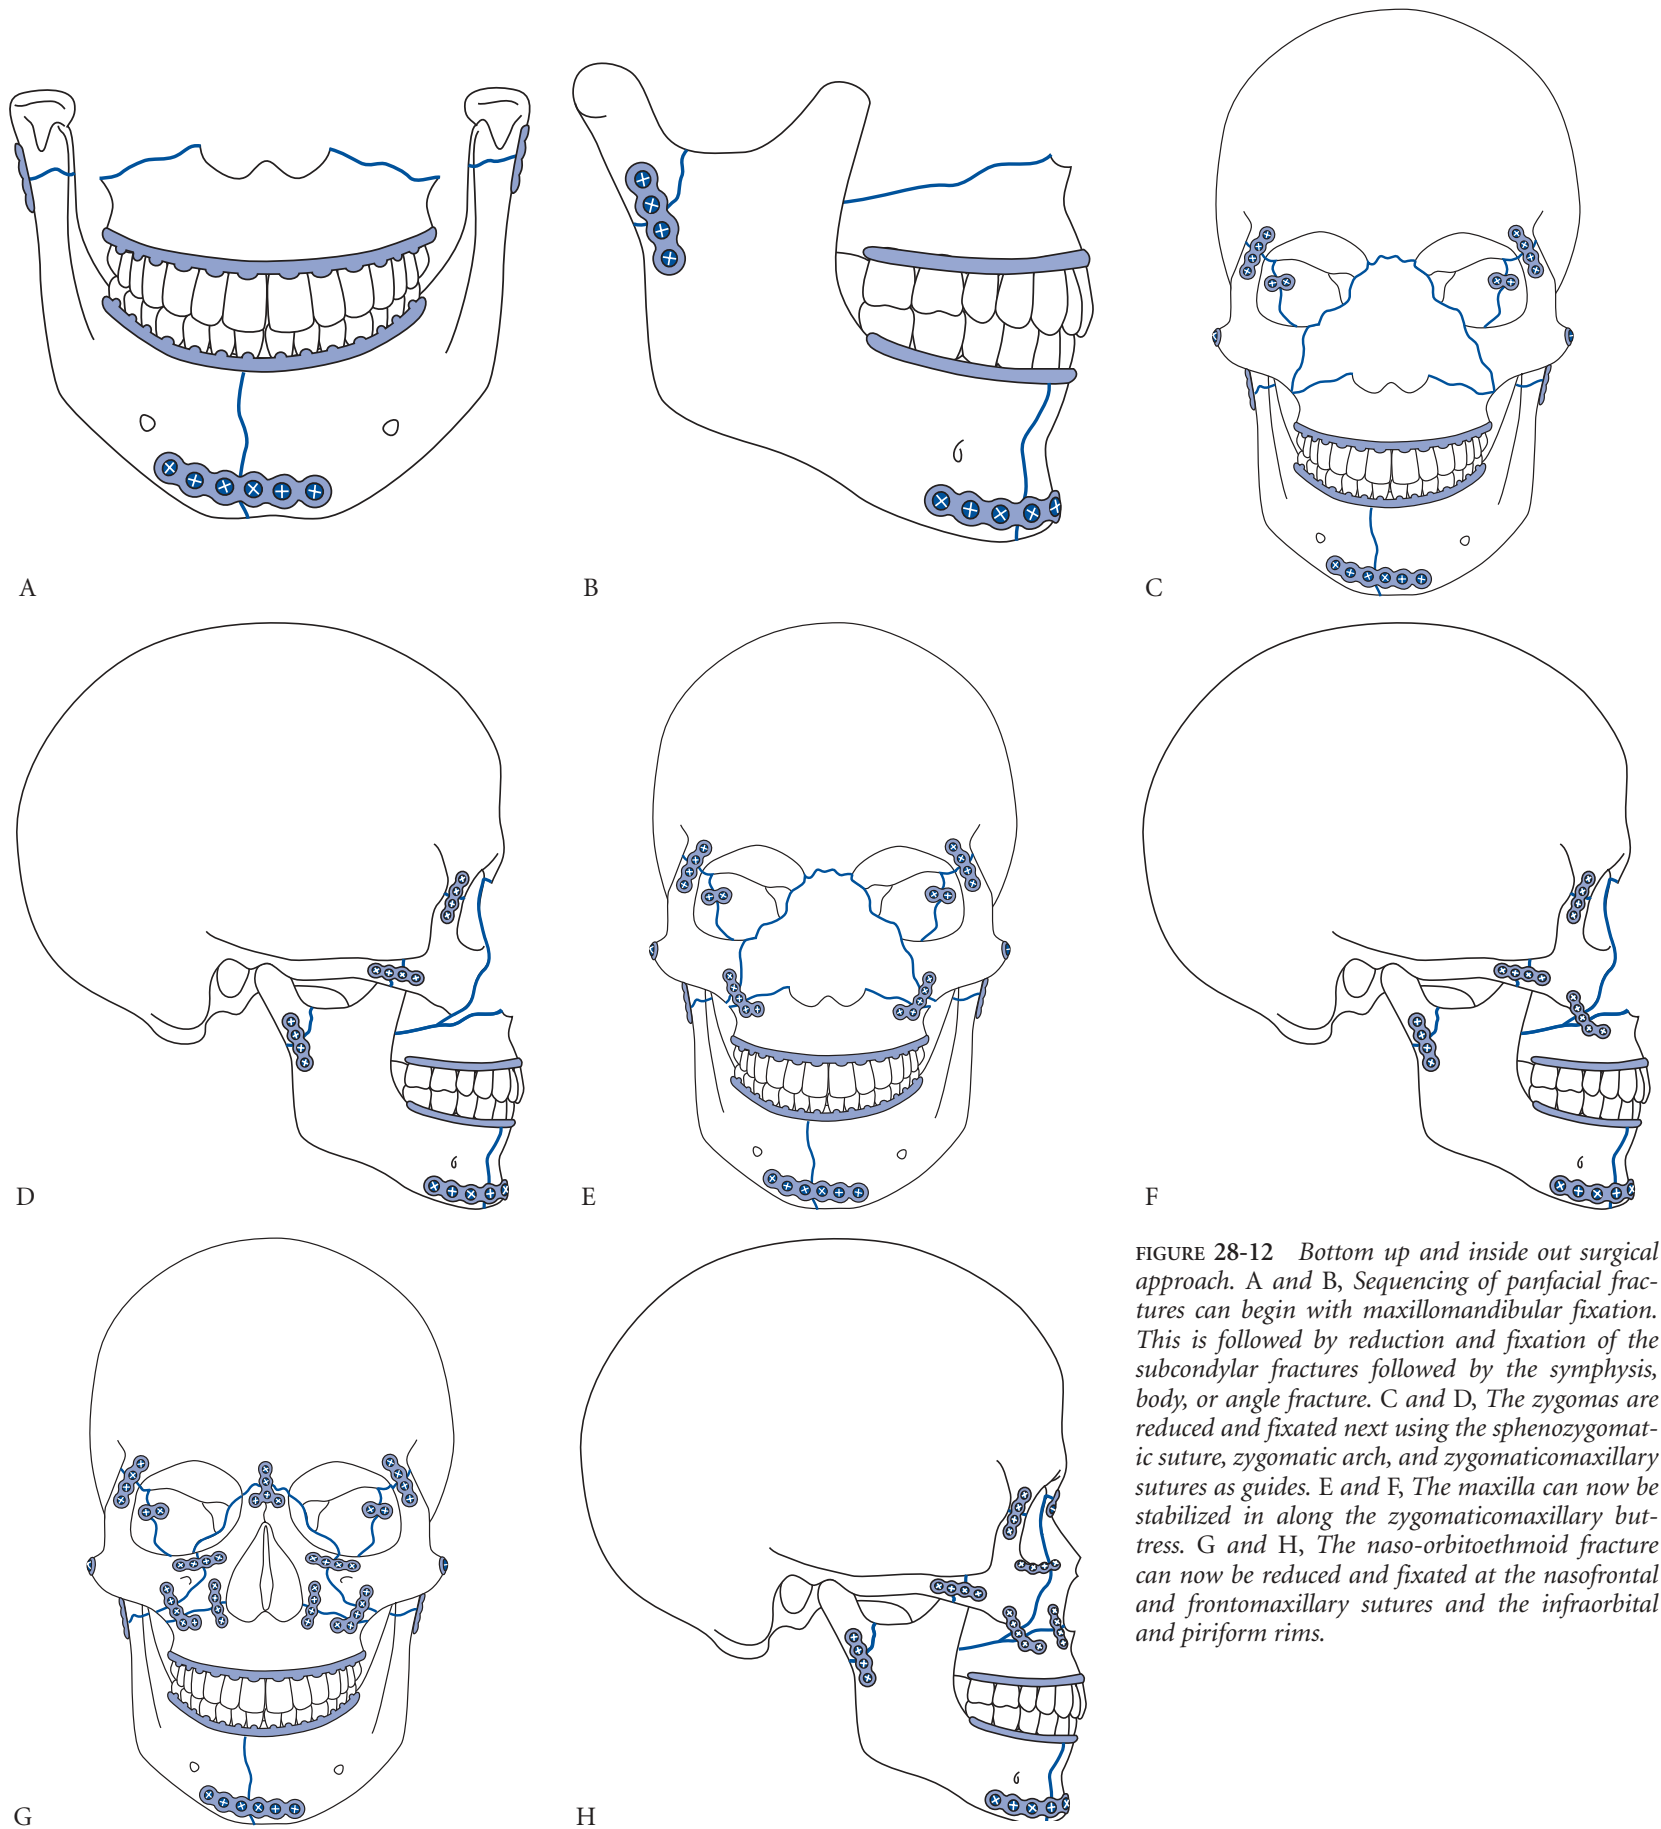

FIGURE 28-12 Bottom up and inside out surgical approach. A and B, Sequencing of panfacial fractures can begin with maxillomandibular fixation. This is followed by reduction and fixation of the subcondylar fractures followed by the symphysis, body, or angle fracture. C and D, The zygomas are reduced and fixated next using the sphenozygomatic suture, zygomatic arch, and zygomaticomaxillary sutures as guides. E and F, The maxilla can now be stabilized in along the zygomaticomaxillary buttress. G and H, The naso-orbitoethmoid fracture can now be reduced and fixated at the nasofrontal and frontomaxillary sutures and the infraorbital and piriform rims.

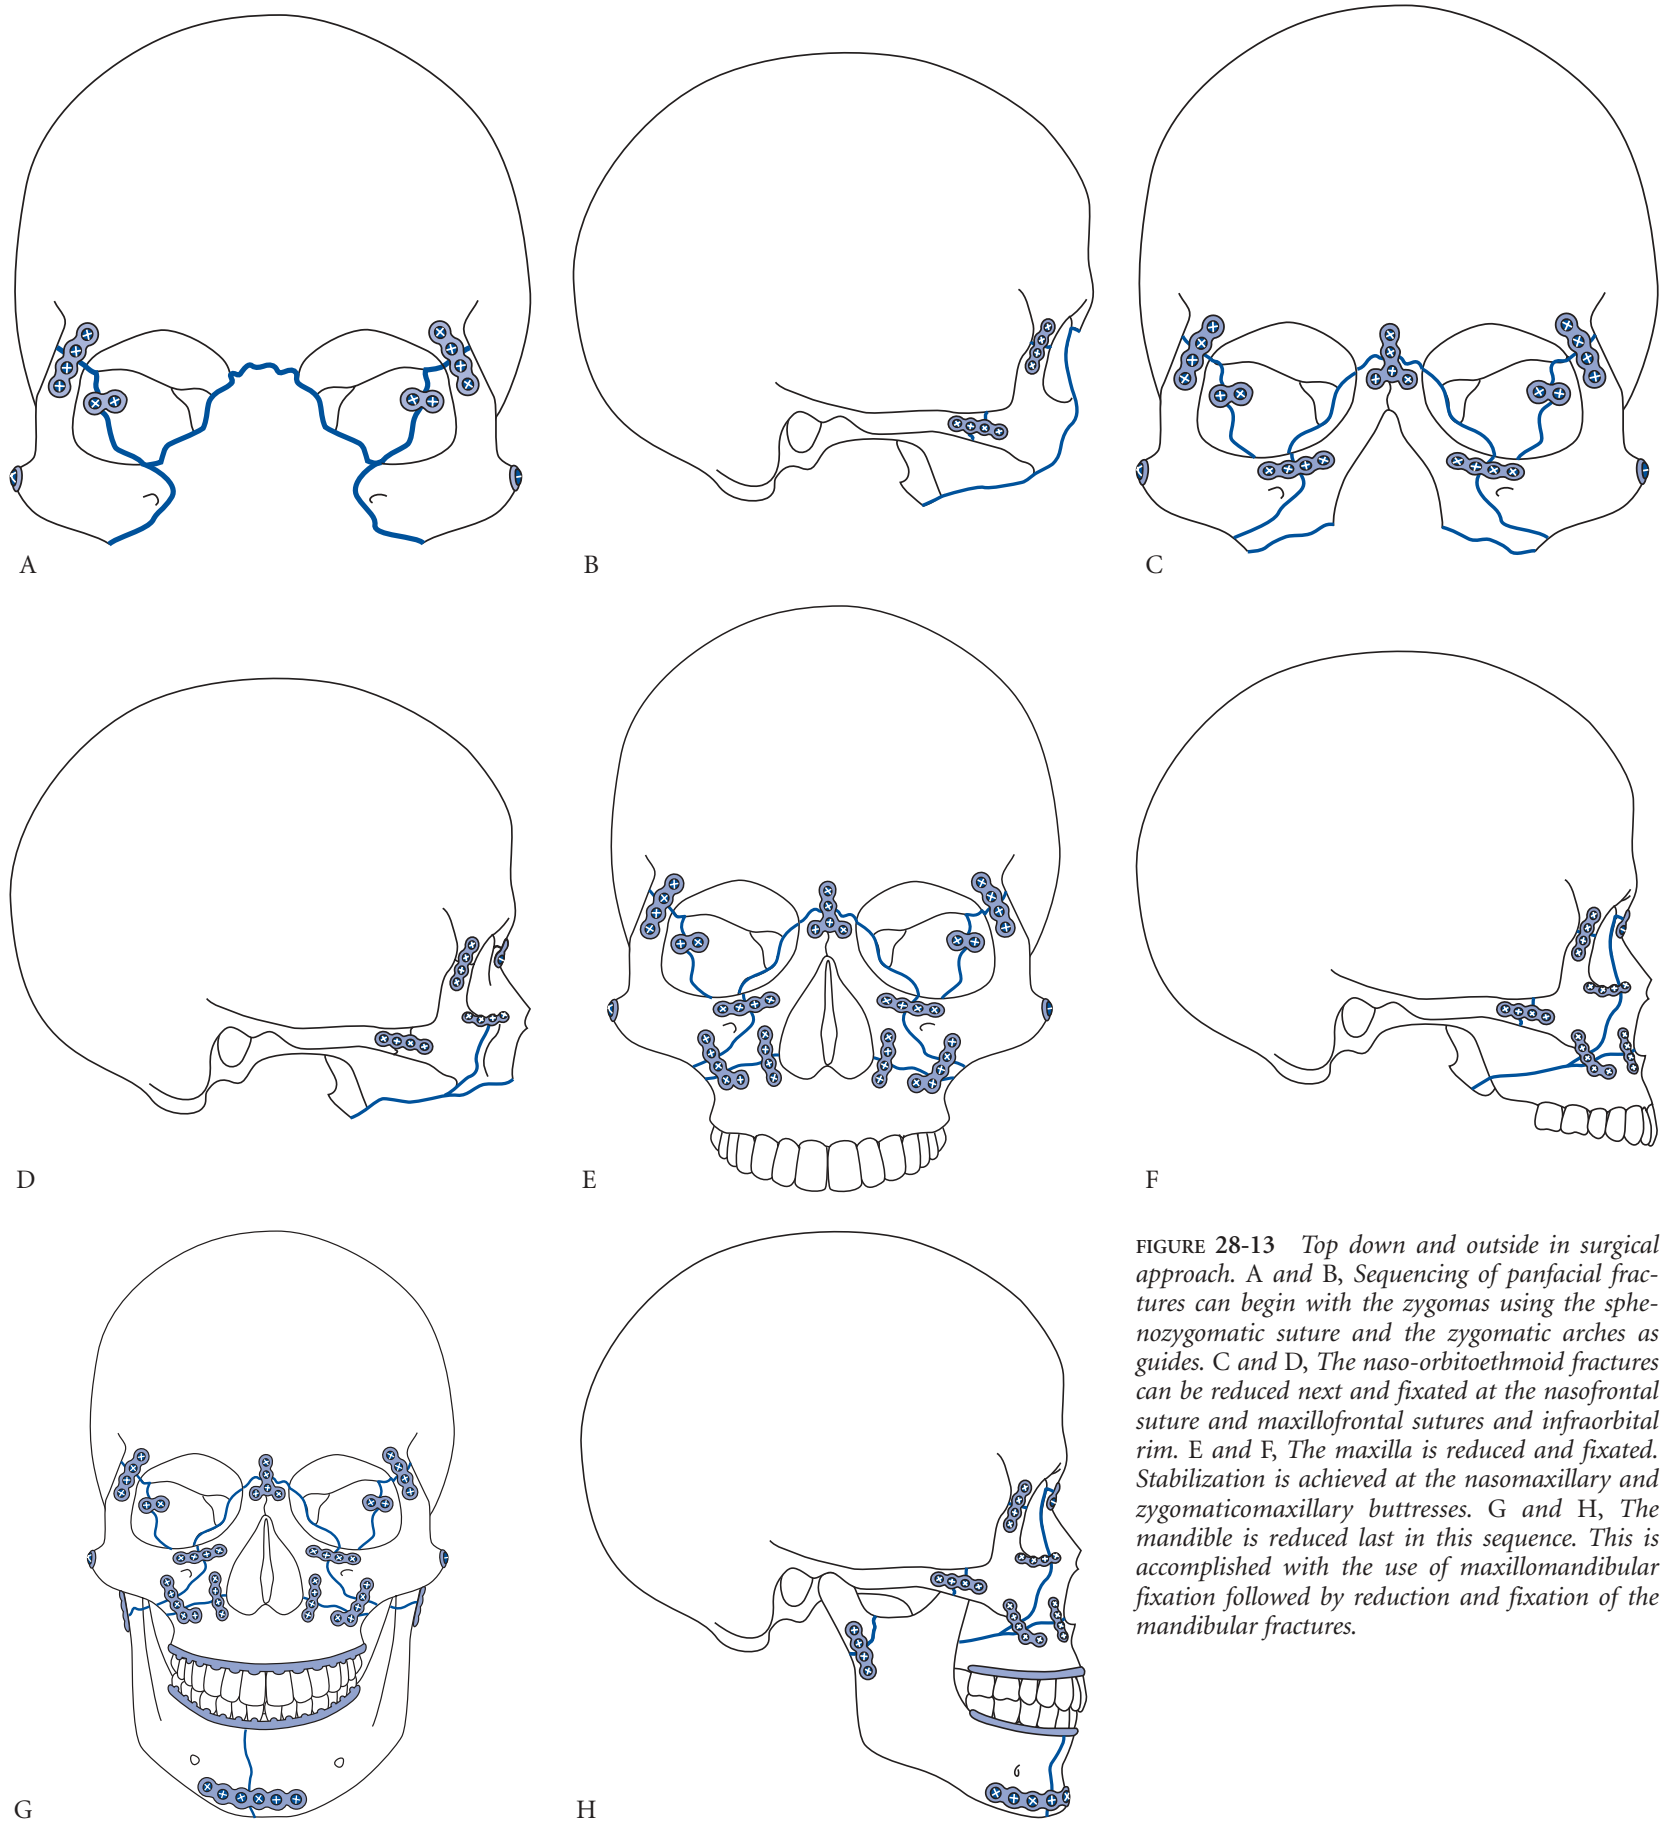

FIGURE 28-13 Top down and outside in surgical approach. A and B, Sequencing of panfacial fractures can begin with the zygomas using the sphenozygomatic suture and the zygomatic arches as guides. C and D, The naso-orbitoethmoid fractures can be reduced next and fixated at the nasofrontal suture and maxillofrontal sutures and infraorbital rim. E and F, The maxilla is reduced and fixated. Stabilization is achieved at the nasomaxillary and zygomaticomaxillary buttresses. G and H, The mandible is reduced last in this sequence. This is accomplished with the use of maxillomandibular fixation followed by reduction and fixation of the mandibular fractures.

and fixated inside the orbit. The zygomatic arch is reduced and plated. If the arches are not properly reduced, underprojection of the midface can result. The alignment of the arch can be verified by the proper position of the sphenozygomatic suture. From this point the zygomas can be further positioned and fixated at the frontozygomatic suture. The naso-orbitoethmoid complex is then positioned to the supraorbital rims, infraorbital rims, and maxillary process of the frontal bones. The maxilla is addressed next using the position of the zygomaticomaxillary buttress and piriform rim as a guide. Maxillomandibular fixation can then be established (Figure 28-13).⁵² Reduction and fixation of the mandibular condyle and the symphysis/body/angle fractures are then performed.

Some surgeons feel that there is a significant advantage to the top down and outside in approach because open treatment of the condyles may not be necessary. The patient is treated with varying periods of maxillomandibular fixation, which may be a valid approach in the case of comminuted intracapsular fractures. Although this is a viable option in some cases, there are two potential complications. One is an unrecognized rotation of the body or ramus of the mandible, resulting in widening. A second complication is temporomandibular joint ankylosis caused by the inability to begin early physical therapy. One author reviewed closed treatment of mandibular condyle fractures and showed compromised results.⁶³ Early function of patients with condylar head fractures is usually indicated, along with guiding elastics to maintain the range of motion of the temporomandibular joint.

Neither one of these techniques will achieve optimal results in every situation. Instead, an approach that goes from known to unknown is certainly more accurate. For example, if there is a significant calvarial injury, it may be difficult to start from the cranium and proceed caudally. In this case, a sequence that starts

caudally and proceeds cranially may achieve more optimal results, allowing the surgeon to reconstruct the damaged cranial portion last. On the other hand, if there is significant comminution of the mandible or if key segments are missing, it may be more appropriate to start cranially and proceed caudally. Thus, the maxillofacial trauma surgeon must be comfortable with both approaches and use known landmarks to achieve optimal results.

In Tables 28-1 and 28-2, two common sequences of management of facial fractures are illustrated. Other sequences exist, but they are variations of these two major approaches.

Complications

There are many complications that are associated with various fractures; these are discussed elsewhere in the text, with reference to the specific fracture type. However, a significant complication associated with panfacial fractures that I will discuss here is widening of the facial complex. This occurs when the surgeon fails to properly reduce key areas that guide in establishing facial width.⁴² If the first area approached is fixated in an improper location, subsequent fragments will be reduced and fixed in an improper spatial arrangement, resulting in a series of errors and, usually, a widened facial complex. To prevent this, the surgeon must use stable segments, known landmarks, and anatomic reduction in the management of panfacial fractures.

If the complication does occur, the surgeon must assess the patient and determine the severity and location of the problem. This is done through physical examination and CT imaging (Figure 28-14). In severe cases three-dimensional computed tomographic reconstruction of the entire facial skeleton can be obtained and, if indicated, a three-dimensional stereolithographic model can be made.^{64,65} The model allows the surgeon to identify and recreate the fractures during model surgery. The fracture may be reduced anatomically and

stabilized with plates, which can then be sterilized and used at the time of surgery. This technique and the use of proper landmarks can aid in the proper reduction and fixation of the fractures.

Conclusions

The management of panfacial fractures is extremely complex. There are, however, many technologic advances that can aid the surgeon in the proper management of these fractures. The most important of these advancements is imaging. With the advent of high-resolution scanners, the surgeon has a more accurate picture of the fracture

Table 28-1 Sequence A: Bottom Up and Inside Out*

1. Tracheostomy
2. Repair of palatal fracture
3. Maxillomandibular fixation
4. Repair of condyle fracture
5. Repair of mandibular fractures (body/symphysis/ramus)
6. Repair of zygomaticomaxillary complex fracture (including arches)
7. Repair of frontal sinus fracture
8. Repair of naso-orbitoethmoid complex fracture
9. Repair of maxilla

*See Figure 28-12.

Table 28-2 Sequence B: Top Down and Outside In*

1. Tracheostomy
2. Repair of frontal sinus fracture
3. Repair of bilateral zygomaticomaxillary complex (including arch) fracture
4. Repair of naso-orbitoethmoid fracture
5. Repair of Le Fort fracture (including midpalatal split)
6. Maxillomandibular fixation
7. Repair of bilateral subcondylar fractures
8. Repair of mandibular fracture (symphysis/body/ramus)

*See Figure 28-13.

FIGURE 28-14 A and B, Twenty-one-year-old male who fell from a height of two stories. Facial fractures included the frontal sinus, naso-orbitoethmoid, bilateral zygomaticomaxillary complex, Le Fort I with midpalatal split and avulsion of tooth no. 9, mandibular symphysis, and bilateral intracapsular condyle fractures. In this photograph it is evident that the patient has significant facial widening owing to a failure to establish proper facial width. He also has bilateral bony ankylosis of the condyles secondary to a closed reduction of the condyle fractures. C and D, Three-dimensional stereolithographic models generated from CT imaging. Note the significant widening of the mandible and midface. E and F, Simulated surgery was performed on this model and mandibular plates were prebent. Note the significant narrowing of the model. Mandibular condyles are now positioned in the fossae. G and H, Model surgery was performed on the dental cast, based on the preorthodontic models that were brought in by the family. A surgical splint was fabricated. (CONTINUED ON NEXT PAGE)

FIGURE 28-14 (CONTINUED) I and J, During the surgical management, the old fractures are exposed via a bicoronal incision with preauricular extension, transconjunctival incisions with lateral canthotomies, a maxillary vestibular incision, and the use of the previous chin scar. The hardware was removed. The previous fractures were recreated by performing bilateral condylar process osteotomies, a symphysis osteotomy, and a Le Fort I with left paramidline split. With the aid of the presurgical splint, the patient was placed in maxillomandibular fixation. The mandible was reconstructed first by reducing and fixating the condyles and with the aid of the prebent plates, and by reducing and fixating the symphysis. The arrow points to the condylar process osteotomy and fixation plate. K and L, A Le Fort III osteotomy is created to imitate the initial fractures. This portion of the upper midface is mobilized and advanced. Greenstick fractures of the zygomatic components of the upper midface are also performed to rotate the posterior aspect medially. Once reduced, these fractures are fixated with miniplates. M, Last, the maxilla is fixated at the piriform rims and the zygomaticomaxillary buttress with miniplates. The patient is taken out of fixation to verify the occlusion and begin early function. N, Early postoperative result. Note the decrease in facial width and increase in facial height. Patient also had zygomatic and recontouring nasal augmentation, bone grafting to the orbits, lateral canthopexy, midface resuspension, and genioplasty. (Courtesy of Dr. Patrick Louis and Dr. John Grant.)

pattern. Once the proper diagnosis is established, the surgeon should be able to institute an appropriate sequence of treatment.

Part 5

MAXILLOFACIAL PATHOLOGY

Differential Diagnosis of Oral Disease

John R. Kalmar, DMD, PhD

Carl M. Allen, DDS, MSD

One of the major roles of the oral and maxillofacial surgeon is that of diagnostician. From private practices in small communities to large tertiary care medical centers, these specialists are called upon to evaluate and diagnose a wide variety of conditions affecting the face, jaws, head, and neck as well as the tissues of the oral cavity. The term *diagnose* comes from the Greek words *dia* (“through,” “apart”) and *gnosis* (“knowledge”), meaning literally to know apart or to distinguish. Indeed, although the ability to correctly diagnose is important to virtually all professions, it is perhaps most strongly linked to the clinical practice of medicine and dentistry. For health care practitioners, a *diagnosis* is defined as the determination of the nature of a disease or pathologic condition. An accurate diagnosis is obviously important and occasionally critical to the patient so that the most appropriate treatment can be initiated as soon as possible. Early determination of the true diagnosis can further benefit the patient by avoiding the need for expensive unnecessary laboratory studies, the use of ineffective or improper medications, and the inconvenience of additional costly consultation(s).

A variety of terms related to the diagnostic process may be used during the

evaluation of the patient. Occasionally the diagnosis is relatively straightforward. Usually, however, a variety of conditions with similar clinical features need to be considered, and a *differential diagnosis* is prepared. The differential diagnosis represents a listing of the more likely diagnostic considerations for a particular pathologic finding or condition, ranked in descending order of probability. Therefore, the number one consideration from the initial differential diagnosis should represent the culmination of the clinician’s evaluation and is termed the *clinical diagnosis* (ie, *working* or *tentative diagnosis*, *clinical impression*). Although construction of the differential is initially based upon clinical signs, symptoms, and history, this list of diagnoses is subject to modification or refinement following additional studies such as radiographic imaging and hematologic or serum analysis (Figure 29-1).^{1,2} As is discussed below, the differential listing may vary widely depending upon the experience and knowledge base of the treating clinician. The designation of *final diagnosis* is used when the clinician believes that the nature of the disease has been identified to a reasonable degree of certainty. This progression from information to possible diagnoses to final diagnosis

is known as the *diagnostic process* or *method*. A case example is provided below. Although the determination of a final diagnosis often represents the end of the diagnostic phase of patient care, it is worth remembering that the “final” diagnosis is not always correct. As is stressed below, observation of the patient’s response to therapy and careful monitoring of the subsequent disease course are essential aspects of comprehensive patient management. Should a lesion or condition not behave in the expected manner, reevaluation and revision of the final diagnosis may ultimately be required.

The Diagnostic Process

The clinician begins the diagnostic process by gathering or accumulating information. In some instances this information includes a significant historic component, whereas in other cases (eg, asymptomatic lesions discovered upon routine examination) the data may be limited strictly to the findings of the physical examination, together with any necessary diagnostic studies or tests. Depending upon the experience and expertise of the practitioner, a confident final diagnosis may require nothing more than clinical inspection. In many cases, however, even the most

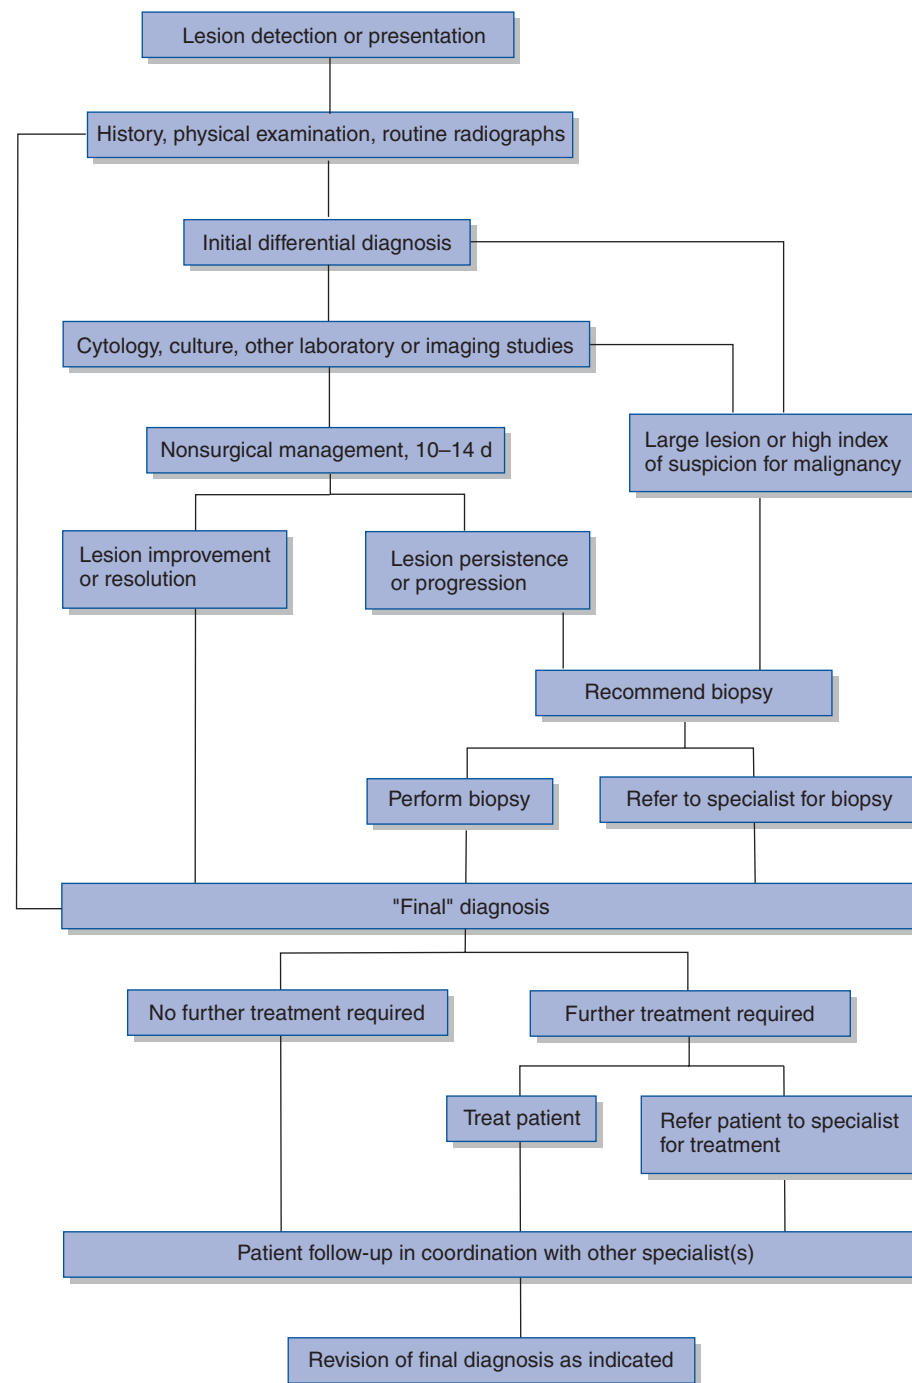

FIGURE 29-1 The diagnostic process. Adapted from Ellis E III.¹

experienced diagnostician requires additional information from appropriate imaging or laboratory studies.

Case Study: From Differential Diagnosis to Final Diagnosis

A 25-year-old male presents with a 3-month history of gradual painless enlargement of the right anterior lower

jaw. His medical history is unremarkable, and he denies recent trauma to the area. Clinical examination reveals a 1.5 cm bony firm swelling of the right mandibular alveolus in the area of teeth no. 26 and 27 causing primarily buccal expansion with an unremarkable overlying mucosa. The area is nontender to palpation, and the adjacent teeth are vital.

Initially, the clinical differential diagnosis focuses on the most common conditions that could present in a fashion similar to the lesion in this patient. Likely considerations include central giant cell granuloma, central ossifying fibroma, ameloblastoma, and odontogenic keratocyst.

Important additional information is easily obtained in this case with routine dental radiography. A panoramic film reveals a 2 cm unilocular radiolucent lesion of the right mandible with a well-defined sclerotic border that contains scattered small particles of radiodense material. With this additional information, the differential diagnosis is revised to exclude conditions not usually associated with calcification and possibly to include other less common conditions that have a radiopaque component: central ossifying fibroma, desmoplastic ameloblastoma, and calcifying epithelial odontogenic tumor.

A biopsy of the lesional tissue reveals a well-circumscribed cellular proliferation of benign spindle cells containing scattered trabeculae of osteoid and bone. The final diagnosis is central ossifying fibroma.

History

Most attempts at formulating a differential diagnosis begin with data gathering that includes the history of the specific problem being investigated as well as the patient's medical and social history. The patient's perception of the duration of the lesion can be important as long-standing lesions may suggest a developmental or benign process, whereas rapidly evolving problems often represent reactive, infectious, or malignant disease. Exceptions to these generalizations are numerous, however, since mycobacterial infections may develop slowly, as do some neoplasms that are considered malignant (eg, basal cell carcinoma). Furthermore, the reliability of the patient to provide an accurate history is occasionally compromised owing to the patient's inattention, limited mental capacity, or denial of disease.

Symptoms, particularly related to pain or tenderness, are important in developing a differential diagnosis. Pain and tenderness (pain on palpation) are often signs of an inflammatory or infectious process, although malignancies can also produce such symptoms, particularly late in their course. A notable exception to this is adenoid cystic carcinoma, which is infamous for the early onset of low-grade intractable pain. Other symptoms such as paresthesia or numbness can also be significant and may be related to pressure on nerves caused by a cystic lesion or tumor mass.

Reported changes in the lesion may also provide important insights. If a mass gradually enlarges, the possibility of neoplasia has to be entertained, whereas a mass that fluctuates in size is more suggestive of a reactive process. In addition, changes in symptoms may be significant. Decreasing pain or tenderness likely represents a resolving inflammatory or infectious process, whereas pain that develops in a long-standing previously asymptomatic mass may be an indication of malignant transformation (eg, carcinoma arising in pleomorphic adenoma).

Clinical Examination

Following a review of the patient's medical history and history of the present lesion or condition, the clinician typically proceeds with gathering objective data through careful clinical examination. A variety of lesional parameters should be evaluated and recorded, including (1) site, (2) size, (3) character (eg, macule, ulcer, mass), (4) color, including an assessment of its homogeneity, (5) surface morphology (eg, smooth, pebbly, granular, verrucous), (6) the border (eg, smooth, irregular, indistinct, sharply defined), (7) consistency on palpation, (8) local symptoms, and (9) the distribution if multiple or confluent lesions are observed.

The precise anatomic site or location of a lesion can provide essential diagnostic information and is discussed later in greater detail.

Lesion size can have diagnostic implications, particularly when combined with an estimate of lesion duration to give an approximate rate of growth or enlargement. The finding of a large lesion may indicate a locally aggressive or malignant neoplasm if the history suggests a relatively recent onset. Yet, even when abnormal tissue has been noted for several months or years, a history of progressive increase in the size of the affected area should be viewed suspiciously (Figure 29-2). As mentioned above, relying on the accuracy (or veracity) of the patient history can be problematic and should be weighted accordingly in the differential diagnosis. Confirmation of the clinical history through other health care practitioners can be helpful in this regard.

Establishing the character of the lesion is an essential aspect of the clinical evaluation. Ulcers can be seen with traumatic, infectious, or neoplastic conditions, whereas masses or swellings more commonly indicate neoplasms, reactive proliferations, cysts, or enlarged lymph nodes. A history or evidence of vesicle or bulla formation might be suggestive of a viral condition, an immunobullous disorder, or possibly an inherited mucocutaneous disease.

Macular lesions, which are completely flat by definition, usually represent an area

of color change. A brown or black macule is often the result of melanin pigment; a red or purple macule usually represents hemoglobin in either its oxygenated or reduced form, respectively. A dull flat white implies keratin production, an area of translucent whitish change may mean increased epithelial edema, and a shiny creamy yellow-white appearance is usually a sign of an ulcer's fibrinous pseudomembrane. A blue or grayish macule is frequently associated with exogenous (amalgam, foreign body) or endogenous (melanin) pigmented material that is deposited within the connective tissue below the level of the epithelium. Although additional information regarding the margin or border of a lesion is provided below, it should be mentioned that most pigmented lesions in the oral cavity are relatively homogeneous in color and have a smooth well-defined margin. By contrast, a pigmented lesion that exhibits significant border irregularity and color variegation should be considered as suspicious for melanoma (Figure 29-3).

The surface morphology of a lesion can be virtually diagnostic for certain conditions. Examples include the "tapioca pudding" appearance of the surface of a lymphangioma or the papillary epithelial fronds of squamous papilloma. Similarly,

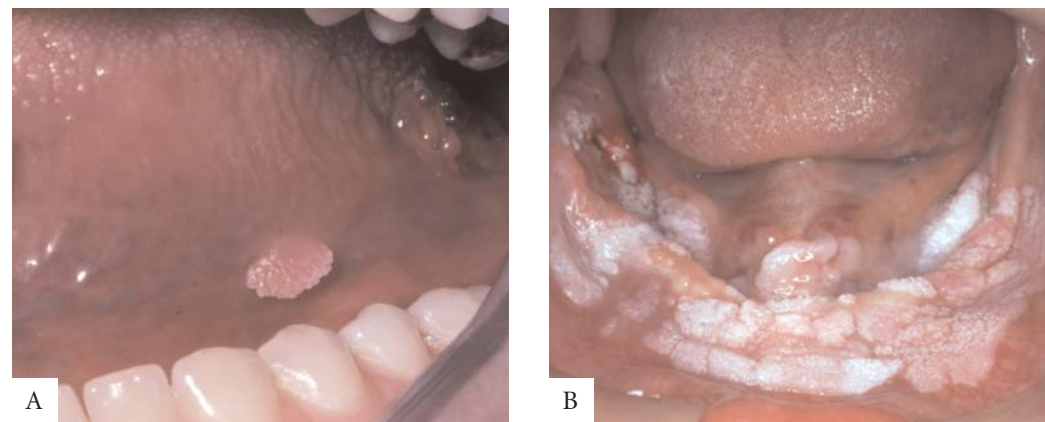

FIGURE 29-2 A, Asymptomatic papillary epithelial lesion in a 50-year-old male that has been present for approximately 2 years without apparent increase in size. Clinical diagnosis: squamous papilloma. B, Asymptomatic epithelial lesion in a 65-year-old male with a papillary or granular surface that has been present for approximately 2 years with slow progressive enlargement. Clinical diagnosis: verrucous carcinoma.

FIGURE 29-3 A, Macular grayish 0.8 cm pigmentation with well-defined borders of right posterior buccal mucosa in a 52-year-old female. The patient reported that it had been present for years. Clinical diagnosis: amalgam tattoo. B, Ulcerated area of macular pigmentation affecting posterior maxillary left alveolar mucosa in a 65-year-old male. Note the border irregularity and color variegation. Clinical diagnosis: melanoma.

an irregularly papular or granular surface architecture can be seen with malignant tumors as well as granulomatous processes that can range from deep fungal or mycobacterial infections to foreign-body reactions to immune-mediated conditions such as Crohn's disease or sarcoidosis.

Palpation of the lesion is necessary to assess its consistency, the lateral or deep margins, and the presence or absence of tenderness. When assessing consistency, detection of a doughy soft mass suggests a cystic lesion or a benign fatty tumor. A rubbery-firm character may be detected with a variety of benign or neoplastic disorders, whereas an even firmer consistency can reflect metastatic disease within a lymph node. A hard or bony consistency naturally indicates a mineralized or calcified component to the lesion.

The border or margin of a primarily submucosal or subcutaneous lesion is usually described as encapsulated, well-demarcated, or infiltrative. An encapsulated process is often freely movable within the deep soft tissues, a finding common to a variety of benign neoplasms and cysts. The margins of some benign lesions (eg, neurofibroma) and some low-grade malignancies (eg, acinic cell carcinoma) may be well-demarcated, but they are gen-

erally less mobile compared with encapsulated lesions. The margins of many malignancies are indistinct, as the tumor invades and blends with the surrounding host tissues.

As noted earlier, the finding of a local symptom such as tenderness is usually associated with an inflammatory process, especially acute inflammation. Although malignant neoplasms may also present with tenderness or dysesthesia (eg, adenoid cystic carcinoma), this feature is usually a later-stage development secondary to tumor invasion of local nerves or surface ulceration. Tenderness may also be a prominent clinical feature of certain benign tumors such as traumatic neuroma.

Finally, the presence of multiple identical or similar lesions can suggest a number of conditions, depending upon their particular character (eg, ulcerations, papules, vesicles) and distribution. Multiple small painful recurrent ulcerations bilaterally on the ventrolateral surface of the tongue in a young adult female patient are most suggestive of the herpetiform variant of recurrent aphthous stomatitis. On the other hand, the finding of a focus of several small relatively painless ulcerations in a unilateral distribution on the left hard palate would be more consistent with

a recurrent intraoral herpes infection. Similarly, multiple purplish plaques involving the oral mucosa and skin of a 35-year-old male who is positive for the human immunodeficiency virus would be strongly suggestive of Kaposi's sarcoma.

Developing the Differential Diagnosis

After collecting the historic and clinical information, the final diagnosis may be obvious; however, in many instances the diagnosis is not readily apparent and the formulation of a differential diagnosis is appropriate. Several approaches have evolved over the centuries of medical practice to assist in the categorization or grouping of diseases. These grouping techniques permit the large number of possible diagnostic considerations for a given lesion to be reduced to the more probable conditions. The resultant narrowing of the differential diagnosis, in turn, aids in the selection of additional diagnostic tests that are most useful in securing a final diagnosis. The major diagnostic strategies or approaches that have been used to group or organize the differential are based on (1) the history and clinical presentation, (2) the potential disease histogenesis, and (3) the disease location (more specifically, the frequency of a given condition in a particular location). In actual practice, more experienced clinicians typically employ all of the categories simultaneously. As a consequence, the specialist is able to rapidly produce a much narrower and usually more precise list of initial diagnostic considerations (see the case study below).

Evaluation of the physical characteristics of a given lesion in the context of the history and clinical setting often permits the clinician to arrive at a reasonable list of diagnostic possibilities. For example, a firm fixed painless 2 cm nodule of uncertain duration in the anterior cervical area of the neck is suspicious for possible metastatic disease or lymphoma. By contrast, if the nodule were soft, mobile, and

tender to palpation, an inflammatory process would be more likely.

Another useful approach to developing a differential diagnosis is to consider whether the clinical and historic aspects of the lesion can be explained by any, some, or all of the broad categories of disease histogenesis. These categories include developmental, inflammatory/immune-mediated, infectious, neoplastic, and metabolic conditions. This is a time-honored systematic method of diagnosis, and many clinicians find it useful to critically consider diagnostic possibilities from each category. For example, an asymptomatic lesion that has been present for several years and feels encapsulated upon clinical palpation would be most consistent with a developmental or benign neoplastic process. Although inflammatory conditions, malignant neoplasms, and metabolic conditions might not be excluded completely, they would not receive primary consideration in the initial differential. Similarly, if the lesion presented as a chronic ulceration of the lateral tongue in an adult patient, disorders from the neoplastic (especially malignancies), infectious (eg, mycobacterial or deep fungal infections), and immune-mediated (eg, Wegener's granulomatosis or regional enteritis) categories would have to be considered.

The third diagnostic grouping strategy relies on the identification of lesions that most commonly present in a particular anatomic location. The tendency for certain conditions to occur with increased frequency at certain sites is well recognized. For example, a nontender bluish fluctuant mass of recent onset involving the lower labial mucosa very likely represents a mucocele. By contrast, mucocele would not be included in the differential diagnosis of a painless persistent bluish mass of the attached gingiva as salivary gland tissue is not normally present at that site. This latter clinical finding would, however, be completely

consistent with a gingival cyst of the adult. A nonhealing relatively insensitive ulceration of the lateral tongue in an adult patient that has no identifiable source of irritation or trauma would be highly suspicious for squamous cell carcinoma. Salivary gland neoplasia would be a strong consideration for a rubbery firm mass of the posterior hard palate.

Case Study: Neophyte versus Expert Clinician

An otherwise healthy 72-year-old woman complains of sores in her mouth for the past year. Her medical history is unremarkable and she is not taking any medications. She has not been aware of any blisters, and she feels the problem is getting worse. The lesions tend to wax and wane in severity and have affected several areas of the mouth, including the hard and soft palates, the labial mucosa, and the ventral tongue.

Examination shows several shallow erosions and ulcerations with ragged margins. The lesions range from 0.5 to 1.0 cm in diameter and involve the lower labial mucosa, the ventral tongue bilaterally, and the anterior soft palate. No vesicles or bullae are seen, and no white striae are evident.

The inexperienced diagnostician who is not very familiar with oral lesions might provide a differential diagnosis based on conditions that are primarily ulcerative: herpesvirus infection, aphthous ulcers, erosive lichen planus, squamous cell carcinoma, and candidiasis. On the basis of this list, the patient would likely be placed on one or possibly more courses of antiviral medication. The patient's condition would not improve, and she might then be switched to antifungal medication(s). After that approach has failed to resolve the problem, topical corticosteroids might be prescribed. Following several weeks of topical corticosteroid use with little or no impact on the patient's oral sores, the diagnostician may recommend that a

biopsy be performed. In this situation, the patient has invested several months' time and spent hundreds of dollars on inappropriate or ineffective medications—all in the absence of a clear diagnosis.

For the experienced diagnostician who is more familiar with oral conditions, the differential would be much smaller: cicatricial pemphigoid or pemphigus vulgaris. With a greater understanding of oral disease, the specialist should be able to eliminate many of the considerations that the first clinician entertained. For example, recurrent herpesvirus infection does not typically affect nonkeratinized mucosa in an immunocompetent patient and would not wax and wane in severity. Although aphthous ulcers often exhibit a waxing-and-waning course, the lesional margins are usually smooth, not ragged. Erosive lichen planus would be considered unlikely owing to the lack of radiating white striae at the periphery of the oral lesions, as well as the lack of buccal mucosa involvement. Squamous cell carcinoma would not be reasonable because of the multifocal presentation and the history of waxing and waning. Finally, although candidiasis is occasionally associated with tenderness or irritation of the oral mucosa, it does not induce true ulceration and would therefore have a low probability of representing the actual diagnosis.

Based on the patient's age, the distribution of the lesions, the history of the process, and the clinical appearance of the lesions, a differential diagnosis that centers on immune-mediated disease would be most appropriate. In this situation biopsies for examination with both light microscopy and direct immunofluorescence (DIF) would be requested or performed after the initial consultation. Histopathologic evidence of acantholysis and DIF findings of interepithelial deposits of immunoglobulin G (IgG) and complement component 3 (C3) would establish the final diagnosis of pemphigus vulgaris in a relatively rapid and

cost-effective manner. Besides the monetary savings, a more timely and correct diagnosis often saves the patient from unnecessary suffering and mental anguish, both by initiating effective treatment earlier and by relieving the anxiety that many patients experience when they do not know the nature of their disease. Early diagnosis and treatment of conditions such as pemphigus vulgaris may also reduce disease progression or the need for more aggressive therapy.

Determining the Final Diagnosis: Additional Diagnostic Methods

If the final diagnosis cannot be determined based on historic findings and physical examination alone, a variety of procedures and tests can be used to assist in the diagnostic process. Generally, diagnostic tests should be ordered so that the most likely diagnosis can be either confirmed or eliminated. The methodic application of this process together with a proper rationale for selecting each test typically leads to the correct diagnosis in the most rapid cost-effective manner. Tests that do not address the most likely diagnostic possibilities should be delayed as the probability that they will provide useful information is small, yet they can dramatically increase costs to the patient. An exception to this statement would be a situation in which a particular test is performed to rule out a rare or unusual condition of serious clinical significance. Finally, diagnostic tests should be interpreted by individuals with specialty training in that area whenever possible to ensure the most timely and accurate result or final diagnosis.

Diagnostic studies are not necessarily complex or expensive. For example, a putative vascular lesion can be evaluated easily by pressing it with a glass slide to test for possible blanching (diascopy). The bruit of a vascular malformation may be heard upon auscultation using a stethoscope. Operative findings at the time of

surgery occasionally provide important diagnostic clues, such as the presence of cheesy keratotic debris within a cystic lesion associated with an impacted tooth, suggestive of an odontogenic keratocyst, or the empty bone cavity seen with traumatic bone cyst. Finally, follow-up evaluation of a lesion is a straightforward procedure that can provide important diagnostic insight with respect to biologic behavior. Those conditions that persist or progress 2 weeks after initial inspection often require additional tests to establish the diagnosis.

Diagnostic Imaging

Depending on the clinical setting, imaging studies may be both appropriate and necessary to the work-up of an oral lesion. Additional information on this topic is available in an excellent radiology text edited by White and Pharoah.³ Briefly, imaging studies can include plain radiographic films, sialography, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), radionuclide imaging, and positron emission tomography (PET).

Plain Films For evaluation of bone lesions, plain films are the most commonly employed imaging modality and, together with CT, are often the most useful. With the increased use of panoramic radiographs as a screening study in many current dental practices, it is not unusual for these films to detect a previously unidentified skeletal abnormality. Evaluation of such a lesion includes an assessment of features such as localization (single, multifocal, generalized), margins (well defined, poorly defined), internal structure (radiolucent, radiopaque, mixed), effects on surrounding structures (teeth, inferior alveolar canal, cortical bone), and whether there have been any associated symptoms. For example, a single radiolucent lesion at the apex of a nonvital tooth most likely represents a periapical cyst or granuloma.

A similar-appearing radiolucency below the level of the inferior alveolar canal in the posterior mandible more likely represents a Stafne defect. Sharply defined margins indicate a benign process in most instances, whereas poorly defined margins can sometimes signify malignancy. Notable exceptions to this rule include osteomyelitis and fibrous dysplasia, both of which typically have borders that blend with the surrounding bone. Radiolucent lesions are produced by conditions that do not generate a calcified product. Radiopaque and mixed lesions represent conditions that can produce a mineralized product, such as bone, cementum, dentin, or enamel. It is generally safe to assume that the vast majority of lesions associated with the crown of an impacted tooth are odontogenic in origin. If the teeth are erupted, however, determining whether a lesion is of odontogenic origin can be problematic since there are few areas in the jaws in which a 2 cm lesion does not appear to be tooth-related. Symptoms such as pain or paresthesia may suggest infection or malignancy, but benign conditions can occasionally present in this fashion.

Sialography Sialography has almost become a lost art. This technique relies on retrograde injection of a radiopaque fluid, also known as contrast medium, into the duct system of either the parotid or submandibular salivary gland. A plain radiograph is made, and the pattern of distribution of the contrast medium is assessed. Many of the previous indications for sialography such as evaluation of salivary gland neoplasia have been supplanted by newer imaging modalities such as MRI. Nonetheless, sialography can be useful in assessing chronic obstructive salivary gland disease and gland function. The characteristic sialographic finding of punctate sialectasis (“blossoms on a branchless tree” pattern) seen in patients affected by Sjögren’s syndrome is helpful in supporting that diagnosis.

Ultrasonography Ultrasonography is most useful in the evaluation of deeply seated masses and is often helpful in distinguishing a solid mass from one that is cystic. This technique relies on the fact that different tissue densities result in different degrees of reflection or echo production of a beam of high-frequency sound waves. Although ultrasonography does not expose the patient to ionizing radiation, the tissue resolution is typically less than that achieved with either CT or MRI technology.

CT CT is a cross-sectional radiologic imaging technique that is particularly useful in the evaluation of bone lesions. Not only can the density and margins of the lesion in question be evaluated with this technique but cortical expansion and fine internal details can often be more readily appreciated compared with plain film images. Use of contrast media has extended the utility of this technique in areas of soft tissue pathology. Furthermore, more recent designs such as spiral CT scanners have made data acquisition much more rapid and have reduced radiation dose to the patient while maintaining or improving resolution.

MRI MRI is a newer form of cross-sectional imaging that does not expose patients to ionizing radiation. Although primarily used in the evaluation of soft tissue lesions, it is also capable of providing diagnostic information regarding bony lesions. Two distinct views are typically generated: T1 and T2. Adipose tissue has the highest signal in the T1-weighted image, and this view is often used for identifying anatomic structures. By comparison, the T2 image highlights tissues with high water content and is especially useful in depicting inflammatory processes and neoplasms.

Radionuclide Imaging Radionuclide imaging relies on the specific uptake of any one of several isotopes by various

types of tissues or cells. Localization of the isotope is determined by examining the patient with a gamma scintillation camera. The most commonly used isotope, technetium 99m pertechnetate, can demonstrate areas of high metabolic activity. It is useful in identifying inflammatory conditions such as osteomyelitis, areas of active skeletal lesions of fibrous dysplasia or osteitis deformans, and metastatic disease.

PET Scan PET scan is the most recently developed cross-sectional imaging technology. This technique relies on the identification of metabolically active cells, such as metastatic deposits of squamous cell carcinoma, that exhibit preferential uptake of radionuclide-labeled glucose. In conjunction with CT/MRI, preoperative PET imaging of patients with head and neck cancer has led to increased sensitivity and specificity for detection of oral cavity carcinoma, esophageal carcinoma, and clinically occult metastatic disease in the neck.⁴⁻⁸ PET scans have proved particularly useful in the post-treatment follow-up by helping to distinguish altered anatomic landmarks or areas of fibrosis from recurrent tumor as well as the detection of distant metastases from head and neck primaries.⁶⁻⁸ The technique is not recommended for neoplasms that are relatively inactive metabolically (eg, low-grade mucoepidermoid carcinoma). In addition, the lower limit of tumor mass detection by current technology is no better than that of CT/MRI, and false-positives owing to inflammatory changes are reported.

Analysis of Lesional Tissue: Histopathologic, Immunopathologic, and Molecular Evaluation

In a large number of cases, the final diagnosis depends on the results of histopathologic examination of lesional tissue. In some situations the diagnosis is straightforward, whereas in others a definitive diagnosis cannot be made until sophisticated immunohistochemical or

complementary DNA studies are performed. As with imaging, a variety of techniques are available to the pathologist, and their selection varies on a case-by-case basis, depending on the diagnostic challenges posed by the individual patient specimen.

Exfoliative Cytology Exfoliative cytology is a relatively inexpensive noninvasive technique that may be used to provide additional information related to lesions of surface origin. The utility of this technique in the diagnosis of conditions such as candidiasis, herpesvirus (herpes simplex virus, human herpesviruses 1 and 2) infections, and pemphigus vulgaris is well documented.

More recently a modified form of cytologic sampling that employs an oral brush instrument to collect epithelial cells followed by automated histopathologic evaluation has been introduced to dentistry. Suggested advantages include improved sampling of all epithelial layers and increased sensitivity and specificity in the detection of precancerous and cancerous lesions versus results with routine exfoliative cytology. This new technique does not provide a definitive diagnosis, however, and cannot be used as a substitute for scalpel biopsy and routine histopathologic examination (see below). Therefore, in a clinical setting where the index of suspicion for possible precancerous or cancerous change is high, such as the high-risk areas for oral cancer (ie, ventrolateral tongue, floor of mouth, tonsillar pillars, soft palate), or in a patient with significant risk factors (ie, heavy smoking, heavy alcohol use, or both), use of brush cytology would not be recommended due to the inherent delay in definitive diagnosis of the lesional tissue and any subsequent treatment. In cases in which a persistent mucosal lesion is identified but the index of suspicion is low, the brush cytology technique may be useful in excluding the presence of precancerous or malignant

epithelial changes. For such innocuous lesions, a finding of abnormal cells could trigger scalpel biopsy (and definitive diagnosis) before the surgical procedure might otherwise have been deemed necessary.

Fine-Needle Aspiration Fine-needle aspiration (FNA) is a useful method for evaluating subcutaneous or more deeply situated mass lesions, although obtaining a diagnostic sample and interpreting the results accurately requires specialized training. This type of procedure is most widely used in determining the nature of salivary gland or neck masses. Currently FNA is available in most large urban areas throughout the United States, usually in conjunction with tertiary care medical centers.

Incisional Biopsy Incisional biopsy is generally indicated for large lesions (> 2 cm) and those that could represent unencapsulated or potentially malignant neoplasms. By definition an incisional biopsy is a diagnostic surgical procedure in which a sample or portion of a lesion is removed for histopathologic review, leaving the remainder of the lesion at the biopsy site. In cases of suspected malignancy, an incisional biopsy is usually the procedure of choice unless the clinician performing the biopsy will also be involved in definitive treatment of the cancer (see below).

Excisional Biopsy Excisional biopsy is typically used to manage clinically benign lesions that are < 2 cm in diameter. An excisional biopsy is defined as a diagnostic surgical procedure in which all clinically abnormal tissue is removed for microscopic analysis. Excision of a small but potentially malignant lesion (eg, squamous cell carcinoma with a primary tumor [T], regional nodes [N], and metastasis [M] staging of T1N0M0) may be appropriate in settings in which the surgeon performing the biopsy is also responsible for final treatment. With rare exceptions, an excisional biopsy should not be performed on a sus-

pected malignant lesion unless the performing clinician is involved in definitive treatment. Otherwise, the surface mucosa may be completely healed by the time the patient is referred to the oncologist, obscuring the extent of the original lesion and unnecessarily hindering definitive treatment planning.

Specimen orientation is recommended whenever a clinician suspects that a neoplastic process may have recurrent or malignant potential, including conditions such as epithelial dysplasia or pleomorphic adenoma. This can be accomplished by careful identification of the anatomic margins of the biopsy specimen with suture(s), an accompanying sketch of the specimen, and its orientation to the surrounding tissues or both. Such anatomic orientation of the tissue sample allows the pathologist to properly subdivide and process the specimen so that the adequacy of excision can be assessed at all surgical margins. The terms *negative* or *clear margins* are used when the surgical margins appear free from tumor involvement. When tumor is transected or lies immediately adjacent to the surgical margin without evidence of a capsule, proper specimen orientation permits the location of the *positive margin(s)* to be determined as precisely as possible. With this information the surgeon can then plan the most conservative surgical approach that will also accomplish the primary goal of therapy: complete removal of residual neoplastic tissue.

Specimen Information Although obtaining an adequate biopsy specimen is an important result of proper surgical technique, proper diagnostic technique requires that the surgeon also transmit adequate clinical information to the pathologist through use of the specimen or biopsy data sheet. Inflammatory, reactive, and even neoplastic conditions can have overlapping histopathologic features that are difficult (if not impossible) to distinguish without an adequate description of

the clinical setting. Lacking this information, the pathologist may not be able to provide a completely accurate or specific diagnosis. Pertinent details from the medical or dental history, the history of the lesion, the location and physical characteristics of the lesional tissue, and, when applicable, the radiographic features can assist with the histopathologic analysis. Clinical findings at the time of biopsy can also provide essential information. A good example is the discovery of an empty cavity during the exploration of a radiolucent lesion of bone. This situation often means that only minimal tissue can be submitted for review; however, the operative finding is virtually pathognomonic for traumatic bone cyst. Quality close-up clinical photographs including digital images can be helpful, particularly for specialists who have dental training such as oral and maxillofacial pathologists. Biopsies of bony pathology should be accompanied by radiographs (originals or copies), whenever possible, as correlation may be needed to help distinguish conditions such as fibrous dysplasia, ossifying fibroma, and focal cemento-osseous dysplasia.

A final piece of information that should always be submitted together with the biopsy specimen is the clinical diagnosis. The clinical diagnosis is important at two levels. First, it helps the pathologist by providing an educated “best guess” as to what the lesional tissue was thought to most likely represent by the clinician. Should the initial histopathology of the submitted specimen appear substantially different from the clinical diagnosis, the pathologist may request deeper sections, rotation of the specimen, or special studies to ensure that all aspects of the biopsy material have been thoroughly examined. Second, in cases where the final histopathologic diagnosis varies significantly from the working diagnosis, it is the clinician who should proceed cautiously. After discussing the case directly with the sign-out pathologist, the surgeon may be

satisfied with the unexpected diagnosis and plan accordingly. If not, the clinician may request a second opinion on the original biopsy material or choose to perform a second biopsy procedure. In essence, the clinical diagnosis serves as a “litmus test” for both the pathologist and surgeon, an important function that ultimately benefits the patient.

For the oral and maxillofacial surgeon, this type of discordance may be minimized if the tissue specimen is initially reviewed by an oral and maxillofacial pathologist. The oral and maxillofacial pathologist receives highly specialized training in the pathology of the head and neck, including odontogenic cysts and tumors and salivary gland diseases. The typical general surgical pathologist, by comparison, has a modest degree of experience with respect to oral conditions and may be unfamiliar with the unique microscopic features of lesions from this area. To give some perspective, individuals trained in oral and maxillofacial pathology programs review tens of thousands of oral biopsy specimens prior to graduation. By contrast, it is unusual for general surgical (anatomic) pathology residents to examine more than a few hundred specimens from the orofacial region during their training. Furthermore, the oral and maxillofacial pathologist has a command of the terminology used by the dental profession to describe oral disease and can more readily correlate the clinical and radiographic features with the microscopic findings. Just as a general surgeon may be able to remove a set of impacted third molars, the general pathologist may be able to provide an adequate diagnosis for an oral biopsy. In most situations, however, the professionals who are trained specifically to manage problems related to the oral and maxillofacial region are able to accomplish their respective tasks more efficiently and accurately.

The Microscopic Differential Diagnosis

On occasion a final diagnosis cannot be made after examining routine hematoxylin and eosin-stained sections of a lesion. In such a situation, the pathologist is faced with a *microscopic* or *histopathologic differential diagnosis*. For some cases, special chemical stains may be useful in the detection of suspected microorganisms or the identification of tissue products such as mucin or amyloid. In other cases, particularly spindle-cell malignancies and a group of undifferentiated neoplasms termed small blue-cell tumors, the final diagnosis can be even more challenging. Thankfully, even though these tumors may appear undifferentiated at the light microscopic level, they often continue to produce molecules that relate either to their cellular origin or to their newly acquired form of differentiation. To more accurately classify such tumors, these molecular products of origin or differentiation are routinely assessed in the lesional cells through the use of *immunohistochemical* (IHC) studies. These techniques employ a wide variety of monoclonal and polyclonal antibodies that are directed against specific cellular or integrated viral antigens (eg, those produced by the Epstein-Barr virus) that are usually expressed even in otherwise “undifferentiated” neoplasms. The antibodies are linked to an enzyme that is capable of cleaving a selected chemical substrate. This activity produces a pigmented product (often brown; hence the term “brown stains”) that is deposited in the tissues wherever the target antigens are expressed. The diagnosis of a particular tumor often requires the analysis of a number of antigens to fully explore the histopathologic differential. In cases of malignant lymphoma, for example, it is not uncommon for a panel of 10 or more “probes” to be used to characterize the neoplastic process and permit a therapy that is optimized for that particular tumor.

Although routine formalin-fixed paraffin-embedded tissue sections can

generally be used to perform most IHC studies, an important exception involves tumors that require analysis by *flow cytometry*. Typically used to permit rapid and highly specific subclassification of lymphomas and leukemias, flow cytometry employs IHC probes, but the tissue samples must not be fixed and should be analyzed immediately following collection. Another exception to this rule concerns the definitive diagnosis of immunobullous disorders such as cicatricial pemphigoid. When such conditions are considered within the differential, perilesional tissue should be obtained and submitted in a special holding medium known as Michel’s solution (Michel’s Media). A holding medium is necessary because the molecular structure of the diagnostic antigens in these conditions (eg, immunoglobulins, complement, and fibrinogen) is usually destroyed by formalin fixation. These specimens are processed as frozen sections and are evaluated by DIF, a special form of IHC that employs antibodies tagged with fluorescent markers. When a special ultraviolet-capable microscope is used, these markers reveal the presence and pattern of immunoreactants necessary to confirm or refute a potential autoimmune disease process. *Indirect immunofluorescence* (IIF) is used for conditions such as pemphigus vulgaris, in which elevated levels of circulating autoantibody are often seen. For indirect immunofluorescent studies, patient serum is incubated with a segment of control substrate (typically monkey esophagus). The serum is removed and the substrate is then incubated with antibody probes similar to those used in DIF studies. As with DIF, ultraviolet microscopy is used to examine the substrate for evidence of serum-derived antibody binding to epithelial or basement membrane components.

In a few instances even the more sophisticated immunohistochemical techniques cannot provide a definitive diagnosis. In those situations newly developed *molecular techniques* are being used with

greater frequency. These techniques include sophisticated cytogenetic studies such as *fluorescence in situ hybridization* (FISH) as well as molecular probes that use complementary deoxyribonucleic acid (cDNA) to identify disease-specific DNA sequences in human tissue samples. Examples include restriction fragment length polymorphism analysis with Southern blot or antigen receptor gene rearrangement analysis by polymerase chain reaction for the determination of clonality in B- or T-cell proliferations.

Patient Follow-Up

One of the most important aspects in the diagnosis and management of a given oral lesion or condition is the follow-up evaluation. This appointment permits the clinician to assess the abnormality for physical or symptomatic changes, gain insight into the kinetics of growth or rate of resolution, and assess the impact of initial conservative treatment measures or recommendations to the patient. These additional pieces of information may support the working diagnosis, and no further work-up may be required (see Figure 29-1). Alternatively, the follow-up findings may indicate that further investigation of

the differential considerations is warranted such as biopsy and histopathologic review. Finally, careful follow-up should be considered mandatory for patients who have been previously diagnosed with or treated for oral dysplasia or carcinoma.

Although an important part of the practice of dentistry and medicine, formal guidelines for the management of oral lesions that are not clearly premalignant or cancerous have only recently been suggested.⁹ Such guidelines are helpful to clinicians as they provide systematic protocols for the management of oral pathologic conditions and serve to reduce the medicolegal risk associated with this important aspect of patient care (Table 29-1).

After the initial evaluation and careful documentation of an oral lesion, a follow-up examination should be scheduled for 7 to 14 days later, with or without any treatment. If there is evidence of lesion enlargement or other physical or symptomatic changes that do not suggest normal healing or resolution, then biopsy is indicated. If the lesion remains relatively unchanged and the index of suspicion for malignancy is low, the clinician should help the patient decide the next course of action based upon experience, advanced training, or

both. Whenever available, referral to an oral and maxillofacial pathologist may be helpful in this regard. If the patient and clinician decide to defer biopsy, this decision should be documented and re-evaluation of the area should be scheduled at 1, 3, 6, and 12 months following the initial examination. During the follow-up period, diagnostic options include the brush cytology technique (to identify evidence of atypical epithelial cells in surface lesions) or incisional biopsy (to establish a firm diagnosis). The need for these options varies depending on the concerns of the patient or the experience and expertise of the clinician. At any time point, however, evidence of significant lesional change should immediately trigger a recommendation of biopsy. After a year most unchanged lesions can be monitored at routine semiannual or annual dental visits.

Finally, it should be recognized that these recommendations, although sound, do not represent rigid guidelines or medicolegal standards of care that cover every clinical scenario. Each patient and abnormality deserves individual attention and management that may vary from the protocol above, based upon training, experience, and the clinical judgement of the practitioner.

Table 29-1 Follow-Up Protocol for Oral Pathology

1. Initial re-evaluation: 7–14 d following lesion detection/examination
2. If no evidence of lesional progression or suspicious clinical alterations, reevaluate at 1, 3, 6, and 12 mo intervals; thereafter, re-examine in conjunction with normal recall visits (every 6–12 mo)
3. If lesional progression or suspicious clinical changes noted, incisional or excisional biopsy should be performed as soon as possible, and specimen should be reviewed by oral and maxillofacial pathologist
4. If no evidence of preneoplastic change (dysplasia) or malignancy (carcinoma or sarcoma) reported, schedule follow-up as in step 2 and document subsequent findings in patient record
5. When diagnosis of dysplasia (pre malignancy) or malignancy is reported, refer or schedule immediately for appropriate work-up and therapy; following definitive treatment, begin follow-up evaluations as in step 2 or similar protocol

Odontogenic Cysts and Tumors

Eric R. Carlson, DMD, MD

Odontogenic cysts and tumors are relatively uncommon lesions of the oral and maxillofacial region that must be considered whenever examining and formulating a differential diagnosis of an expansile process of the jaws. The clinical presentation, radiographic appearance, and natural history of these lesions varies considerably, such that odontogenic cysts and tumors represent a diverse group of lesions of the jaws and overlying soft tissues. Collectively speaking, their occurrence is frequent enough to warrant a thorough discussion. As a whole, these pathologic entities have been studied and reported on extensively.

Purely defined, *odontogenic* refers to derivation from a tooth-related apparatus. Tooth formation is a complex process that involves both connective tissues and epithelium. Three major tissues are involved in odontogenesis including the enamel organ, the dental follicle, and the dental papilla. The enamel organ is an epithelial structure that is derived from oral ectoderm. The dental follicle and dental papilla are considered ectomesenchymal in nature because they are in part derived from neural crest cells.

For each tooth, odontogenesis begins with the apical proliferation from the oral mucosa of epithelium known as the dental lamina (Figure 30-1). The dental lamina, in turn, gives rise to the enamel organ, a cap-shaped structure that subsequently

evolves into a bell shape. After forming the enamel organ, the cord of dental lamina normally fragments and degenerates; however, small islands of the dental lamina may remain after tooth formation and are believed to be responsible for the development of several of the odontogenic cysts and tumors.

The enamel organ has four types of epithelium. The innermost lining is referred to as the inner enamel epithelium and becomes the ameloblastic layer that forms tooth enamel. The second layer of cells adjacent to the inner enamel epithelium is the stratum intermedium. Adjacent to this layer is the stellate reticulum, followed by the outer enamel epithelium. Surrounding the enamel organ is loose connective tissue known as the dental papilla. Contact with the enamel organ epithelium induces the dental papilla to make odontoblasts that form dentin. As the odontoblasts deposit dentin, they induce the ameloblasts to begin forming enamel.

Following the initial formation of the crown, a thin layer of the enamel organ epithelium known as Hertwig's root sheath proliferates apically to provide the stimulus for odontoblastic differentiation in the root portion of the developing tooth. This epithelial extension later becomes fragmented but leaves behind small nests of epithelial cells known as rests of Malassez in the periodontal ligament space. The rests of Malassez are

FIGURE 30-1 The enamel organ is seen emanating from the dental lamina (hematoxylin and eosin; original magnification $\times 20$) Reproduced with permission from Cawson RA, Eveson JW, editors. *Oral pathology and diagnosis. Color atlas with integrated text.* Philadelphia (PA): W.B. Saunders; 1987.

believed to be the source of epithelium for most periapical cysts but generally are not believed to give rise to any of the odontogenic neoplasms, with the possible exception of the squamous odontogenic tumor.

In the development of a tooth, following completion of enamel formation, the

enamel organ epithelium atrophies to form a thin flattened layer of cells that covers the enamel of the unerupted tooth. This layer of epithelium is known as the reduced enamel epithelium. In the normal sequence of events, this reduced enamel epithelium later merges with the surface epithelium and forms the initial gingival crevicular epithelium of the newly erupted tooth. However, if fluid accumulates between the reduced enamel epithelium and the crown of the tooth before tooth eruption, a cyst is formed that is known as a dentigerous or follicular cyst.

An understanding of the progression of odontogenic cysts and tumors within the oral and maxillofacial region requires a thorough knowledge of the cell cycle of these lesions and an appreciation of the concept of proliferation versus apoptosis (programmed cell death). Most of the pathogenetic mechanisms of odontogenic cysts and tumors can be explained via the cell cycle (Figure 30-2). Normally cell division is divided into four phases: G₁ (gap 1), S (deoxyribonucleic acid synthesis), G₂ (gap 2), and M (mitosis). A key event is the progression from G₁ to the S phase. Genetic alterations, if unrepaired in the G₁

phase, may be carried into the S phase and perpetuated in subsequent cell divisions. The G₁-S checkpoint is normally regulated by a well-coordinated and complex system of protein interactions whose balance and function are critical to normal cell division.¹ As can be seen in Figure 30-2, once genetic change occurs that encourages the development of an odontogenic cyst or tumor, a series of events mediated by the odontogenic lesion occur that may promote proliferation. Such events support the pathogenetic mechanism involved in the progression of the cyst or tumor.

It is the purpose of this chapter to review the clinically significant and more commonly encountered odontogenic cysts and tumors. In so doing, salient clinical and radiographic features are discussed, as are the pathogenetic mechanisms supporting proliferation of some of the more aggressive odontogenic cysts and tumors. Recommendations for treatment and prognostic information are also offered.

Odontogenic Cysts

With rare exceptions, epithelium-lined cysts in bone are seen only in the jaws.² Other than a few cysts that may result

from the inclusion of epithelium along embryonic lines of fusion, most jaw cysts are lined by epithelium that is derived from odontogenic epithelium, hence the term *odontogenic cysts*. These cysts are subclassified as developmental or inflammatory in nature. Although the cell type is often known, developmental cysts are of unknown origin; however, they do not seem to be the result of an inflammatory reaction. Inflammatory cysts, on the other hand, are the result of inflammation (Table 30-1).

Dentigerous Cyst

By definition, a dentigerous cyst occurs in association with an unerupted tooth, most commonly mandibular third molars. Other common associations are with maxillary third molars, maxillary canines, and mandibular second premolars.² They may also occur around supernumerary teeth and in association with odontomas; however, they are only rarely associated with primary teeth.^{2,3} Although dentigerous cysts occur over a wide age range, they are most commonly seen in 10- to 30-year-olds. There is a slight male predilection, and their prevalence appears to be higher in Whites than in Blacks. Many dentigerous cysts are small asymptomatic lesions that are discovered serendipitously on routine radiographs, although some may grow to considerable size causing bony expansion that is usually painless until secondary infection occurs.

Radiographically, the dentigerous cyst presents as a well-defined unilocular radiolucency, often with a sclerotic border (Figure 30-3). Since the epithelial lining is derived from the reduced enamel epithelium, this radiolucency typically and preferentially surrounds the crown of the tooth. A large dentigerous cyst may give the impression of a multilocular process because of the persistence of bone trabeculae within the radiolucency. However, dentigerous cysts are grossly and histopathologically unilocular processes

FIGURE 30-2 The cell cycle—a concept of proliferation versus apoptosis. PCNA = proliferating cell nuclear antigen.

and probably are never truly multilocular lesions.² Three types of dentigerous cyst have been described radiographically, including the *central* variety, in which the radiolucency surrounds just the crown of the tooth, with the crown projecting into the cyst lumen. In the *lateral* variety, the cyst develops laterally along the tooth root and partially surrounds the crown. The *circumferential* variant of the dentigerous cyst exists when the cyst surrounds the crown but also extends down along the root surface, as if the entire tooth were located within the cyst.

FIGURE 30-3 This unilocular radiolucency of the left mandibular ramus associated with impacted tooth no. 17 was discovered serendipitously when the patient was evaluated for routine dental work.

One diagnostic dilemma for oral and maxillofacial surgeons is distinguishing between a dentigerous cyst and an enlarged dental follicle. This distinction becomes clinically significant when the surgeon considers whether to submit tissue removed with an impacted third molar for histopathologic examination as opposed to clinical designation as a follicle, with simple disposal of the tissue. The radiographic distinction becomes somewhat arbitrary; however, any pericoronal radiolucency that is > 4 or 5 mm is considered suggestive of cyst formation and should be submitted for microscopic examination. It is noteworthy that pathologists also struggle with the distinction between dental follicles associated with developing teeth and odontogenic lesions.^{4,5} It seems that odontogenic cysts, odontogenic fibroma, and odontogenic myxoma are the lesions most often inappropriately diagnosed by surgical pathologists owing to a general unfamiliarity with the normal process of odontogenesis.⁴

Of perhaps even greater concern is the large unilocular radiolucency. Although most commonly classified radiographically as dentigerous cysts, it is incumbent upon the surgeon to section these excised specimens in the operating room and to consider frozen-section analysis. In fact, some specimens may contain a focus of unicystic ameloblastoma and therefore require consideration of more extensive treatment.

The histologic features of dentigerous cysts may vary greatly depending mainly on whether or not the cyst is inflamed. In the noninflamed dentigerous cyst, a thin epithelial lining may be present with the fibrous connective tissue wall loosely arranged (Figure 30-4). In the inflamed dentigerous cyst, the epithelium commonly demonstrates hyperplastic rete ridges, and the fibrous cyst wall shows an inflammatory infiltrate.

Treatment and Prognosis Most dentigerous cysts are treated with enucleation of the cyst and removal of the associated

FIGURE 30-4 The biopsy of the radiolucency in Figure 30-3 shows an atrophic stratified squamous epithelium without significant associated inflammation. The diagnosis is dentigerous cyst (hematoxylin and eosin; original magnification $\times 40$).

tooth, often without a preceding incisional biopsy (Figure 30-5). Larger cysts that are treated in the operating room should probably undergo frozen-section diagnosis and appropriate treatment that might be dictated by other diagnoses. Curettage of the cyst cavity is usually advisable at the time of removal of the cyst in the event that a more aggressive cyst is diagnosed histopathologically following removal in an office setting. Such diagnoses would include odontogenic keratocyst and unicystic ameloblastoma.

Large dentigerous cysts may be treated with marsupialization (Figure 30-6) when enucleation and curettage might otherwise result in neurosensory dysfunction or predispose the patient to an increased chance of pathologic fracture. Some patients who are not candidates for general anesthesia may also be treated with a marsupialization procedure in an office setting under local anesthesia. This permits decompression of the large dentigerous cyst with a resultant reduction in the size of the cyst and bony defect. At a later date the reduced cyst can be removed in a smaller-scale surgery.

I emphasize the need for histopathologic examination of all radiolucencies that are empirically diagnosed as dentigerous cysts. This includes those that are enucleated as well as those that undergo marsupialization, during which it is important to inspect the cyst lumen and submit a

FIGURE 30-5 A, The dentigerous cyst in Figure 30-3 is treated with enucleation and curettage of the cyst and removal of the etiologic tooth. B, The 5-year postoperative radiograph shows an acceptable bony fill.

representative piece for histopathologic examination. Support of this statement stems from the occasional formation of a squamous cell carcinoma, mucoepidermoid carcinoma, or ameloblastoma from or in association with a dentigerous cyst.⁶⁻⁸ The prognosis for most histopathologically diagnosed dentigerous cysts is excellent, with recurrence being a rare finding.

Odontogenic Keratocyst

The odontogenic keratocyst is a distinctive form of developmental odontogenic cyst that deserves special consideration because of its specific histopathologic features and aggressive clinical behavior. Two variants of

this cyst are well known; the sporadic cyst and the cyst associated with the nevoid basal cell carcinoma syndrome. Both variants of the odontogenic keratocyst are believed to be derived from remnants of the dental lamina. This cyst shows a different growth mechanism and biologic behavior from the previously described dentigerous cyst. Most authors believe that dentigerous cysts continue to enlarge as a result of increased osmotic pressure within the lumen of the cyst. This mechanism does not appear to hold true for odontogenic keratocysts, and their growth may be related to unknown factors inherent in the epithelium itself or enzymatic activity in the fibrous wall.⁹

Adequate diagnosis and treatment of the odontogenic keratocyst is important for three reasons: (1) this cyst is recognized as being more aggressive than other odontogenic cysts,¹⁰ (2) the odontogenic keratocyst has a higher rate of recurrence than other odontogenic cysts,¹¹ and (3) the association with nevoid basal cell carcinoma syndrome requires that the clinician examine a patient with multiple cysts of the jaws for physical findings that might diagnose this syndrome.¹²⁻¹⁴

Odontogenic keratocysts may be found in patients ranging in age from infancy to old age; however, 60% of cases are seen in people between 10 and 40 years old.¹⁵ In his series of 312 cases, Brannon found a mean age of nearly 38 years.¹⁶ The peak prevalence was in the second and third decades of life, with only 15% occurring past the age of 60 years. Woolgar and colleagues reviewed 682 odontogenic keratocysts from 522 patients and found a mean age of 40 years for patients with single nonrecurrent cysts and 26.2 years for patients with multiple cysts of the nevoid basal cell carcinoma syndrome.¹⁷ A slight male predilection is usually seen, and 60 to 80% of cases involve the mandible, particularly in the posterior body and ascending ramus.² Although it is rare for a dentigerous cyst to appear multilocular on radiographs, it is most common for odontogenic keratocysts to appear multilocular (Figure 30-7). Many

FIGURE 30-6 A, This large biopsy-proven dentigerous cyst occurred in an elderly patient who had coronary artery disease. Owing to the size of the cyst and the compromised cardiac status of the patient, a relatively noninvasive marsupialization was performed. B, An acrylic plug with a wire handle was placed in a small surgical entrance into the cyst cavity. The cyst shrunk considerably, after which time the etiologic impacted tooth was removed with a small remnant of dentigerous cyst. C, The 5-year postmarsupialization radiograph shows an excellent fill of bone.

FIGURE 30-7 This multilocular radiolucency, present in a 54-year-old man, should suggest an odontogenic keratocyst when formulating a differential diagnosis.

appear unilocular and can therefore be confused with dentigerous cysts. It is clear, therefore, that the differential diagnosis of a unilocular radiolucency must include both entities and that treatment should include curettage in the event that the diagnosis is odontogenic keratocyst. When multiple multilocular radiolucencies are noted on a panoramic radiograph, the clinician must perform an incisional biopsy and investigate the possibility of nevoid basal cell carcinoma syndrome (Table 30-2).

Histologically, the odontogenic keratocyst is readily recognized. A uniform layer of stratified squamous epithelium, usually six to eight cells in thickness, is present (Figure 30-8). The parakeratotic surface is characteristically corrugated. The wall is usually thin and friable, which can pose problems for removal in one piece intraoperatively. Epithelial budding and the presence of daughter cysts may be noted in the connective tissue wall. It is generally advisable to ask the pathologist to examine the sections carefully for these two features as they generally impart a more aggressive character to the cyst.

Treatment and Prognosis Like the treatment of most odontogenic cysts, the odontogenic keratocyst may be treated with enucleation and curettage and must

be removed in one piece, which requires acceptable access and lighting (Figure 30-9). As such, many patients are suitably treated in an operating room setting under general anesthesia. This is particularly helpful when removing large cysts. It is my experience and that of others that a large majority of sporadic odontogenic keratocysts may be effectively managed with a thorough enucleation and curettage surgery.^{18,19} MacIntosh has advocated the resection of odontogenic keratocysts with 5 mm linear margins as the preferred primary method of treatment, and has reported on 37 patients with 43 lesions emphasizing the efficacy and superior

results of resection over all other therapeutic undertakings.²⁰

The reported frequency of recurrence of the odontogenic keratocyst ranges from 2.5% to 62.5% in various studies.¹¹ This wide variation may be related to the total number of cases studied, the length of follow-up periods, and the inclusion or exclusion of orthokeratinized cysts in the study group. Several reports that include large numbers of cases indicate a recurrence rate of approximately 30%.² Regezi and colleagues point out that the recurrence rate for solitary odontogenic keratocysts is 10 to 30%.²¹ They indicate that approximately 5% of patients with odontogenic keratocysts have multiple sporadic jaw cysts (nonsyndromic) and that their recurrence rate is greater than that for solitary lesions.²¹ Brannon has suggested three mechanisms responsible for recurrence: (1) remnants of dental lamina within the jaws not associated with the original odontogenic keratocyst being responsible for de novo cyst formation; (2) incomplete removal (persistence) of the original cyst secondary to a thin friable lining and cortical perforation with adherence to adjacent soft tissue; and (3) remaining rests of dental lamina and satellite cysts following enucleation.²² Vedtofte and Praetorius reviewed 72 patients with 75 odontogenic keratocysts and observed remnants of dental lamina between the cyst membrane

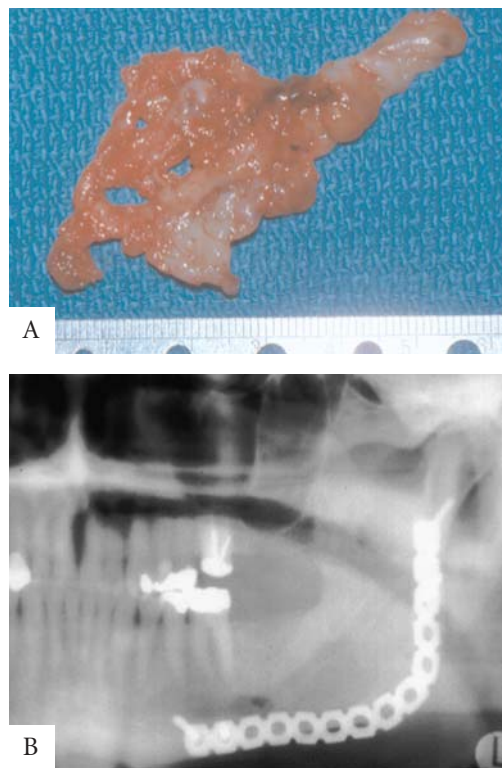

FIGURE 30-9 A, A very thin cyst lining was encountered when performing the enucleation and curettage of the odontogenic keratocyst in Figure 30-7. B, The 7-year postoperative radiograph shows an excellent fill of bone. A reconstruction bone plate was placed at the time of the enucleation and curettage to prevent a pathological fracture of the mandible.

and overlying mucosa.²³ As such, they advocated the excision of overlying mucosa in conjunction with removal of the cyst. Williams and Connor recommended a primary enucleation and curettage surgery for odontogenic keratocysts, including the use of methylene blue as a marking agent, followed by a 3-minute application of Carnoy's solution.¹¹ They indicated that resection should be considered for the treatment of a recurrent odontogenic keratocyst, with inclusion of appropriate bone and soft tissue margins.

Pathogenetically, the odontogenic keratocyst expresses cell cycle phenomena that support its proliferation.²¹ These include the release of the cytokines interleukin 1a (IL-1a) and IL-6 as well as parathyroid hormone-related protein that encourage resorption of bone.^{21,24} Moreover, the

expression of proliferating cell nuclear antigen (PCNA) in odontogenic cysts has been assessed. It is hypothesized that the identification of the proliferative activity in odontogenic cysts and tumors may be useful to predict their biologic behavior. The same may be true of the Ki-67 antigen. In fact, two studies have been performed that have quantified these parameters.^{25,26} The conclusion of both studies is that an increased proliferative activity for the odontogenic keratocyst in comparison with the dentigerous cyst is noted consistently. These results are in agreement with the more aggressive behavior seen with the odontogenic keratocyst.

The orthokeratinized odontogenic cyst, once thought to be a variant of the odontogenic keratocyst, is now generally well accepted as being a different clinicopathologic entity from the more common parakeratinized odontogenic keratocyst; it should therefore be placed in a different category. These cysts usually appear as unilocular radiolucencies, but occasional examples have been multilocular. A majority of these cysts are encountered in a lesion that appears clinically and radiographically to represent a dentigerous cyst, most often involving an unerupted mandibular third molar tooth. Histologically, the epithelium is thin and orthokeratinized, and a prominent palisaded basal layer, characteristic of the odontogenic keratocyst, is not present. Enucleation and curettage of the orthokeratinized cyst is curative in most cases. The reported rate of recurrence of 2% is far lower than the previously quoted statistics for recurrence of the odontogenic keratocyst.²

Nevoid Basal Cell Carcinoma Syndrome

The nevoid basal cell carcinoma syndrome (basal cell nevus syndrome, Gorlin's syndrome) is an autosomal-dominant inherited condition that exhibits high penetrance and variable expressivity. It is caused by mutations in the *PTCH* tumor suppressor gene, mapped to chromosome

9q22.3-q31. Affected patients (Figure 30-10A) may demonstrate frontal and temporoparietal bossing, hypertelorism, and mandibular prognathism (see Table 30-2).¹⁴ Other frequent skeletal anomalies include bifid ribs and lamellar calcification of the falx cerebri (Figure 30-10B).¹⁴ The

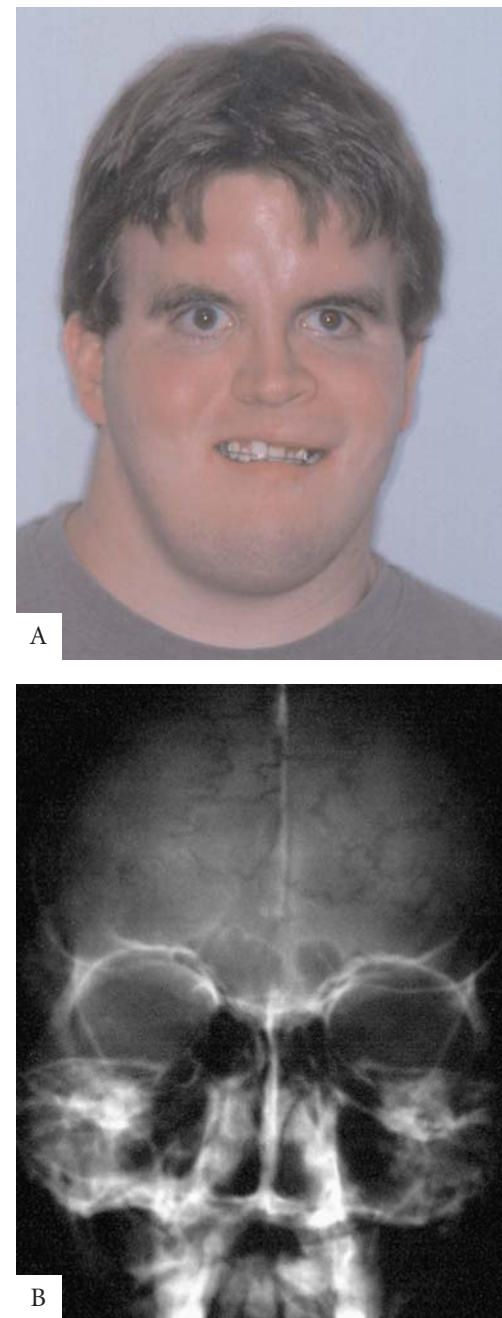

FIGURE 30-10 A, This 18-year-old shows some of the clinical features of the nevoid basal cell carcinoma syndrome including frontal bossing and mandibular prognathism. B, The radiograph from another patient shows a calcified falx cerebri.

most significant clinical feature is the tendency to develop multiple basal cell carcinomas that may affect both exposed and non-sun-exposed areas of the skin. Pitting defects on the palms and soles can be found in nearly two-thirds of affected patients (Figure 30-11). The discovery of multiple odontogenic keratocysts is usually the first manifestation of the syndrome that leads to the diagnosis. For this reason, any patient with an odontogenic keratocyst should be evaluated for this condition. Although the cysts in patients with nevoid basal cell carcinoma syndrome cannot definitely be distinguished microscopically from those not associated with the syndrome, they often demonstrate more epithelial proliferation and daughter cyst formation in the cyst wall.

The treatment of the odontogenic keratocyst in patients with nevoid basal

cell carcinoma syndrome can be difficult owing to the large number of “recurrences” in these patients. As a matter of point, I choose to refer to these as new primary cysts owing to the autosomal-dominant penetrance of the syndrome and cyst development. It is certainly possible that many of these cysts are persistent, particularly when considering how common it can be to retain rests of the dental lamina when enucleating an odontogenic keratocyst. Whatever the mechanism, a resection hardly seems to be warranted. Marsupialization is a more desirable procedure (Figure 30-12) and has been shown to result in complete resolution of the sporadic cyst, with no histologic signs of cystic remnants, daughter cysts, or budding of the basal layer of the epithelium.²⁷ Although all of the eight cases in the series by Pogrel and Jordan were sporadic cysts,²⁷ a similar approach to syndrome patients with odontogenic keratocysts that had been operated on multiple times has been performed with success in a small sample size.¹⁸

Glandular Odontogenic Cyst

The glandular odontogenic cyst (sialodontogenic cyst) is a rare and recently described cyst of the jaws that is capable

of aggressive behavior and recurrence. Although it is generally accepted as being of odontogenic origin, it shows glandular or salivary features that seem to point to the pluripotentiality of odontogenic epithelium as cuboidal/columnar cells, mucin production, and cilia are noted in these cysts. Glandular odontogenic cysts occur most commonly in middle-aged adults, with a mean age of 49 years at the time of diagnosis.² Eighty percent of cases occur in the mandible,²¹ and a strong predilection for the anterior region of the jaws has been reported, with many mandibular lesions crossing the midline (Figure 30-13). These cysts may appear either unilocular or multilocular radiographically.

There is a histologic similarity between the glandular odontogenic cyst and the predominantly cystic intraosseous mucoepidermoid carcinoma. However, the epithelial lining of the glandular odontogenic cyst is typically thinner and does not show evidence of the more solid or microcystic epithelial proliferations seen in mucoepidermoid carcinoma (Figure 30-14). Waldron and Koh reviewed the similarities between the two lesions and concluded that it is entirely possible that some cases previously diagnosed as central mucoepidermoid

FIGURE 30-11 Plantar pitting can be observed by immersing the foot in povidone-iodine solution followed by a conservative wash of the foot with saline. The solution is taken up in the pits present in the plantar surface of the foot.

FIGURE 30-12 The patient in Figure 30-10A had previously undergone three enucleation and curettage surgeries for bilateral maxillary odontogenic keratocysts. A, Development of new large cysts in this area led to additional treatment with marsupialization. B, Six months later the axial computed tomography shows regression of the cysts.

FIGURE 30-13 A and B, This glandular odontogenic cyst presented with a unilocular radiolucency of the anterior mandible crossing the midline.

tumors may be reclassified as examples of glandular odontogenic cysts.²⁸

Treatment and Prognosis Most glandular odontogenic cysts are treated with enucleation and curettage (Figure 30-15). Some authors, however, point to a recur-

FIGURE 30-14 Histopathology of the lesion in Figure 30-13 shows a nonkeratinized stratified squamous epithelium with intraepithelial mucous cells and cilia (hematoxylin and eosin; original magnification $\times 40$).

rence rate of approximately 30% and therefore recommend resection.²⁹

Calcifying Odontogenic Cyst

The calcifying odontogenic cyst (COC), or Gorlin's cyst, is an uncommon lesion that demonstrates considerable histopathologic diversity and variable clinical behavior. Although designated as a cyst, some investigators provide evidence for subclassification as a neoplasm as well.^{30,31} In addition, the COC may be associated with other recognized odontogenic tumors, most commonly the odontoma. Adenomatoid odontogenic tumors and ameloblastomas have also been associated with the COC. Ghost cell keratinization, the characteristic microscopic feature of this cyst, is also a defining feature of the cutaneous lesion known as the calcifying epithelioma of Malherbe or pilomatixoma. The World Health Organization's classification of odontogenic tumors groups the COC with all its variants as an odontogenic tumor rather than an odontogenic cyst. The commentary on the second edition by Kramer, Pindborg, and Shear points out that some COCs appear to be non-neoplastic, but others show an infiltrative pattern of growth.³² They further indicate that more experience with the COC may provide reliable criteria for their reclassification. The review by Hong and colleagues designated 79 of 92 cases of COC as cysts with the remaining 13 cases being non-neoplastic in nature.³⁰

The COC is predominantly an intraosseous lesion, although 13 to 30% of reported cases occur as peripheral lesions.² Both the peripheral and central lesions occur with about equal frequency in the maxilla and mandible. There appears to be a predilection for the incisor and canine areas. Patients range in age from infant to elderly, with a mean age of occurrence of about 30 years. COCs that are associated with odontomas tend to occur in younger patients, with a mean age of 17 years.² The more rare neoplastic variant of the COC appears to occur in elderly patients. Most

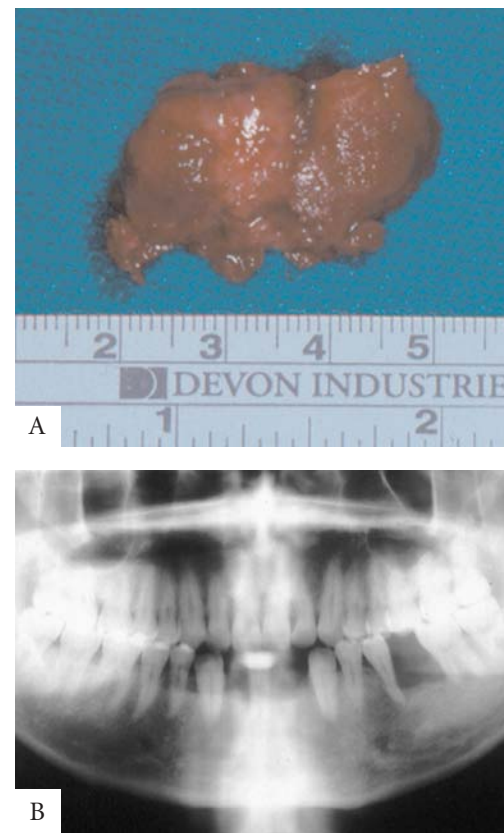

FIGURE 30-15 A, The patient whose radiograph appears in Figure 30-13 underwent an enucleation and curettage of the cyst as well as removal of the anterior mandibular teeth. B, The 3-year postoperative radiograph shows acceptable bony fill.

COCs appear radiographically as unilocular well-defined lesions. The radiopaque structures within the lesions have been described as either irregular calcifications or toothlike densities.

Treatment and Prognosis The standard treatment for the COC is enucleation and curettage (Figure 30-16). A limited number of recurrences have been reported after such treatment. When a COC is associated with another recognized odontogenic tumor such as an ameloblastoma, the treatment and prognosis are likely to be the same as for the associated tumor. Although only a few cases have been reported,³¹ a carcinoma arising in a COC may occur. One such reported case resulted in multiple pulmonary metastases and was referred to as an odontogenic ghost

FIGURE 30-16 A, This calcifying odontogenic cyst appears as a mixed radiolucent/radiopaque lesion on the occlusal radiograph. B, This patient underwent enucleation and curettage of the lesion. C, The histopathology shows characteristic ghost cells (hematoxylin and eosin; original magnification $\times 40$).

cell carcinoma by the authors.³³ It has not been demonstrated whether the malignant COC arose from previously benign lesions and, if so, whether that precursor was the cystic or neoplastic type.

Odontogenic Tumors

Odontogenic tumors comprise a complex group of lesions of great importance to oral and maxillofacial surgeons. Many of these lesions are true tumors, whereas some are hamartomas. Like normal odontogenesis, odontogenic tumors demonstrate varying inductive interactions between odontogenic epithelium and odontogenic ectomesenchyme. This ectomesenchyme was formerly referred to as *mesenchyme* because it was thought to be derived from the mesodermal layer of the embryo. It is now accepted that this tissue differentiates from the ectodermal layer in the cephalic portion of the embryo; hence, the designation *ectomesenchyme*. Odontogenic tumors are typically subclassified by their tissues of origin (Table 30-3). Tumors of odontogenic epithelium are composed only of odontogenic epithelium without any participation of the odontogenic ectomesenchyme. Other odontogenic neoplasms, referred to as mixed odontogenic tumors, are composed of odontogenic epithelium and ectomesenchymal elements. A third group, tumors of odontogenic ectomesenchyme, includes those tumors composed principally of ectomesenchymal elements. Although some odontogenic epithelium may be included within these lesions, it does not appear to play an essential role in their pathogenesis.

The frequency of odontogenic tumors seems to be geographically determined (Table 30-4). Studies from North America seem to indicate that odontogenic tumors represent approximately 1% of all accessions in oral pathology laboratories,^{34,35} whereas African studies have a much higher incidence of odontogenic tumors.³⁶⁻⁴¹ Moreover, the ameloblastoma is more commonly encountered in African and other underdeveloped countries than in North America.

Ameloblastoma

The ameloblastoma is the most common clinically significant and potentially lethal

odontogenic tumor. Excluding odontomas, its incidence equals or exceeds the combined total of all other odontogenic tumors. These tumors may arise from rests of the dental lamina, a developing enamel organ, the epithelial lining of an odontogenic cyst, or the basal cells of the oral mucosa.² The ameloblastoma occurs in three different variants, each with specific implications for treatment and a unique prognosis: solid or multicystic, unicystic, and peripheral. In an analysis of the international literature, 3,677 cases of ameloblastoma were reviewed, of which 92% were solid or multicystic, 6% were unicystic, and 2% were peripheral.⁴²

Solid or Multicystic Ameloblastoma
This variant of the ameloblastoma is

encountered in patients over a wide age range.⁴³ It is rare in children in their first decade of life and relatively uncommon in the second decade.⁴⁴ The tumor shows a relatively equal rate of occurrence in the third through seventh decades. There is no gender predilection, and racial predilection is most controversial. About 85% of this variant of the ameloblastoma occur in the mandible, most commonly in the molar/ramus region.⁴⁵ About 15% of multicystic ameloblastomas occur in the maxilla, usually in the posterior regions.⁴⁶⁻⁴⁹ A painless expansion of the jaws is the most common clinical presentation; neurosensory changes are uncommon, even with large tumors (Figure 30-17). Slow growth is the rule, with untreated tumors leading to tremendous facial disfigurement (Figure 30-18).⁵⁰

The most common radiographic feature is that of a multilocular radiolucency. Buccal and lingual cortical expansion is common, frequently to the point of perforation. Resorption of adjacent tooth roots is common. Histologic patterns include *follicular*, in which the stellate reticulum is located within the center of the odontogenic island (Figure 30-19); *plexiform*, in which the stellate reticulum is located outside of the odontogenic rest; *acanthomatous*, in which squamous differentiation of the odontogenic epithelium is present; *granular cell*, in which the tumor islands exhibit cells that demonstrate abundant

granular eosinophilic cytoplasm; *desmoplastic* owing to extremely dense collagenized stroma that supports the tumor; and the least common *basal cell* variant, in which nests of uniform basaloid cells are present, with a strong resemblance to basal cell carcinoma. In this latter tumor stellate reticulum is not present in the central portions of the nests. One additional exception surrounds the desmoplastic variant, which is generally not a radiolucent tumor radiographically owing to its high content of collagenized stroma.

Pathogenetically, the proliferative capacity of ameloblastomas has been studied. As might be conjectured, the recurrent ameloblastoma is associated with the highest number of PCNA-positive cells, followed by the previously unoperated ameloblastomas.²⁶ The nuclear PCNA positivity of the unicystic ameloblastoma was notably lower than the positivity of the solid multicystic ameloblastoma.²⁶ Other cell cycle features supporting the aggressive behavior of the ameloblastoma include the overexpression of *BCL2* and *BCLX*, as well as the expression of IL-1 and IL-6.⁵¹

Treatment and Prognosis The ameloblastoma continues to be a subject of fascination in the international literature. Unfortunately, although most agree that aggressive treatment is essential for cure of this tumor, the fact remains that a consensus has not been reached on the biologic behavior of

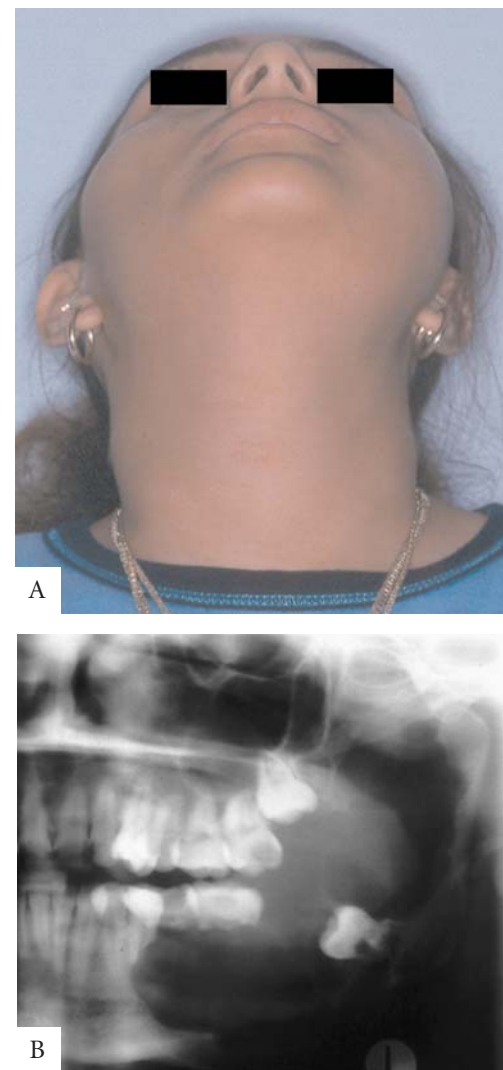

FIGURE 30-17 A 17-year-old girl with obvious facial expansion (A) related to a multilocular radiolucency of the left mandible associated with impacted tooth no. 17 (B). Note the advanced root resorption on teeth no. 18 and 19, indicative of the aggressive nature of this tumor. The incisional biopsy showed solid/multicystic ameloblastoma.

this neoplasm and how best to treat it.⁵² The literature is therefore paradoxically a source of both information and misinformation. Conflicting opinion, extending backward in time, has served both to educate and to confuse, and it has been left to generations of surgeons to sift and interpret what they consider to be clinically valid. It is my strong opinion that this neoplasm is both highly aggressive and curable. This notwithstanding, numerous methods of treatment have

FIGURE 30-18 Twenty years of undisturbed growth of a solid/multicystic ameloblastoma led to significant facial disfigurement (A), with an impressive radiographic appearance (B). A segmental resection of the right mandible was performed (C).

been recommended, ranging from simple enucleation and curettage to resection.^{53–59} The solid or multicystic ameloblastoma tends to infiltrate between intact cancellous bone trabeculae at the periphery of the tumor before bone resorption becomes radiographically evident. Therefore, the actual margin of the tumor often extends beyond its apparent radiographic or clinical margin.⁶⁰ Attempts to remove the tumor by curettage, therefore, predictably leave behind small islands of tumor within the bone, which are later determined to be recurrent disease. These must be realized as *persistent disease* as the tumor was never controlled from the outset. When a small burden of tumor is left behind, it may be

FIGURE 30-19 The incisional biopsy of the patient in Figure 30-17 shows follicular variant of the solid/multicystic ameloblastoma (hematoxylin and eosin; original magnification $\times 60$).

decades before this persistent disease becomes clinically and radiographically evident, and long after a surgeon falsely proclaimed the patient to be cured.

Owing to the highly infiltrative and aggressive nature of the solid or multicystic ameloblastoma, I recommend resection of the tumor with 1.0 cm linear bony margins (Figure 30-20). This linear bony margin should be confirmed by intraoperative specimen radiographs. Soft tissue margins are best managed according to the anatomic barrier margin principles whereby one uninvolved surrounding anatomic barrier is sacrificed on the periphery of the specimen.⁶¹ When all soft and hard tissue margins are histologically negative, the patient is likely to be cured of this neoplasm. Unfortunately, any less aggressive treatment modality may be fraught with inevitable persistence discovered at variable times postoperatively.⁶² Moreover, although the persistent and occasionally nonresectable ameloblastoma is radiosensitive, once this otherwise benign tumor defies curative surgical therapy, radiation is of questionable use in salvaging these patients.^{63,64}

Unicystic Ameloblastoma In 1970 Vickers and Gorlin published their findings regarding the histologic alterations associ-

ated with neoplastic transformation of ameloblastomatous epithelium.⁶⁵ These histologic changes were (1) hyperchromatism of basal cell nuclei of the epithelium lining the cystic cavities, (2) palisading and polarization of basal cell nuclei of the epithelium lining the cystic cavities, and (3) cytoplasmic vacuolization, particularly of basal cells of cystic linings. They referred to these changes as early histopathologic features of neoplasia. *Unicystic ameloblastoma* refers to a pattern of epithelial proliferation that has been described in dentigerous cysts of the jaws that does not exhibit the histologic criteria for ameloblastoma published by Vickers and Gorlin.^{66–69} This entity deserves separate consideration based on its clinical, radiographic, and pathologic features. Moreover, in many cases it may be treated more conservatively than the solid or multicystic ameloblastoma with the same degree of cure.⁷⁰

Unicystic ameloblastomas are most commonly seen in young patients, with about 50% of these tumors being diagnosed during the second decade of life. The average age of patients with unicystic ameloblastomas has been reported as 22.1 years, compared with 40.2 years for the solid or multicystic variant.⁴² More than 90% of these tumors are found in the

A

B

FIGURE 30-20 A, Treatment of the ameloblastoma of the patient in Figure 30-17 required a disarticulation resection of the left mandible. B, The effectiveness of the bony linear margin should always be evaluated by intraoperative specimen radiographs.

mandible, usually in the molar/ramus region.⁷¹ A unilocular radiolucency, mimicking a dentigerous cyst, is the most common radiographic presentation for the unicystic ameloblastoma (Figure 30-21). Most, if not all, unicystic ameloblastomas are unilocular radiolucencies.² Three histopathologic variants of unicystic ameloblastoma have been described that impact treatment and prognosis. In the *luminal unicystic ameloblastoma*, the tumor is confined to the luminal surface of the cyst (Figure 30-22). The lesion con-

FIGURE 30-21 This unilocular radiolucency associated with tooth no. 17 should generate a differential diagnosis of dentigerous and other odontogenic cysts.

sists of a fibrous cyst wall with a lining that consists totally or partially of ameloblastic epithelium. The *intraluminal unicystic ameloblastoma* contains one or more nodules of ameloblastoma projecting from the cystic lining into the lumen of the cyst. These nodules may be relatively small or largely fill the cystic lumen, and are noted to show a plexiform pattern that resembles the plexiform pattern seen in conventional ameloblastomas. As such, these tumors are referred to as plexiform unicystic ameloblastomas. In the third variant, known as *mural unicystic ameloblastoma*, the fibrous wall of the cyst is infiltrated by typical follicular or plexiform ameloblastoma. The extent and depth of the ameloblastic infiltration may vary considerably.

Pathogenetically, the unicystic ameloblastoma seems to have a proliferative capacity between that of the odontogenic keratocyst and the solid or multicystic ameloblastoma.²⁶

Treatment and Prognosis The clinical and radiographic findings in most cases of unicystic ameloblastoma suggest that the lesion is an odontogenic cyst, most commonly a dentigerous cyst. Under the circumstances

the surgeon should routinely open a “cystic” lesion and look for luminal proliferation of tumor. When able, histopathologic examination of such a process should occur with frozen sections. This is particularly important when dealing with large cysts. With a histologic diagnosis of unicystic ameloblastoma, the surgeon should request the pathologist to obtain multiple sections through many levels of the specimen to properly subclassify the variant of unicystic ameloblastoma. When the ameloblastic elements are confined to the lumen of the cyst with or without intraluminal tumor extension, the enucleation has probably been curative treatment. When the cyst wall has been violated by the tumor as in a mural variant of unicystic ameloblastoma, the most appropriate surgical management is quite controversial. If this diagnosis is made postoperatively, the surgeon may wish to adopt close indefinite follow-up examinations of the patient. If a preoperative incisional biopsy provides a diagnosis of mural unicystic ameloblastoma, the surgeon might recommend a resection of the tumor owing to the fact that this variant of the unicystic ameloblastoma has a higher rate of persistence than do the luminal or intraluminal unicystic ameloblastomas.

The treatment of a luminal or intraluminal variant of the unicystic ameloblastoma is enucleation and curettage (Figure 30-23). In a collective sense, the “recurrence” rate of all unicystic ameloblastomas

FIGURE 30-22 The histopathology of the lesion in Figure 30-21 shows luminal unicystic ameloblastoma (hematoxylin and eosin; original magnification $\times 40$).

FIGURE 30-23 A, The luminal unicystic ameloblastoma in Figure 30-21 is treated with an enucleation and curettage surgery. B, The 5-year postoperative radiograph shows an acceptable bony fill.

has been reported as 10 to 20% following enucleation and curettage.⁷⁰ This is significantly lower than that of enucleation and curettage of the solid or multicystic ameloblastoma. The question then arises as to when to resect a unicystic ameloblastoma. Three instances are likely to require such treatment. The first is the recurrent unicystic ameloblastoma. A tumor that recurs following a well-performed enucleation and curettage should probably be approached with the more aggressive resection. Second is the mural ameloblastoma. This variant of the unicystic

ameloblastoma is probably more aggressive than the luminal and intraluminal variants of the unicystic ameloblastoma owing to the presence of tumor in the cyst wall and therefore closer to the surrounding bone. It seems logical to approach these tumors with a surgery similar to that for the solid or multicystic ameloblastoma (Figure 30-24). The final indication for resection of a unicystic ameloblastoma is in the management of very large tumors

(see Figure 30-24) with significant expansion such that an enucleation and curettage surgery would effectively result in a resection of the involved jaw.

Peripheral Ameloblastoma The peripheral or extraosseous ameloblastoma is the most rare variant of the ameloblastoma. This tumor probably arises from rests of dental lamina or the basal epithelial cells of the surface epithelium and shows the

FIGURE 30-24 This 18-year-old presented with significant right facial expansion (A) associated with the destructive radiolucency of the right mandible noted on the panoramic radiograph (B). The incisional biopsy documented the mural variant of unicystic ameloblastoma (hematoxylin and eosin; original magnification $\times 20$) (C). A disarticulation resection was performed (D).

same features of the intraosseous form of the tumor.⁷² Clinically, these tumors present as nonulcerated sessile or pedunculated gingival lesions (Figure 30-25). Most examples are < 1.5 cm and usually occur over a wide age range, with an average reported age of 52 years. Although these tumors do not infiltrate bone, they may be seen to “cup out” bone in the jaws (Figure 30-26).

Treatment and Prognosis The peripheral ameloblastoma is most appropriately treated with a wide local excision. When surgical margins are negative for tumor, cure is the likely consequence. Malignant transformation of a peripheral ameloblastoma is very rare.⁷³

A

B

FIGURE 30-25 This lesion of the right palatal mucosa (A) showed peripheral ameloblastoma on incisional biopsy (hematoxylin and eosin; original magnification $\times 40$)(B).

FIGURE 30-26 A “cupped out” lesion in bone at tooth no. 4 is noted in the patient in Figure 30-25.

Malignant Odontogenic Tumors

Malignant odontogenic tumors are very rare. They may arise from the epithelial components of the odontogenic apparatus. The rests of Malassez, the reduced enamel epithelium surrounding the crown of an impacted tooth, the rests of Serres in the gingiva, and the linings of odontogenic cysts represent the precursor cells for malignant transformation. Odontogenic carcinomas are classified in Table 30-5.⁷⁴ In general, all of these tumors exhibit typical microscopic features of malignancy, with the exception of the malignant (metastasizing) ameloblastoma and the clear cell odontogenic carcinoma. Behaviorally, all of these tumors have the potential for either regional nodal or distant metastases.

Malignant (Metastasizing) Ameloblastoma Malignant ameloblastomas are best described as neoplasms that have the histologic features of benign ameloblastoma as shown by the primary growth in the jaws and by any metastatic growth.⁷⁵

The most common sites of metastatic disease are the lungs (Figure 30-27), followed by the cervical lymph nodes and visceral

Table 30-5 Classification of Odontogenic Carcinomas

organs.^{76–78} Lung metastases have sometimes been regarded as aspiration phenomena, yet the peripheral location of many of these deposits supports hematogenous spread. Eversole points out that instances of metastasis have arisen from solid or multicystic ameloblastomas rather than unicystic tumors.⁷⁴

Ameloblastic Carcinoma Ameloblastic carcinomas are malignant epithelial odontogenic tumors that exist in the background of benign ameloblastomas. This designation is reserved for an

FIGURE 30-27 Histologically benign ameloblastoma is noted in the lung. This finding satisfies the definition of malignant ameloblastoma (hematoxylin and eosin; original magnification $\times 20$).

ameloblastoma that has cytologic features of malignancy in the primary tumor (Figure 30-28), in a recurrence, or in any metastatic deposit. Although ameloblastic carcinomas have been reported to metastasize to the lungs and distant organs,^{79,80} many cases do not metastasize. In Corio and colleagues' series of eight cases of ameloblastic carcinoma, rapid growth and pain were common symptoms.⁸¹ These symptoms are recognized as being uncommon in patients with benign ameloblastomas.

Primary Intraosseous Squamous Cell Carcinoma Squamous cell carcinomas that are encountered in the jaws, lack any continuity with the oral or antral mucosa, and occur in the absence of a primary carcinoma located elsewhere are termed primary intraosseous squamous cell carcinomas. These cases are assumed to arise from odontogenic epithelium. They typically occur in elderly patients and tend to occur in the mandibular

body region. The 5-year survival rate is 30 to 40%.⁷⁴ Squamous cell carcinomas may also arise from the linings of odontogenic cysts. Cystogenic carcinomas are seen in patients > 50 years of age and typically occur in the mandible. Finally, dentigerous cysts can undergo glandular metaplasia, and there are rare instances of central mucoepidermoid carcinomas reported to arise from odontogenic cyst lining.

Clear Cell Odontogenic Carcinoma Although the clear cell odontogenic carcinoma is of putative odontogenic origin, histologic similarities to the developing tooth germ are lacking in many instances.⁷⁴ The differential diagnosis includes metastasis from a distant site, especially the kidney. The clear cell variant of renal cell carcinoma is the chief entity to consider. The clear cell odontogenic carcinoma is generally seen in elderly women, with the maxilla and mandible being affected equally.

Malignant Epithelial Odontogenic Ghost Cell Tumor The epithelial odontogenic ghost cell tumor, also known as dentinogenic ghost cell tumor, is the solid variant of the calcifying odontogenic cyst. Both epithelial and ectomesenchymal odontogenic elements are present; however, only the epithelial component shows cytologic features of malignancy.

Ameloblastic Fibroma

The ameloblastic fibroma is considered to be a true tumor in which the epithelial and mesenchymal tissues are both neoplastic. This is in distinction to the ameloblastic fibro-odontoma and odontoma that represent developmental stages of the same hamartomatous lesion.^{82,83} The ameloblastic fibroma tends to occur in young patients in the first two decades of life. The posterior mandible is affected in 70% of cases (Figure 30-29). Radiographically, either a unilocular or multilocular lesion is observed.

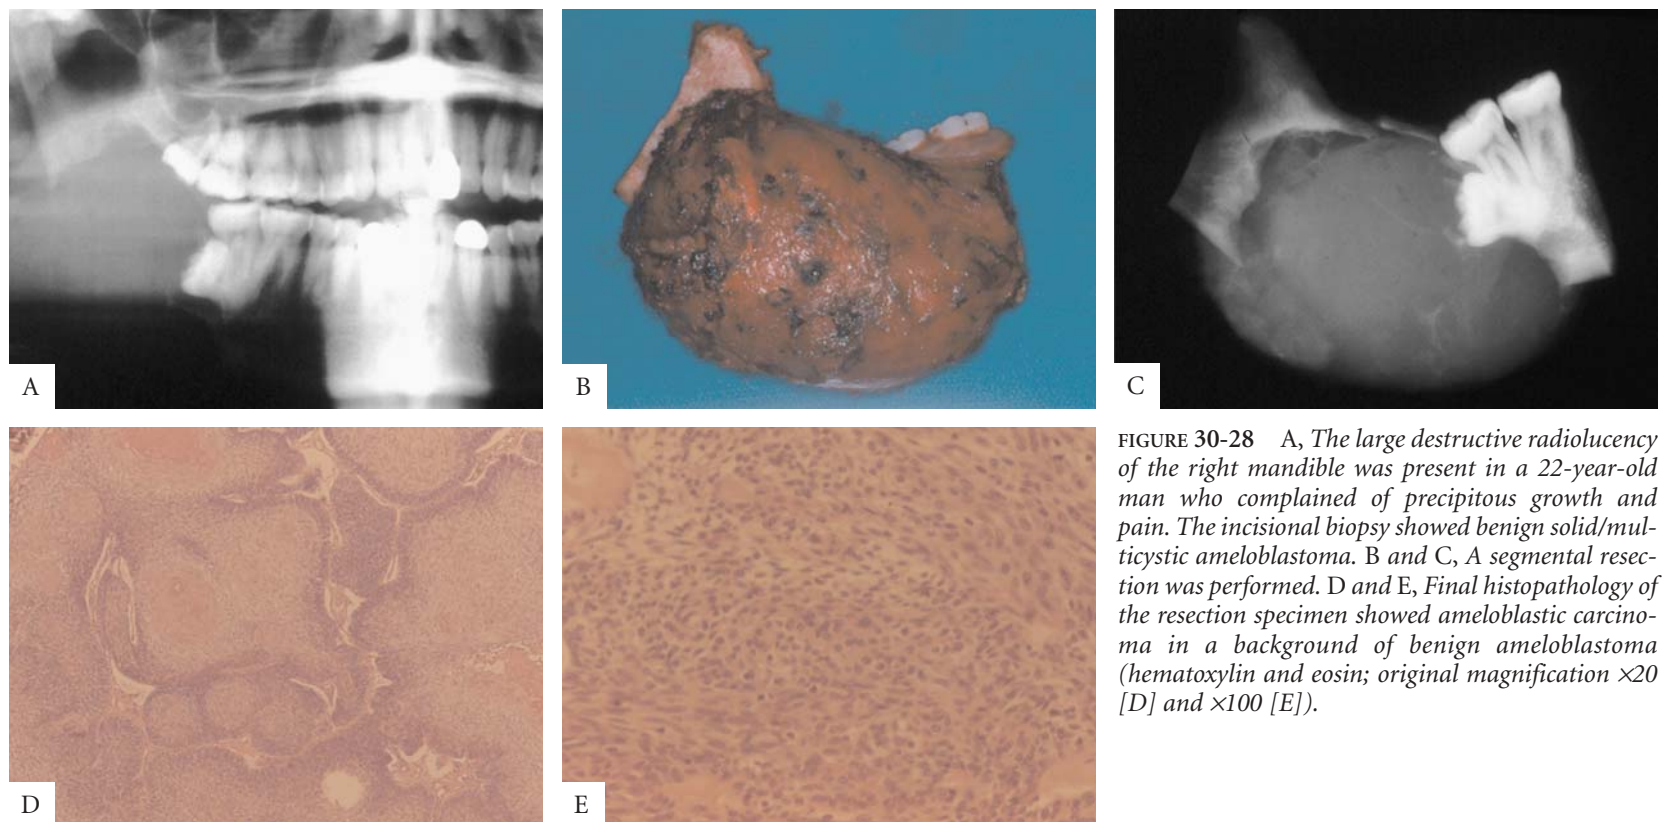

FIGURE 30-28 A, The large destructive radiolucency of the right mandible was present in a 22-year-old man who complained of precipitous growth and pain. The incisional biopsy showed benign solid/multicystic ameloblastoma. B and C, A segmental resection was performed. D and E, Final histopathology of the resection specimen showed ameloblastic carcinoma in a background of benign ameloblastoma (hematoxylin and eosin; original magnification $\times 20$ [D] and $\times 100$ [E]).

FIGURE 30-29 A, A destructive unilocular radiolucency is present in a 15-year-old boy. B, Incisional biopsy confirmed ameloblastic fibroma (hematoxylin and eosin; original magnification $\times 40$).

Treatment and Prognosis The ameloblastic fibroma is recognized as an indolent tumor that is effectively treated by an enucleation and curettage surgery (Figure

FIGURE 30-30 An enucleation and curettage surgery is performed in the patient in Figure 30-29. The associated permanent teeth are removed with the tumor.

30-30). Although recurrence is rare under the circumstances, resection should be reserved for recurrent lesions. Approximately 45% of ameloblastic fibrosarcomas develop in the setting of a recurrent ameloblastic fibroma.²

Ameloblastic Fibro-odontoma

The ameloblastic fibro-odontoma, as previously discussed, probably represents a hamartoma. Moreover, some investigators believe that this lesion is only a stage in the development of an odontoma and does not represent a separate entity. Slootweg points out that when one considers the data on age, site, and sex, it seems that the ameloblastic fibro-odontoma is an immature complex odontoma.⁸² As with ameloblastic fibromas, the ameloblastic fibro-odontoma occurs more frequently in the posterior regions of the jaws. This lesion is commonly asymptomatic and is discovered serendipitously or when radiographs are exposed to provide a diagnosis for asymmetric eruption of the dentition in children (Figure 30-31). These lesions are distinctly well circumscribed and appear as mixed radiopaque/radiolucent masses.

Treatment and Prognosis The ameloblastic fibro-odontoma is treated effectively

FIGURE 30-31 A panoramic radiograph of a 9-year-old boy shows a mixed radiolucent/radiopaque lesion of the left posterior mandible. Ameloblastic fibro-odontoma is a likely diagnosis owing to the patient's age as well as the radiographic character of the lesion.

with an enucleation and curettage surgery (Figure 30-32). Recurrence after this approach is very rare. Malignant transformation of ameloblastic fibro-odontoma has been reported but is exceedingly rare.⁸⁴

Odontoma

Odontomas are the most frequently occurring odontogenic tumors, with prevalence exceeding that of all other odontogenic tumors combined. As stated

FIGURE 30-32 A, Enucleation and curettage is performed of the lesion in Figure 30-31. The permanent tooth is removed with the lesion. B and C, The histopathology shows ameloblastic fibro-odontoma (hematoxylin and eosin; original magnification $\times 20$).

previously, these lesions are generally well accepted as representing hamartomas. Odontomas present centrally within the jaws in one of two forms: compound, in which multiple small toothlike structures exist; and complex, in which irregular masses of dentin and enamel are present with no anatomic resemblance to a tooth. Compound odontomas are predominantly seen in the anterior maxilla (Figure 30-33), whereas complex odontomas are typically seen in the posterior maxilla or mandible (Figure 30-34).

Treatment and Prognosis Odontomas are treated with simple enucleation and curettage and are not known to recur.

Odontogenic Myxoma

The odontogenic myxoma is an uncommon benign neoplasm of the jaws that is thought to be derived from ectomes-

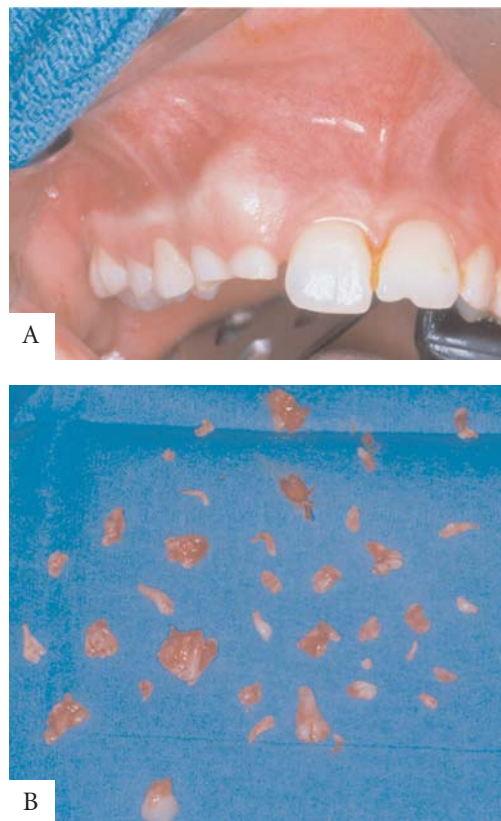

FIGURE 30-33 A, An expansile lesion of the right maxilla. B, Multiple small toothlike calcified structures are removed that represent compound odontoma.

FIGURE 30-34 A complex odontoma of the left posterior mandible.

enchyme and histologically resembles the dental papilla of the developing tooth. These tumors are slow growing with a potential for aggressive behavior and a high recurrence rate after subtherapeutic removal.⁸⁵ They occur over a wide age range but seem to occur most commonly in the third decade of life. Although the tumor can occur anywhere in the jaws, the posterior mandible is most common location (Figure 30-35). Histologically, the tumor is composed of haphazardly arranged stellate, spindle-shaped, and round cells in an abundant loose myxoid stroma that contains only a few collagen fibrils (Figure 30-36). Radiographically, the odontogenic myxoma appears as a unilocular or multilocular radiolucency that may displace or cause root resorption of teeth in the area of the tumor. Although not pathognomonic of the odontogenic myxoma, the radiolucent defect may contain thin wispy trabeculae of residual bone, which are often arranged at right angles to one another in a “stepladder” pattern (see Figures 30-35B and 30-37). In some patients the tumor may have a greater tendency to form collagen fibers; such lesions are designated fibromyxomas.

Pathogenetically, the proliferation and aggressive behavior of the odontogenic myxoma may be related to overex-

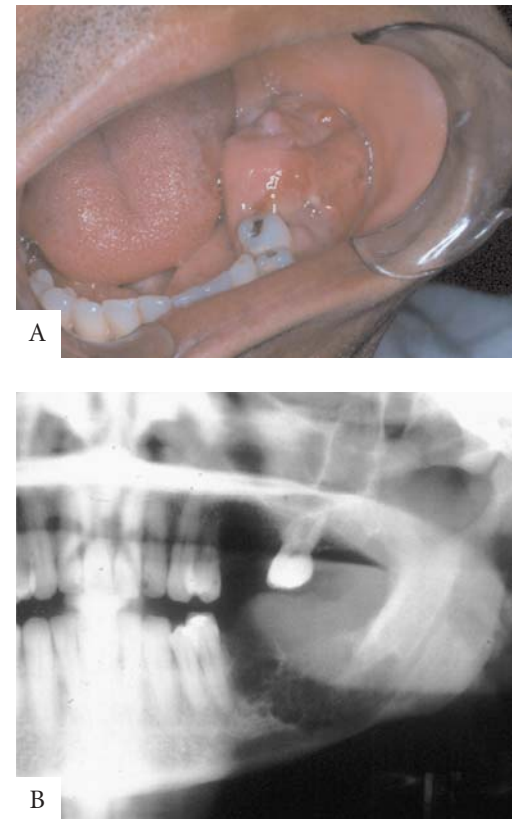

FIGURE 30-35 A large soft tissue mass of the left posterior mandibular gingiva (A) associated with an underlying radiolucent lesion of the mandible (B).

pression of antiapoptotic cytokines *BCL2* and *BCLX*.⁵¹

Treatment and Prognosis Odontogenic myxomas should be treated with resection with 1.0 cm bony linear margins as confirmed with a specimen radiograph (Figure

FIGURE 30-36 The odontogenic myxoma shows a loose myxoid stroma, in this case, eroding into the cementum of a tooth root (hematoxylin and eosin; original magnification $\times 40$).

30-37). These tumors are not encapsulated and tend to infiltrate the surrounding bone such that complete removal by curettage is nearly impossible. Resection of the tumor with a normal surrounding margin of bone and soft tissue that shows negative margins should be curative.

Calcifying Epithelial Odontogenic Tumor

The calcifying epithelial odontogenic tumor, also known as the Pindborg tumor, is an uncommon lesion that accounts for < 1% of all odontogenic tumors. It is particularly noteworthy that the three studies depicted in Table 30-4 reported only 15 cases of this odonto-

genic tumor among a collective series of 1,440 odontogenic tumors. Fewer than 200 cases have been reported in the international literature. Although this tumor has been reported over a wide age range, it is most often encountered in patients between 30 and 50 years of age.⁸⁶ Approximately two-thirds of these neoplasms occur in the mandible.⁸⁷ A painless slow-growing mass is the most common presenting sign. Radiographically, the most common presentation is a mixed radiopaque/radiolucent lesion, frequently associated with an impacted tooth (Figure 30-38).

Histologically, the Pindborg tumor is quite unique. Discrete islands, strands, or sheets of polyhedral epithelial cells in a fibrous stroma are noted. Large areas of amorphous eosinophilic hyalinized (amyloid-like) material are also present. Calcifications, which are a distinctive feature of the tumor, develop within the amyloid-like material and form concentric rings, known as Liesegang rings (Figure 30-39). The precise nature of the amyloid-like material is unknown. The material does stain as amyloid when stained with Congo red or thioflavine T. After Congo red staining, the amyloid exhibits apple-green birefringence when viewed with polarized light. It has been illustrated that the amyloid-like material may actually represent amelogenins or other enamel proteins secreted by the tumor cells.⁸⁸

Treatment and Prognosis Although slow growing, the Pindborg tumor is highly infiltrative and destructive and is capable of aggressive behavior.^{88,89} Owing to the small number of reported cases and lack of consistent follow-up, evidence-based recommendations for treatment are not available. Nonetheless, the tumor is generally recommended to be treated identically to the ameloblastoma and odontogenic myxoma, with 1.0 cm bony linear margins and the appropriate attention to soft tissue anatomic barriers (Fig-

FIGURE 30-38 A 40-year-old woman with a 5-year history of an expansile mass of the left maxilla (A). The panoramic radiograph (B) and the coronal computed tomography scan (C) show a mixed radiolucent/radiopaque lesion of the left posterior maxilla.

FIGURE 30-37 A, The patient in Figure 30-35 underwent a segmental resection of his odontogenic myxoma. B, As with the ameloblastoma, specimen radiographs should be obtained when resecting an odontogenic myxoma to verify the bony linear margin. A better depiction of the "stepladder" pattern of the odontogenic myxoma is noted on this specimen radiograph.

FIGURE 30-39 Incisional biopsy of the patient in Figure 30-38 shows signs indicative of the Pindborg tumor including discrete islands of odontogenic epithelium, calcification (Liesegang rings), and hyalinized material suggestive of amyloid (hematoxylin and eosin; original magnification $\times 40$).

Adenomatoid Odontogenic Tumor

The adenomatoid odontogenic tumor, regarded by many as a hamartoma, is an uncommon odontogenic lesion, accounting for 3 to 7% of all odontogenic tumors. This lesion was once believed to be a variant of ameloblastoma and was previously designated *adenoameloblastoma*.^{90,91} Its clinical features and biologic behavior permit distinction from the ameloblastoma (Figure 30-41). These lesions are limited to young

FIGURE 30-40 The patient with the Pindborg tumor in Figure 30-38 is treated with hemimaxillectomy.

patients, and two-thirds of all cases are diagnosed in the second decade.^{92–95} The tumor is extremely uncommon in patients > 30 years. It has a predilection for the anterior region of the jaws and is found twice as often in the maxilla than in the mandible. Females are affected about twice as often as males. Most adenomatoid odontogenic tumors are small, rarely exceeding 3 cm in diameter. In about 75% of cases, the lesion appears as a well-circumscribed unilocular radiolucency that involves the crown of an erupted tooth, frequently a canine.

Histologically, the adenomatoid odontogenic tumor is a well-defined lesion that is usually surrounded by a thick fibrous capsule (Figure 30-42). When the lesion is bisected, the central portion of the tumor may be essentially solid or may show varying degrees of cystic change with intraluminal proliferation of tissue. The lesion is composed of

FIGURE 30-41 An expansile lesion of the lingual aspect of the left mandible (A) associated with a unilocular radiolucency of the left mandible (B).

FIGURE 30-42 Incisional biopsy of the lesion in Figure 30-41 shows a well-encapsulated lesion (hematoxylin and eosin; original magnification $\times 10$) (A) with duct-like structures and rosettes (hematoxylin and eosin; original magnification $\times 40$) (B). These findings are indicative of the adenomatoid odontogenic tumor

spindle-shaped epithelial cells that form sheets, strands, or whorled masses of cells in a scant fibrous stroma. The epithelial cells may form rosette-like structures about a central space that may be empty or contain small amounts of eosinophilic material that may stain for amyloid.^{96–98} Tubular or duct-like structures are characteristic for the adenomatoid odontogenic tumor (see Figure 30-42). These consist of a central space surrounded by a layer of columnar or cuboidal epithelial cells whose nuclei exhibit reverse polarization.

Treatment and Prognosis Owing to this lesion being encapsulated, it separates easily from the surrounding bone. As such, an enucleation and curettage surgery is curative (Figure 30-43). Of the 499 cases of adenomatoid odontogenic tumor reported in the literature, only 1 acceptable case of recurrence has been documented.⁹⁹

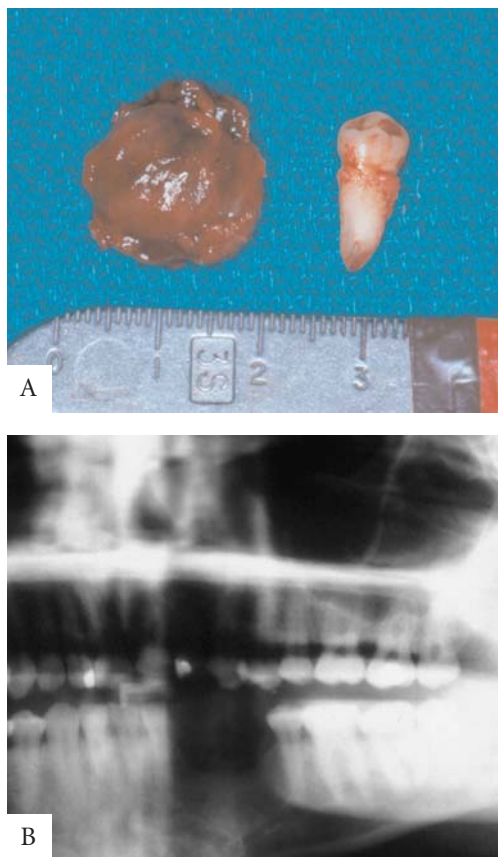

FIGURE 30-43 A, An enucleation and curettage surgery is performed for the patient in Figure 30-41, along with removal of the involved teeth. Erosion of the cementum of the premolar tooth is noted. B, The 5-year postoperative radiograph shows acceptable bony healing.

Benign Nonodontogenic Lesions of the Jaws

M. Anthony Pogrel, DDS, MD

Benign nonodontogenic lesions of the jaws represent a mixed group of tumors, which in many cases are difficult to classify. Additionally, there are some lesions within this group that actually only seem to occur in the jaws, and, therefore, although they do not contain any histologic or immunohistochemical evidence of odontogenic structures, the mere fact that they only occur in the jaws may mean that they are in fact odontogenic.

The subjects discussed in this chapter are fibro-osseous disease, osteoblastoma and osteoid osteoma, aggressive mesenchymal tumors of childhood, benign tumors of bone-forming cells, synovial chondromatosis and osteochondroma, lesions containing giant cells, vascular malformations, Langerhans cell histiocytosis, nonodontogenic cysts of the jaws, neurogenic tumors, Paget's disease, massive osteolysis (Gorham's disease), and tori.

Benign Fibro-osseous Disease

Differences remain in the classification and diagnosis of fibro-osseous disease.¹ There is a general consensus that the common entity for all of the lesions is the replacement of normal bone with a tissue composed of collagen fibers and fibroblasts that contain varying amounts of mineralized substance, which can be either bone or cementum-like material. It is difficult to differentiate con-

clusively between bone and cementum with light microscopy.

For the purposes of this chapter, the term *fibro-osseous disease* is taken to include the following groups of lesions: fibrous dysplasia, cemento-osseous dysplasia, and fibro-osseous neoplasms.

Fibrous Dysplasia

Fibrous dysplasia is considered to be a developmental hamartomatous fibro-osseous disease of unknown etiology. It may represent developmental arrest in a benign fibro-osseous proliferation that lacks the ability to fully differentiate.² Somatic mutations in the *GS α*-gene have been proposed to cause monostotic and polyostotic conditions and Albright's syndrome.^{3,4}

Fibrous dysplasia is normally subdivided into four different forms:

1. Monostotic fibrous dysplasia affecting only one bone
2. Polyostotic fibrous dysplasia affecting multiple bones
3. Albright's syndrome in which multiple lesions are associated with hyperpigmentation and endocrine disturbances, predominantly precocious puberty and/or hyperthyroidism⁵
4. Craniofacial fibrous dysplasia confined to bones of the craniofacial complex

The jaws are commonly associated with all forms of fibrous dysplasia. In the jaws the onset is usually during the first and second decades, and it produces painless swelling of the involved bones (Figure 31-1). Classically, the radiographic appearance shows a ground-glass opacity without clearly defined borders (Figure 31-2). In its craniofacial form the maxilla, zygoma, sphenoid, frontal bones, nasal bones, and base of the skull can be involved. Expansion can cause compression of nerves and blood vessels. The optic canal can be narrowed by fibrous dysplasia, although it seems unlikely that

FIGURE 31-1 Swelling of the left mandible and maxilla owing to fibrous dysplasia.

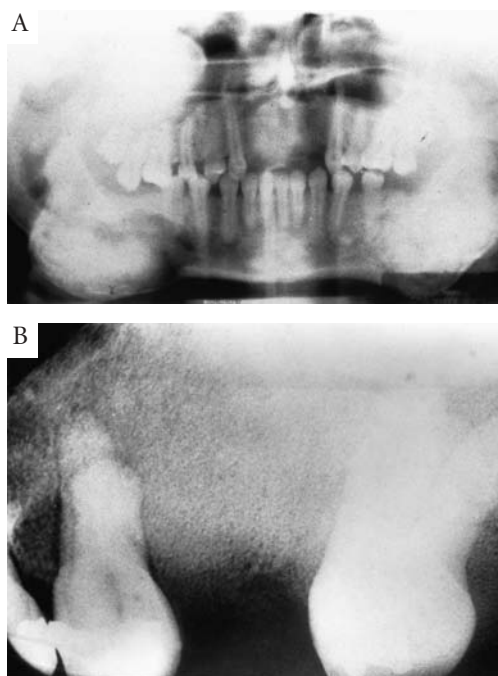

FIGURE 31-2 A, Radiographic appearance of patient in Figure 31-1 showing ground-glass appearance of lesions. B, Periapical view of typical ground-glass appearance of fibrous dysplasia.

any associated vision loss can be relieved by orbital decompression.⁶ The maxilla appears to be affected more often than the mandible, and females are affected more commonly than males. Typically lesions undergo periods of activity and periods of quiescence. When they are active, they are often symptomatic in that the patient may perceive a throbbing or discomfort, the

FIGURE 31-3 Bone scan of patient in Figures 31-1 and 31-2 showing area of increased uptake of isotope in both sides of the mandible and the left maxilla (arrow). The isotope used was Tc 99m diphosphonate.

swelling increases, and the lesions appear hot on a bone scan (Figure 31-3) and can, in fact, mimic osteomyelitis.⁷⁻¹¹ In a quiescent phase they may be totally asymptomatic. Teeth can be displaced by the lesion (Figure 31-4). Familial cases of fibrous dysplasia have been noted.¹²

The lesions of fibrous dysplasia may be under hormonal control, particularly in Albright's syndrome, and cases of increased activity and reactivation during pregnancy have been noted.^{13,14} Although not normally recognized as a premalignant lesion, sarcomatous change has been noted in fibrous dysplasia.^{15,16} Early cases appear to have been associated with the use of radiation therapy for treatment,^{17,18} but cases of spontaneous sarcomatous degeneration have been noted.¹⁹ Additionally, some cases have been difficult to diagnose and may have represented a low-grade osteosarcoma from the outset.²⁰

Classically, fibrous dysplasia appears to be a lesion that "burns itself out" when the patient is in the late teens or early twenties, although cases of active fibrous dysplasia have been noted much later than this.

Treatment is generally symptomatic; if the lesions are asymptomatic, a biopsy diagnosis alone may be adequate without carrying out any definitive treatment. Surgical treatment should be limited during an active phase because the lesions are vascular and can bleed quite profusely. Treatment is best reserved for quiescent periods, at which time cosmetic recontouring is the normal treatment of choice. Regrowth, however, can be expected following this treatment in 25 to 50% of cases, particularly if undertaken at a young age. Some investigators have suggested more aggressive surgical procedures including mandibular and maxillary resections.²¹

Cemento-osseous Dysplasia

The cemento-osseous dysplasias represent a pathologic process of the tooth-bearing areas and probably represent the commonest manifestation of fibro-osseous disease;

however, since they are frequently asymptomatic and require no treatment, they are less of a diagnostic and clinical dilemma than are the other forms of fibro-osseous disease. In this condition there is a disordered production of bone and cementum-like tissue in the jaws. The three forms include periapical, focal, florid osseous dysplasias, and familial gigantiform cementoma, which are probably variants of the same pathologic process but which can be differentiated by clinical and radiographic features. The etiology of these lesions remains in doubt, but local trauma may play some part, even such benign trauma as abnormal occlusal forces. There is a predominance of cases occurring in females and also in African Americans.²² It is suspected that the periodontal ligament may be the origin of the fibrous tissue found in the cemento-osseous dysplasias. Histologically the three types of cemento-osseous dysplasia are indistinguishable, showing new woven bone trabeculae and/or spherules of cementum-like material, which often blend into the cortical bone. A fibrous tissue stroma is present. There is very little inflammatory component. Traumatic bone cysts have been reported in conjunction with this lesion.²³

Periapical Cemento-osseous Dysplasia

Periapical cemento-osseous dysplasia presents as circumscribed lesions in periapical areas associated with vital teeth, with the anterior mandible being most usually

FIGURE 31-4 Teeth displaced by lesions of fibrous dysplasia.

involved. African American females are predominantly affected. Radiographically the lesions can be radiolucent, of mixed density, or radiopaque, depending on their stage of development (Figure 31-5). Studies indicate that they may occur in around 6% of African American females.²⁴

Focal Cemento-osseous Dysplasia Lesions of focal cemento-osseous dysplasia have a predilection for middle-aged African American females and present as nonexpansile radiolucencies with associated opacities, often in edentulous areas of the mandible. They frequently occur in sites of previous dental extractions and may represent some type of abnormal healing following dental extraction. Since they are usually asymptomatic, cases are often noted on routine panoramic radiographs. They are normally well circumscribed and rarely exceed 2 cm. Differentiation from ossifying fibroma may be difficult.²⁵

Florid Cemento-osseous Dysplasia Florid cemento-osseous dysplasia has a predilection for middle-aged African American females and presents as a painless nonexpansile lesion often involving two or more jaw quadrants. Radiographically it appears as multiple confluent lobular radiopaque masses in tooth-bearing areas (Figure 31-6). Lesions may be associated with superimposed infection and osteomyelitis, and have also been associated with idiopathic bone cysts.²⁶ Histologically they have an unencapsulated proliferation of cellular fibrous tissue with trabeculae or woven bone and calcification. More mature lesions may become acellular and avascular with coalescent sclerotic bone masses. Although common in African Americans, florid cemento-osseous dysplasia has been noted in all racial groups. Many patients are partially or totally edentulous when the condition is first discovered. Cortical expansion is usually absent or of limited degree. It has been suggested that chronic diffuse sclerosing osteomyelitis may represent a variant of

FIGURE 31-5 *Periapical cemento-osseous dysplasia of the left maxilla (an atypical site). All associated teeth are vital. The patient is a 48-year-old African American female.*

this condition, but it probably represents a different condition, inflammatory in nature. The differences between the two conditions have been noted and described.^{8,27,28} However, the role of bacteria in chronic diffuse sclerosing osteomyelitis has proven elusive, and, in general, even authorities who strongly support an infectious origin have had difficulty isolating organisms.^{29,30}

Familial Gigantiform Cementoma Familial gigantiform cementoma represents an autosomal dominant variant of osseous dysplasia usually involving multiple quadrants with variably expansile lesions, often in the anterior mandible.³¹ This particular form of osseous dysplasia has no racial predilection. The lesions often evolve during childhood and can grow rapidly. Treatment is usually surgical and symptomatic and is limited to cosmetic recontouring.

FIGURE 31-6 *Florid cemento-osseous dysplasia of the mandible in a 49-year-old African American female. All associated teeth are vital.*

Fibro-osseous Neoplasms

Ossifying Fibroma Ossifying fibroma (cemento-ossifying fibroma) usually presents as a well-demarcated mixed radiolucency/radiopacity with smooth and often sclerotic borders (Figure 31-7). The lesions are usually solitary and most commonly occur in the mandible. Histologically they contain a relatively avascular cellular fibrous stroma with reticular bone trabeculae and cementum-like spherules. Most authorities now feel comfortable clearly differentiating this lesion from fibrous dysplasia. Chromosomal abnormalities have been identified in an ossifying fibroma and a cementifying fibroma.^{32,33} The ossifying fibroma is felt to be a true neoplasm and occurs at a later age than does fibrous dysplasia, being most common later in the third and early in the fourth decades. Ossifying fibroma appears to be confined to the jaws and craniofacial complex, although similar lesions have been reported in the long bones.³⁴⁻³⁶ There is, again, a female predominance but no racial predominance, and growth rates are variable. Since it is felt to be a neoplasm, the treatment is surgical; in fact, the lesions often shell out easily at surgery, although there is recurrence, the rate of which has variously been reported from 1 to 63%.³⁷⁻³⁹ For these reasons, some authorities recommend aggressive treatment for more aggressive lesions, including aggressive curettage,

FIGURE 31-7 *Ossifying fibroma of the left mandible. It appears as a well-defined mixed radiolucency/ radiopacity.*

localized surgical resection, and segmental mandibular resection.^{40,41} When present in the craniofacial complex, treatment may have to be more aggressive to protect the vital structures.⁴²

Juvenile Aggressive Ossifying Fibroma

Juvenile aggressive ossifying fibroma was first described in 1952 as a variant of ossifying fibroma.⁴³ The lesions classically occur in younger children and adolescents and present with an aggressive behavior, but they have been noted in older patients and are not always particularly aggressive. The World Health Organization defines juvenile aggressive ossifying fibroma as “an actively growing lesion mainly affecting individuals below the age of 15 years, which is composed of a cell-rich fibrous tissue containing bands of cellular osteoid without osteoblastic rimming together with trabeculae of more typical woven bone. Small foci of giant cells may be present, and in some parts there may be abundant osteoclasts related to the woven bone. Usually no fibrous capsule can be demonstrated, but the lesion is well demarcated from the surrounding bone.”⁴⁴ Two variants have been described: trabecular and psammomatous. The trabecular variant usually occurs in childhood, with a slight maxillary predominance, and may contain clustered multinuclear giant cells. The psammomatous variant can occur in adults as well as adolescents and often affects the orbit and paranasal tissues; frequently it contains a whorled pattern of closely packed spheric ossicles and a myxoid component with aneurysmal bone cyst-like areas.

Although felt to be more aggressive than the commoner ossifying fibroma that is found at a later age, this condition is not considered to necessitate truly aggressive surgery; conservative excision is still the recommended treatment, although lesions involving the craniofacial structures may require more extensive surgery. Recurrence rates of between 20 and 50% have

been reported, and recurrences may be commoner in younger patients.¹

Osteoblastoma and Osteoid Osteoma

Osteoblastoma and osteoid osteoma are generally felt to be variants of the same lesion and are related to fibro-osseous disease. Cementoblastoma and gigantiform cementoma are the equivalent cemental lesions and are associated with teeth. The alternative name for the osteoblastoma is giant osteoid osteoma, and it is generally felt to represent a larger version of the osteoid osteoma. Both are benign processes and are felt to represent true neoplasms. The osteoblastoma occurs primarily in the vertebrae and long bones, but it has been described in the jaws.^{45–47} Clinically it often grows rapidly and the predominant clinical feature is pain, which is generally localized to the lesion itself. Although felt to be a true neoplasm, there have been reports of regression after biopsy or incomplete removal, which could point to it being a reactive process of some kind.⁴⁸ Most cases of osteoblastoma occur in the second decade of life; they rarely occur after age 30 years. Males appear to be affected more commonly than females. In the head and neck, the mandible is the most common site.

Radiographic features are variable, usually consisting of a combination of radiolucency and radiopacity (Figure 31-8). The designation *osteoblastoma* is normally reserved for lesions > 2 cm in diameter. They are well circumscribed radiographically with a thin radiolucency surrounding the variably calcified contents. A sunray pattern of new bone formation similar to that described in malignant bone tumors may be evident.

The histologic appearance shows irregular trabeculae of osteoid and immature bone within a predominantly vascular stromal network. There are various degrees of calcification present. Stromal cells are generally small and slender. Differentiation

FIGURE 31-8 Osteoblastoma of the left mandible in 24-year-old female. Note mixed radiolucency/radiopacity with a radiolucent rim.

must be made from the ossifying fibroma, fibrous dysplasia, and osteosarcoma.

Treatment of the osteoblastoma is generally confined to conservative surgical excision either with curettage or local excision. Recurrences are rare but have been reported and may necessitate more aggressive treatment such as en bloc resection.⁴⁹ Rare examples of malignant transformation have been reported,^{50,51} but some of these may be related to an incorrect initial diagnosis.⁴⁵

The osteoid osteoma represents a smaller version of the osteoblastoma and is felt to be a true neoplasm. It is normally < 2 cm in diameter clinically and radiographically. It again occurs in the second and third decades of life with a male predominance. Pain is again the major clinical feature. Classically, the pain is worse at night and is relieved by acetylsalicylic acid. If the lesion is located near the cortex, it may produce a localized tender swelling. Radiographically the lesion again shows a well-defined mixed radiolucency/radiopacity with a small radiolucent rim around the lesion, which is walled by sclerotic bone. Histologically it resembles the osteoblastoma with a rich vascular stroma with trabeculae of osteoid and immature bone. The bone is rimmed by layers of active osteoblasts. Histologically it is impossible to differentiate it from the osteoblastoma. Treatment is again conservative surgical excision. Spontaneous regression has also been reported clinically.

Chondroma

A chondroma is a benign tumor of mature cartilage. The occurrence of these lesions in the jaws is extremely rare⁵²; in fact, whether they ever occur in the jaws or whether they are usually described as chondromyxomas or chondromyxoid fibromas has been questioned.^{53–57} In many cases the true diagnosis in those reported cases is actually low-grade chondrosarcoma.⁵⁸ Most reports concern the mandibular condyle, suggesting that these lesions may arise from cartilaginous remnants.^{59,60} The chondroma presents as a painless slowly progressive swelling, which may result in mucosal ulceration. The gender distribution is equal, and most tumors occur under the age of 50 years. Radiographically they present as irregular radiolucent lesions, although foci of calcification may occasionally be present. Resorption of tooth roots has been reported. Histologically the lesions contain well-defined lobules of mature hyaline cartilage. Treatment is localized, and conservative surgical excision is normally recommended. Because of the doubtful nature of these lesions and the always-present possibility of a lesion representing a low-grade chondrosarcoma, some authorities have suggested wide excision for all of these lesions as a kind of insurance policy.⁵⁸

Osteoma

Osteomas are benign tumors consisting of mature compact or cancellous bone. They may arise on the surface of bone (periosteal osteomas) or centrally within the bone (endosteal osteomas).⁶¹ They are often discovered as asymptomatic radiopacities.

Osteomas are most commonly discovered during the second and fifth decades of life, although they have been noted in all age groups. Males appear to be affected more frequently than females.

Gardner's syndrome is an autosomal dominant condition in which patients have intestinal polyposis, multiple osteomas (usually endosteal) of the jaws, fibro-

mas of the skin, epidermal cysts, impacted teeth, and odontomas.^{62–65} The specific gene associated with the condition has now been identified on the long arm of chromosome 5.^{66–68} Many cases of incomplete manifestation of the syndrome have been reported. The clinical significance of this syndrome is that the intestinal polyps, which frequently occur in the colon and rectum, are premalignant and have a very high rate of malignant transformation. The associated osteomas are often found in the jaws, particularly in the angle region of the mandible, as well as the facial bones and long bones. It has been suggested that any patient with multiple mandibular osteomas should be investigated for the possibility of Gardner's syndrome. Investigation should include a detailed history of gastrointestinal disturbance and, if positive, follow-up with colonoscopy; if the diagnosis is confirmed, a prophylactic colectomy should be performed.

Periosteal osteomas usually present as asymptomatic slow-growing bony masses. Endosteal osteomas are usually asymptomatic and are noted on routine radiographs. Radiographically they appear as well-circumscribed sclerotic radiopaque masses (Figure 31-9). Histologically they consist of either dense compact bone with sparse marrow spaces or lamellar trabeculae of cancellous bone with fibrofatty marrow spaces. Osteoblastic activity is often predominant.

Treatment of osteomas is surgical excision (Figure 31-10). This is often necessary

FIGURE 31-9 Radiograph of an endosteal osteoma in the ascending ramus of the left mandible.

FIGURE 31-10 Surgical specimen from the osteoma shown radiographically in Figure 31-9.

to establish the diagnosis. Asymptomatic cases may be followed up clinically and radiographically without treatment. Following excision, recurrences are very rare.

Synovial Chondromatosis and Osteochondroma

Both synovial chondromatosis and osteochondroma are conditions that occur in the temporomandibular joints and may be considered variants of the chondroma and osteoma. In synovial chondromatosis there is a proliferation of small particulate, generally unattached chondromas within the confines of the joint capsule. Although most frequently found in the knee, they have been reported in most joints. Well-recognized cases have occurred in the temporomandibular joints with symptoms normally consisting of pain and swelling but most often with deviation of the mandible toward the unaffected side (Figure 31-11).^{69,70} The etiology is unknown, but trauma has been suggested.⁷¹ When

FIGURE 31-11 Panoramic radiograph showing a number of radiopaque foreign bodies in the right temporomandibular joint (arrow).

these lesions become symptomatic, they should be removed via a standard preauricular approach. Since it is felt that they arise from metaplasia within the synovial lining cells of the joint, it is often advocated that the lining be removed at the same time.⁷² Cases have been reported in which up to 200 of these bodies were present within the temporomandibular joint (Figure 31-12).¹² Following removal, recurrence has not been reported.

The osteochondroma is felt to be a benign lesion that arises predominantly in long bones from a herniation of cartilage through the epiphyseal plate. It tends to present with a predominantly osseous core with a cartilaginous cap. The lesion becomes symptomatic when function is affected, for example, a malocclusion or mandibular asymmetry develops (Figure 31-13). Cases have been reported in the mandibular condyle.⁷³ Cases in the temporomandibular joints appear identical in all respects to lesions in other bones of the body. However, the association with the epiphyseal plate that occurs in the long bones is not present in the temporomandibular joint. On magnetic resonance imaging it appears as an extraneous appendage to the temporomandibular joint and is usually more radiopaque than the surrounding mandible (Figure 31-14). Treatment is symptomatic; when symptoms occur, localized excision is recommended via the nor-

FIGURE 31-13 A malocclusion caused by an osteochondroma of the left temporomandibular joint.

mal temporomandibular approach. Recurrence has been reported but is unusual.⁷⁴⁻⁷⁷

Aggressive Mesenchymal Tumors of Childhood

It is recognized that children and young adults can develop an aggressive and rapidly growing tumor of bone, which, although often having a benign mesenchymal appearance, nevertheless behaves very aggressively. The exact nature of these lesions remains unknown, but many have been classified as desmoplastic fibromas, which is the hard tissue equivalent of fibromatosis in the soft tissues. Any bone can be affected including the jaws.

The etiology and pathogenesis are in doubt since their aggressive behavior suggests a neoplastic process, but genetic, endocrine, and traumatic factors have also been suggested. Most occur in persons under the age of 20 years, and there is no gender predilection. The mandible is affected more frequently than the maxilla.⁷⁸ Radiographically a unilocular or multilocular radiolucency is noted with poorly defined margins, cortical perforation, and root resorption often being present (Figures 31-15 and 31-16). Histologically the lesion consists of interlacing bundles in a whirled aggregate of collagenous tissue with elongated and spindle fibroblasts. Hypocellularity is often present. However, atypia and mitotic features are not found. Osteoid material is not produced by this lesion.

FIGURE 31-14 Magnetic resonance image of an osteochondroma of the left temporomandibular joint (arrow) in the patient shown in Figure 31-13.

In treating this lesion, the adage “treat the biology, not the histology” is of paramount importance. Although the lesion looks benign histologically, it often behaves aggressively,⁷⁹ and the appropriate treatment is aggressive surgery, which often involves mandibular or maxillary resection (Figure 31-17). This is psychologically difficult for the surgeon to perform in a young child without a histologic diagnosis of malignancy, but the recurrence rate is very high following more conservative procedures. For lesions in inaccessible areas such as the base of the skull, radiation therapy and/or chemotherapy has been attempted with variable degrees of success.^{80,81}

Lesions Containing Giant Cells

There are a number of lesions that occur in the jaws that contain giant cells within them. Their relationship to each other, however, is ill defined. Histologically all of the giant cell lesions appear similar, if not identical, and they usually cannot be distinguished on light microscopy alone. The clinical history, immunohistochemistry, or genetic markers have to be used to differentiate the lesions.

Central Giant Cell Granuloma

Central giant cell granuloma is a lesion occurring almost exclusively in the jaws. (A similar lesion has been described in the small bones of the fingers and toes, but its relationship to the central giant cell granuloma is unknown.⁸²) Although not normally considered an odontogenic lesion,

the fact that it only occurs in the jawbones probably indicates some relationship to the teeth or tooth-bearing structures. It occurs primarily in the anterior parts of the jaws in people in the second and third decades of life, but it has been recorded in all sites at all ages. Its histogenesis remains speculative. When first described it was called a reparative giant cell granuloma,⁸³⁻⁸⁵ and it was considered a reparative lesion that was essentially self-healing. There was little evidence of this, however, and only oblique references to its self-healing properties can be found. Worth showed in a study of a number of non-treated lesions that resolution often did occur as seen radiographically; even when the lesions did not resolve completely radiographically, only a fibrous scar was noted on surgical exploration.⁸⁶ The current consensus, however, is that these are not reparative lesions and that if they are not treated, they are progressive. Most appear to follow a fairly benign course, but more aggressive lesions have been noted.⁸⁷⁻⁸⁹ The true nature of the central giant cell granuloma remains speculative. It has been suggested that it may be an inflammatory lesion, a reactive lesion, a true tumor, or an endocrine lesion. It may behave most like a reactive lesion.

Older theories about the origin of these lesions suggested that they may be derived from the odontoclasts that were responsible for resorption of the deciduous teeth; this was said to explain why they

are normally found in areas where deciduous teeth were present and are found after the deciduous teeth have resorbed.

Radiographically the central giant cell granuloma can take a number of forms from a well-defined radiolucency, a more ill-defined radiolucency or a multilocular radiolucency. Teeth can be displaced by the lesion, although resorption of teeth is uncommon (Figures 31-18 and 31-19).

Histologically these granulomas contain focal arrangements of giant cells within a vascular stroma with thin-walled capillaries adjacent to the giant cells. There is a spindle cell stroma. Immunohistochemistry has shown that the giant cells are in fact osteoclasts,⁹⁰ and the spindle cells are probably the cells of origin of this lesion.⁹¹

Treatment is usually surgical and consists of local curettage, which is usually curative.⁹² However, there is a 15 to 20% recurrence rate, and if the lesions are large, even conservative curettage may involve the loss of many teeth and possibly the inferior alveolar nerve in the mandible, and it may have sinus and nasal implications in the maxilla. With the aggressive variants, more aggressive surgery has been suggested including mandibular resection and appropriate reconstruction.⁹³

Since the central giant cell granuloma and the brown tumor of hyperparathyroidism cannot be separated histologically, it is advocated that hyperparathyroidism be excluded from the diagnosis by serum calcium, phosphate, and parathormone

FIGURE 31-17 A, Resected specimen from the patient in Figure 31-15. B, Immediate reconstruction with ribs can often be performed in young children. Reconstruction plate and rib grafts in place.

FIGURE 31-18 A central giant cell granuloma of the anterior mandible causing the displacement of teeth.

FIGURE 31-19 A central giant cell granuloma of the left angle region of the mandible, appearing as an ill-defined multilocular radiolucency, causing resorption of the distal root of the first molar (unusual).

and parathormone-related protein assays in all but the single small and more benign lesions.⁹⁴

A number of nonsurgical treatments have been suggested, all of which have their advocates. Intralesional steroids (usually triamcinolone injected into the lesion once per week for 6 wk) have been advocated and have shown some success.⁹⁵⁻⁹⁸ Their mode of action is unknown, but they may work by suppressing the inflammatory component of the lesion. They are probably best reserved for smaller lesions that can be more easily treated by intralesional injections (Figure 31-20).

Calcitonin given by subcutaneous injection has also been advocated and has met with some success (Figure 31-21).⁹⁹⁻¹⁰⁶ The theory behind this treatment is that the lesion may be caused by an as-yet undiscovered parathormone-like hormone, and that the use of calcitonin antagonizes its action and allows the lesion to heal. Since some of the giant cells have been shown to have calcitonin receptors on them, this may explain calcitonin's effectiveness.⁹⁴

α -Interferon given by subcutaneous injection has also been advocated in the treatment of the central giant cell granuloma and has again met with some success.^{106,107} The rationale for this therapy is that the antiangiogenic action of the α -interferon suppresses the angiogenic component of this lesion, causing healing to occur. In most cases surgery is still

required after the α -interferon treatment, but it may be less radical surgery and there may be a smaller chance of recurrence.

It has again been suggested that the central giant cell granuloma may, in fact, be a self healing lesion, with the natural healing process stimulated by the nonsurgical therapy employed.¹⁰⁵

Giant Cell Tumor

The giant cell tumor is normally found in the long bones and its presence in the jaws is not universally accepted; if it does occur, it is extremely rare. This lesion is an aggressive one and is felt by some to be a variant of a low-grade osteosarcoma. The recurrence rate after local curettage is high, and the appropriate treatment is in doubt. Some authorities advocate local curettage, whereas some have advocated resection. Histologically it is very similar to the central giant cell granuloma, except that the giant cells are larger with more nuclei, and they are more evenly spread throughout the lesion and not as focally placed as in the central giant cell granuloma. However, in any particular case it may be extremely difficult to make this distinction.⁴⁵

Hyperparathyroidism

In hyperparathyroidism (primary, secondary, or tertiary), calcium is mobilized from the bones into the blood stream to maintain homeostasis in the face of increased renal excretion. Mobilization from bone takes place focally and produces lesions in the bones (including the jaws) that are known as brown tumors because of their fairly distinctive coloration on surgical exploration.¹⁰⁸ Clinically and histologically they are identical to the central giant cell granuloma and cannot be distinguished on either clinical or histologic grounds (Figure 31-22). Therefore, whenever a lesion such as this is recurrent, aggressive, or multiple, hyperparathyroidism must be excluded by means of serum calcium, phosphate, and parathormone and parathormone-related protein assays. If these confirm a diagnosis

FIGURE 31-20 A, A central giant cell granuloma of the right mandibular bicuspid region causing displacement of the root of the first bicuspid (arrow). B, One year after a course of six intralesional injections of triamcinolone (10 mg/cc). Note that the area is now radiopaque.

of hyperparathyroidism, it should be treated appropriately. The lesions normally resolve without any further treatment being required.

Cherubism

Cherubism is a familial genetically dominant condition first described by Jones in a family in 1933.¹⁰⁹ Affected family members have multiple lesions mainly affecting the facial bones. Because of the involvement of the maxilla and orbital floor, the face has a rounded appearance and the eyes tend to look upward, giving the patient a cherubic appearance (Figure 31-23). The genetic defect in this condition has been identified on chromosome 4p16.3.^{110,111}

Expression is variable, with some patients having subclinical lesions discovered only on radiographs and some having extensive and clinically obvious lesions. Spontaneous mutations also occur. Radiographically the lesions appear honeycombed and can be very extensive. Teeth are often displaced, and in active periods the lesions are extremely vascular (Figures 31-24 and 31-25).

FIGURE 31-21 A, A central giant cell granuloma of the left posterior mandible (same case as Figure 31-19). B, Same case 2 years after an 18-month course of subcutaneous calcitonin injections. Note the continued development of the roots of the second molar, the cessation of resorption of the distal root of the first molar, and the radiopacity replacing radiolucency.

Histologically the lesions are very similar to central giant cell granuloma, with focal accumulations of giant cells in a spindle cell matrix. Perivascular cuffing is often present, and in some cases can be used to differentiate the two lesions.

FIGURE 31-22 Hyperparathyroidism showing a recurrent lesion of the left mandible with a pathological fracture and a lesion of the right mandible.

FIGURE 31-23 A 7-year-old female with cherubism affecting the maxillofacial region.

Because of its histologic similarity to central giant cell granuloma, calcitonin has been used in an attempt to cause resolution, but it has not met with success, suggesting that they are, in fact, different lesions.¹¹²

Treatment of cherubism is usually conservative and expectant and into the teenage years is devoted to trying to aid eruption of the teeth, which is often abnormal. Later it is directed toward cosmetic recontouring of the affected bones. The lesions normally become less active and less vascular toward the end of the second decade and into the third decade, and it is at this time that most cosmetic remodeling is carried out.

FIGURE 31-24 A panoramic radiograph of the patient shown in Figure 31-23. Note the extensive multilocular radiolucencies.

FIGURE 31-25 A coronal computed tomographic scan of the patient in Figure 31-23, showing extensive involvement of the mandible and maxilla by cherubism.

Aneurysmal Bone Cyst

Aneurysmal bone cyst is most commonly found in the jawbones and appears to be a combination of a sinusoidal vascular lesion with a giant cell component. Radiographically the lesion appears as a well-circumscribed soap bubble-type lesion (Figure 31-26). Histologically the giant cell component resembles the central giant cell granuloma, whereas the vascular component is thin-walled sinusoids. Some authorities consider this to be a vascular variant of a central giant cell granuloma; others consider it a separate lesion. It responds well to moderately aggressive curettage, although hemorrhage can be a problem. Recurrences are rare.

Vascular Malformations

Vascular malformations can occur anywhere in the body and are felt to be developmental lesions, which can occur in soft tissue or bone. Central vascular malformations of the jaws are a rare but well-documented entity. They are in contrast to the true hemangioma, which is a neoplasm of vascular endothelium and is normally present at birth, often enlarges, and then frequently involutes.¹¹³ The vascular malformation generally is not present at

FIGURE 31-26 A, The “soap bubble” appearance of an aneurysmal bone cyst of the right maxilla. B, An axial computed tomographic scan of an aneurysmal bone cyst of the angle of the right mandible (arrow).

birth, appears later, and does not involute. Vascular malformations can take a number of forms. The most practical classification is to divide them into high-flow and low-flow vascular malformations. The high-flow vascular malformations are either arterial lesions or arteriovenous fistulas. The low-flow malformations are mainly venous in nature. The clinical significance of a vascular malformation is that a central high-flow vascular malformation can cause torrential hemorrhage when surgical intervention ensues. This has been fatal on occasion.¹¹⁴ Many of these lesions are asymptomatic and may even be difficult to detect preoperatively

on radiographs. If there is a clinical presentation, it is often a slow-growing asymmetric expansile lesion of the jaw, and if it is high flow, it may be associated with a bruit. Radiographically a high-flow malformation may appear as an irregular poorly defined soap bubble-type lesion, which may cause resorption of the roots of teeth and does not normally cause nerve involvement (Figure 31-27). Low-flow malformations are similar but are often somewhat better defined and may contain calcifications or phleboliths within them. The presence of phleboliths is

FIGURE 31-27 Radiograph of a high-flow vascular malformation of the left mandible crossing the midline. It appears as an ill-defined “soap bubble” radiolucency causing some root resorption.

FIGURE 31-28 Subtraction angiogram of a high-flow vascular malformation of the mandible. Oblique lateral view with lower incisors (arrow).

diagnostic of a low-flow malformation. Diagnosis is usually confirmed by computed tomography.

To avoid the possibility of inadvertently carrying out a tooth removal or a biopsy in the presence of a high-flow malformation, a diagnostic needle aspiration should be carried out preoperatively. If bright red blood under pressure is encountered, surgery should be abandoned. Since the radiographic and clinical appearances of a vascular malformation are not diagnostic, the differential diagnosis normally includes a number of odontogenic and nonodontogenic lesions, including the central giant cell granuloma, the aneurysmal bone cyst, ameloblastoma, odontogenic keratocyst, and odontogenic myxoma. All of these lesions should undergo needle aspiration prior to biopsy or surgical treatment to rule out a high-flow vascular malformation. When a vascular malformation is suspected or diagnosed, selective angiography is normally performed via a femoral approach (Figure 31-28). If a high-flow vascular malformation is diagnosed, treatment is normally preoperative embolization followed by wide resective surgery. The embolization can involve a number of materials, including muscle, polyvinyl, pellets, and platinum coils, which are inserted via the angiography catheter or on direct puncture. On entering the lesion they unwind and expand (Figure 31-29).^{115,116} Postembolization angiography carried out immediately after the embolization normally shows a diminution in blood flow to the lesion. However, because of the powerful angiogenic effect of these lesions (probably by production of angiogenesis growth factor), reestablishment of smaller collateral vessels usually occurs within a few days, and it is often impossible to reembo- lize these smaller collateral vessels. Therefore, definitive surgery should be carried out within a small number of days of embolization. Definitive surgery normally takes the form of resection under

FIGURE 31-29 A high-flow vascular malformation embolized with a platinum coil.

hypotensive anesthesia with adequate resuscitative measures available.¹¹⁷⁻¹¹⁹ Following resection appropriate reconstruction can be performed. This can include the re-insertion of the resected portion of bone after curettage, thinning, perforation, and simultaneous bone grafting (Figure 31-30). Other approaches such as injection of a variety of substances into the lesion including glue, fibrin gel, and platinum coils,¹¹⁵ for example, have been attempted; also, case reports exist of lesions being treated by means of local curettage following embolization, but this is not normally recommended.

Low-flow or venous malformations are not as life-threatening and are normally treated with direct puncture and an attempt to thrombose the lesion by

intralesional injection of a variety of agents, including sclerosing agents, an absorbable gelatin sponge, and platinum coils. This may bring about thrombosis, allowing the necessary dental or surgical treatment to be carried out. Often mandibular resection is not necessary but, rather, a local surgical procedure.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis is the term currently employed for what was previously known as histiocytosis X, and before that the three separate conditions Letterer-Siwe disease, Hand-Schüller-Christian disease, and eosinophilic granuloma. Lichtenstein first suggested that the three diseases were related and that the common factor was the presence of histiocytes.¹²⁰ The cells of origin of this disease have now been identified as the Langerhans cells, which are dendritic cells in the skin and mucosa that have a macrophage-like function. At the present time what causes these cells to proliferate in a clonal fashion with phenotypic evidence of activation and give rise to Langerhans cell disease is unknown.¹²¹ The nature of this disease also eludes us. Some recent studies have suggested that it may have some of the properties of a tumor or have a viral etiology.^{122,123} Other studies propose that it may be a response to an overwhelming allergenic challenge, and they report cases of

eosinophilic granuloma that have resolved spontaneously, further adding to the puzzle.^{121,124} The Histiocyte Society has attempted to define all of the histiocytic diseases in a logical manner,¹²⁵ and Letterer-Siwe disease is now felt to represent the acute disseminated form of Langerhans cell histiocytosis, whereas Hand-Schüller-Christian disease represents the chronic disseminated form, and eosinophilic granuloma represents the chronic localized form.

The acute disseminated form usually affects young children. It is multisystem in nature, affecting the skin, bones, and internal organs (especially lungs and liver), and is frequently fatal. Treatment is chemotherapy.

The chronic disseminated form of the disease is classically associated with a triad of punched-out bone lesions (often affecting the skull and jaws), diabetes insipidus (owing to posterior pituitary involvement), and exophthalmos (owing to deposits in the posterior orbit). This normally affects an older age group, often in the second and third decades but sometimes much older. The bone lesions often affect the jaws. Although they usually appear as fairly well-defined punched-out radiolucencies (Figure 31-31), they can also be less well defined and can affect the apices of the teeth only and lead to a possible differential diagnosis of periapical infection. A frequent aspect of presentation is loose teeth; radiographically they often appear as “floating teeth” (Figure 31-32). The treatment of the chronic disseminated form of the disease is variable, and for well-circumscribed lesions can consist of local curettage. However, for more aggressive forms, chemotherapy is frequently employed as well. Low-dose radiation therapy has also been used on isolated lesions, and it does remain one of the very few indications for low-dose radiation therapy, often in the region of a few hundred centigray.

The chronic localized form of the disease is commonly found in the jaws and usually shows as a well-defined radiolu-

FIGURE 31-30 A, Resected mandible containing a high-flow vascular malformation that had been embolized previously. B, The same resected specimen reduced to a hollow perforated tray, filled with autogenous iliac crest cancellous bone, and replaced for an immediate reconstruction. (Photographs courtesy of J.S. Lee, DDS, MD.)

FIGURE 31-31 The multiple irregular radiolucent lesions of chronic disseminated Langerhans cell histiocytosis in a 53-year-old male whose son died of the acute form of the disease at age 11 years.

ency, often in the bicuspid region and more frequently in the mandible. Differential diagnosis in this case includes any fairly well-defined radiolucency. Treatment usually consists of aggressive local curettage, and the recurrence rate is low. Teeth are sacrificed as necessary. Intralesional steroids have also been employed with some success, and cases of spontaneous regression have been reported.^{124,126}

It is generally felt that the occurrence of Langerhans cell histiocytosis is sporadic, but clusters have been noted and there are a number of reports of a familial incidence.¹²¹ I have seen the disease in a father and son. The father was diagnosed with the chronic disseminated form of the disease at age 53 years (see Figure 31-31), whereas his son died from the acute disseminated form of the disease at age 11 years.

Nonodontogenic Cysts of the Jaws

In this section the following are discussed: globulomaxillary lesion, nasolabial lesion, median mandibular cyst, nasopalatine duct cyst, all of which are also known as fissural cysts, traumatic bone cyst, and Stafne's bone cyst. Aneurysmal bone cyst has been discussed under "Lesions Containing Giant Cells," above.

Globulomaxillary Lesion

Globulomaxillary lesion was initially defined as a globulomaxillary cyst and was felt to be

FIGURE 31-32 The "floating teeth" of Langerhans cell histiocytosis.

a fissural cyst caused by retained epithelial remnants at the fusion of the maxillary process with the globular process. It is normally found in the second or third decade. In the classic description, the lesion presents as a pear-shaped well-defined radiolucency in the maxilla between the lateral incisor and canine. Associated teeth are classically vital, and the lesion is lined by cystic epithelium with occasional globular or ciliated epithelia.

Current thinking is that although this lesion does exist as a radiographic and clinical entity (Figure 31-33), it is not, in fact, a fissural cyst since the proposed embryonic derivation is now known to be flawed and the supposed fusion line does not exist. It is felt that most lesions previously diagnosed as globulomaxillary cysts can now be reclassified as odontogenic keratocysts, radicular cysts, periapical granulomas, lateral periodontal cysts, central giant cell granulomas, calcifying odontogenic cysts, and odontogenic myxomas.⁴⁵

Tooth roots may be diverged by the lesion, and biopsy is usually necessary to confirm the diagnosis and enable appropriate surgical treatment to be carried out. Treatment normally consists of enucleation and curettage.

Nasolabial Cysts

The nasolabial cyst was felt to be the soft tissue counterpart of the globulomaxillary cyst. Again, it was felt to be formed at the lines of fusion of the globulomaxillary processes. Similarly, this lesion does exist,

but its true origin remains in doubt. It could be derived from remnants that form the nasolacrimal duct. This cyst manifests itself as a soft tissue swelling in the lateral aspect of the upper lip, fairly high in the sulcus (Figure 31-34). The cyst lining is typically a pseudostratified columnar type with numerous goblet cells. Treatment is local excision.

Median Mandibular Cyst

Median mandibular cyst is a rare cyst found in the midline of the mandible. It was originally felt to form at the line of fusion of each half of the mandibular arch. Again, the embryologic theory behind this lesion is no longer felt to be applicable, and it is believed that those lesions found in the anterior mandible represent some other type of odontogenic cyst or tumor.

Nasopalatine Duct Cyst

Nasopalatine duct cyst is also known as incisive canal cyst and is generally located on the palatal end of the nasopalatine duct. It frequently presents as a soft swelling behind the upper anterior teeth. It is felt to be derived from the epithelial remnants of the paired embryonic nasopalatine ducts within the incisive canal, and that either infection or trauma may be the stimulus for the cells to proliferate and form a cyst. These cysts appear to occur more frequently in males than in females and are commonest in the fourth to sixth decades of life. Most cases are asymptomatic and are either found by chance on radiograph or present as a soft tissue swelling in the palate. Radiographically this cyst appears as a well-defined radiolucency found in the midline of the anterior palate (Figure 31-35). In many patients the nasopalatine duct can be identified on an occlusal radiograph; the question then arises as to when the diagnosis of nasopalatine duct cyst should be entertained. A fairly arbitrary cutoff point of 7 mm has been suggested—if the nasopalatine duct appears to be > 7 mm in diameter, the presence of a cyst should be suspected.¹²⁷

FIGURE 31-33 A globulomaxillary cyst appearing as a pear-shaped swelling between the lateral incisor and canine tooth.

Diagnosis is by biopsy, which normally shows a pseudostratified columnar epithelium lining. Treatment, if required, is surgical and consists of local curettage. This almost inevitably requires the sacrifice of the nasopalatine vessels and nerves, which results in a small area of anesthesia over the anterior palate behind the upper incisor teeth. Some patients (particularly more elderly patients) find this particularly troublesome in the articulation of some words. Recurrence rate is very low following treatment.

Traumatic Bone Cyst

Traumatic bone cyst has been called a number of names, including idiopathic bone cyst, simple bone cyst, and latent bone cyst. It is almost always asymptomatic and a chance finding on radi-

FIGURE 31-34 A, A nasolabial cyst causing a swelling in the buccal sulcus in the lateral incisor area. B, The enucleated cyst, which was confined to the soft tissues with no bony extension. Histology showed squamous epithelium with goblet cells.

FIGURE 31-35 A, Palatine duct cyst appearing as a well-defined midline radiolucency. B, The same cyst enucleated.

ographs. It occurs most commonly in the mandible, particularly in the posterior mandible. It classically appears on a radiograph as a fairly well-defined radiolucency, which usually has a scalloped margin beneath the tooth roots (Figure 31-36). It is not quite as well defined as an odontogenic cyst, and the description made by Howe was that it appears as a “pencil sketch for a final pen and ink drawing.”¹²⁸

The etiology of this lesion is in doubt, and suggestions have included that it may result from intramedullary hemorrhage from trauma, which can be quite mild. Instead of organization and new bone formation occurring, for some reason the

blood clot liquefies and is then resorbed, leaving an empty space. On surgical exploration these lesions are normally found to have either no lining whatsoever or just a very thin filmy lining. They are normally empty except, possibly, for a little straw-colored fluid in the base of the lesion, which could represent the last remnants of an absorbing blood clot. Studies have shown that the gaseous contents of the lesion are mainly nitrogen, and this is presumably because they contain air and the oxygen is absorbed preferentially into the blood stream.¹²⁹

Although these lesions have been shown to regress spontaneously, a biopsy is almost always performed to determine a diagnosis. The biopsy is normally curative since anything that causes bleeding into the lesion causes resolution. Suggested treatments have included everything from no treatment whatsoever to curettage or injection of autologous blood or packing with an absorbable gelatin sponge.¹³⁰ Recurrences are extremely rare but have been reported, as have bilateral cases.¹³⁰

Stafne's Bone Defect

Stafne's bone defect is also known as static bone cyst; it is always asymptomatic and found by chance on a radiograph. It

FIGURE 31-36 A, Bilateral poorly defined traumatic bone cysts. (Bilateral cysts are unusual.) B, Same radiograph shown in Figure A with cysts outlined, showing the size and scalloped margins around teeth.

presents as a well-defined radiolucency on the lower border of the mandible, below the inferior alveolar nerve (Figure 31-37). The appearance is so diagnostic that biopsy is often not required. When this defect is explored surgically, one normally finds that it is not a totally intrabony lesion but, in fact, an indentation of the mandible on the lingual side (Figure 31-38). The indentation is normally filled with an offshoot of the submandibular salivary gland. This can be confirmed by sialography, which

FIGURE 31-37 Appearance of a Stafne's bone defect on panoramic radiograph below the inferior alveolar nerve on the right body of the mandible.

shows filling of the defects with the radiopaque media. Cases have also been seen that include lymphoid tissue in the cavity. It is felt that these may represent developmental lesions, although they may not present until adult life. Such lesions may represent the entrapment of the salivary gland or lymphoid tissue during development of the mandible or the subsequent erosion of the lingual plate of the mandible by the tissue. Treatment is unnecessary, but enucleation is often performed as a process of diagnosis.¹³¹

Neurogenic Tumors

Schwannoma

The schwannoma is a benign tumor of the neurilemma or nerve sheath. Although usually found in the soft tissues, it can occur in bone, where it usually exists as a well-defined radiolucency. Following biopsy to confirm the diagnosis, treatment usually consists of surgical excision. Recurrences are rare. Histologically lesions are well encapsulated and predominantly of spindle cells showing either an Antoni A (spindle cells arranged in palisaded whorls and waves) or Antoni B (spindle cells with a more haphazard appearance).

Neurofibroma

Neurofibromas are felt to be derived from the fibrous elements of the neural sheath and may exist as solitary lesions or as part of generalized neurofibromatosis or von Recklinghausen's disease. This latter condition is autosomal dominant, and two distinct subsets have been defined associated with the *NF1* and *NF2* genes.

Although most commonly reported in soft tissues, neurofibromas do occur in bone and have been reported on the inferior alveolar nerve, where they appear as a fusiform swelling in continuity with the inferior alveolar canal (Figure 31-39). Other bone changes associated with neurofibromatosis can include cortical erosion from adjacent soft tissue lesions or medullary resorption

FIGURE 31-38 Clinical photograph of a Stafne's bone defect on the lingual side of the mandible. This defect contained lymphoid tissue.

from interosseous lesions. In cases associated with the inferior alveolar nerve, pain or paresthesia can result.

The normally recommended treatment following biopsy is localized excision. The lesions are often vascular, and extensive blood loss has been reported from surgical management of mandibular lesions. Mandibular resection has been advocated by some authorities. The malignant transformation rate to neurogenic sarcoma of

FIGURE 31-39 A neurofibroma on the left inferior alveolar nerve presenting as a large fairly well-defined radiolucency in the mandibular ramus (arrow). The patient also had café-au-lait spots.

5 to 15% in the generalized form of the disease could be a further indication for surgical removal of these lesions.

Traumatic Neuroma

Traumatic neuroma represents a misguided attempt at nerve regeneration whereby following an injury to a nerve, neurons sprout from the site of injury but for anatomic or physiologic reasons cannot result in a functional nerve repair. If a nerve is sectioned, an amputation neuroma can develop on the stump; if a nerve is injured along its length, either an discontinuity or lateral neuroma can result (Figure 31-40). In the oral cavity these latter neuromas are most often noted on the lingual and inferior alveolar nerves. On the inferior alveolar nerve they can occur as a fusiform enlargement of the inferior alveolar canal and result most commonly following mandibular trauma, resection of pathologic lesions, and nerve involvement following dentoalveolar surgery (Figure 31-41).

If the symptoms are severe, appropriate treatment is resection of the neuroma and appropriate nerve reconstruction. Since the inferior alveolar nerve cannot be stretched significantly in the canal, repair normally involves a graft of some kind. Nerve grafts from the sural nerve or great auricular nerve have been reported, as have vein

FIGURE 31-40 An excised lateral neuroma that was on the lingual nerve.

grafts, with some success.¹³² The approach can be either intraoral or extraoral, but the extraoral approach generally gives better access and clinical results. However, it does have a higher morbidity, with possible risks of scarring and of damage to the mandibular branch of the facial nerve.

Paget's Disease

First described by Sir James Paget in 1876,¹³³ this entity still carries his name. Its alternative name is osteitis deformans. It is a slowly progressive bone condition of unknown etiology, predominantly affecting males over the age of 50 years. One unproven theory is that Paget's disease may be a delayed or slow reaction to a myxovirus stimulus.

Clinically there is hyperactive bone turnover with alternate resorption of bone, a vascular phase, and finally a sclerosing phase. Most bones of the body are involved, and the disease can result in considerable deformity. In the facial region the maxilla is affected more often than the mandible. Family histories have been obtained in this disease, and the genetic basis of the condition is being defined.

The classic presentation used to be a patient whose hat or gloves no longer fitted correctly, or in whom false teeth, particularly the maxillary denture, did not fit owing to bone swelling. Today these presentations are much fewer since well-fitting hats, gloves, and dentures are less commonly encountered. Initial presentation is usually related to bone deformity or pain. In the head and neck, headaches and symptoms owing to vascular and nerve compression have been noted.

The classic radiographic appearance is of a "cotton-wool" appearance in the skull and maxilla of affected patients (Figure 31-42), with hypercementosis around the roots of teeth, and loss of lamina dura and obliteration of the periodontal ligament space. This does make tooth extraction extremely difficult in these patients. Root resorption has also been noted.

FIGURE 31-41 An discontinuity neuroma on the inferior alveolar nerve (arrow) as a result of the removal of a third molar. The nerve is exposed via an extraoral approach and lateral corticotomy.

The histopathology shows the typical reversal lines of alternate resorption and bone deposition (Figure 31-43). Classically, patients have markedly elevated serum alkaline phosphatase levels.

Treatment is both systemic and local. Systemic treatment currently consists of

FIGURE 31-42 A, Lateral and B, frontal radiographs of a patient with Paget's disease showing typical "cotton wool" appearance.

FIGURE 31-43 Histology of Paget's disease showing reversal lines of new bone deposition and resorption ($\times 40$ original magnification; stained with hematoxylin and eosin).

the use of salmon calcitonin or diphosphonates to inhibit bone resorption. Calcitonin can be taken either subcutaneously or by nasal spray, and diphosphonates are taken orally or by injection. Treatment causes stabilization of the bone and a lowering of the raised alkaline phosphatase levels. Localized treatment is directed to cosmetic and/or functional recontouring of bone. It should be noted that the bone of Paget's disease is often vascular, and bleeding during recontouring can be extensive. Somewhat paradoxically, however, healing is often delayed owing to the intervening sclerotic areas of bone.

The classic causes of death in patients with Paget's disease are heart failure and osteosarcoma. Heart failure caused by the excessive blood supply to the remodeling bone can cause high output or left heart failure in elderly persons. Sarcomatous change has been reported in 5 to 15% of patients with Paget's disease, which should be considered a premalignant condition.¹³⁴

Gorham's Disease

Although first described in 1838,¹³⁵ this disease was named after Gorham, who reviewed the literature and added three new cases in 1954.¹³⁶ Its alternative name is massive osteolysis. Gorham's disease is a rare disease of unknown etiology, usually occurring in the second to third decades of life, although it has been reported in all age

groups. There is no sex or racial predilection, although an autosomal dominant inheritance pattern has been suggested. The diagnosis is usually one of exclusion. Any bone can be affected, and there is usually massive osteolysis, which is generally asymptomatic until a pathologic fracture occurs (Figures 31-44 and 31-45). The bone is usually replaced with fibrous tissue. The majority of cases are monostotic, but polyostotic cases have been reported.¹³⁵ There is no specific treatment for this disease; however, radiation therapy and surgical resection have been beneficial in selected cases. Serum biochemistry is usually normal, and isotope bone scans do not show excessive activity. Osteoclasts are not a prominent feature of the condition. The long-term prognosis is uncertain, but some long-term remissions have been reported.¹³⁵

Tori

Torus Palatinus

The palatine torus appears as a bony hard swelling along the midline of the palate. It can be discrete or may be large and lobular (Figure 31-46). It usually occurs in the second or third decade of life, and has a tendency to grow throughout life. It is tempting to feel that these lesions may be embryologic in their development and form at the line of fusion of the two palatal plates, but this is probably incorrect and the true nature of these lesions remains unknown. Larger versions may require surgical removal because of their interference either with speech or feeding or with prosthodontic reconstruction. The common surgical approach is via a double Y-shaped incision (Figure 31-47) and subsequent bone removal. The bone is virtually always solid cortical bone and is actually fairly difficult to remove. The recommended technique is to make a number of vertical cuts in the bone with a fissure bur (Figure 31-48). Then the intervening ridges of bone can be snapped off and a final smoothing of the residual bone car-

FIGURE 31-44 Early case of Gorham's syndrome with a partial loss of the right body of the mandible.

FIGURE 31-45 Axial computed tomographic scan of patient in Figure 31-44 2 years later; note the complete loss of the right mandible.

ried out, taking care not to perforate through into the nasal cavity (Figure 31-49). It may be advisable to insert a dressing plate after the procedure to prevent excessive hematoma formation and possible recurrence of the torus (Figure 31-50).

FIGURE 31-46 Large bilateral torus palatinus.

FIGURE 31-47 *Torus palatinus in Figure 31-46 exposed via a double Y-shaped incision.*

Torus Mandibularis

Mandibular tori are bony exophytic growths that present on the lingual aspect of the mandible opposite the bicuspids (Figure 31-51). They are virtually always

FIGURE 31-48 *Diagram of the method of reducing a large torus palatinus with a number of parallel grooves.*

FIGURE 31-49 *Torus palatinus in Figures 31-46 and 31-48 removed with the technique described in the text.*

FIGURE 31-50 *Dressing plate sutured in place over the wound.*

bilateral. Again, they present in early midlife and tend to grow with age. Larger versions may require removal because they interfere with tongue positioning, speech, and prosthodontic reconstruction, as well as with oral hygiene around the lower posterior teeth. The etiology of these lesions is in doubt; again, it is tempting to think of them as being embryologic lesions formed at the junction of the original Meckel's cartilage and the neomandible, but this is almost certainly not correct.

If surgical removal is required, it is carried out via an extensive gingival margin incision with a possible lingual-releasing incision, followed by removal of the bone. This is carried out by making a number of vertical cuts with a fissure bur, as with the maxillary torus, and then snapping off the intervening ridges of bone with a periosteal elevator. The residual irregularities are then smoothed with a larger bur. Occasionally mandibular tori

FIGURE 31-51 *Large bilateral torus mandibularis.*

are on a fairly narrow neck and can be removed in toto with a well-directed blow from a mallet and chisel.

Recurrence of tori is rare, and it has often been noted that palatal and mandibular tori rarely occur in the same patients.

Oral Cancer: Classification, Staging, and Diagnosis

G. E. Ghali, DDS, MD

M. Scott Connor, DDS, MD

Estimates indicate that more than 1.3 million new cancers will be diagnosed in the United States this year, and 27,700 will be located in the mouth and oropharynx.¹ This number represents approximately 3% of all cancers and is the eighth most common cancer affecting males in the United States. Globally, more than 360,000 new cases of oral cancer will be diagnosed this year.² Mortality rates remain high despite some advances in locoregional control. There will be approximately 200,000 deaths worldwide, of which 7,200 will occur in the United States. Most patients will present for diagnosis with either regional or distant disease. Data have shown a trend for African Americans to have more advanced disease compared with white Americans (68% vs 52%) at the time of diagnosis. Even more alarming is the fact that, when compared with equal stages at the time of diagnosis, African Americans have a poorer 5-year relative survival rate compared with other races. A review of trends in 5-year relative survival rates over the past three decades has shown a statistical difference between the time periods of 1974 to 1976 and 1992 to 1996 (54% vs 59%); the improvement in sur-

vival again fails to hold true for the African American population.¹

Approximately 85 to 95% of all oral cancer is squamous cell carcinoma (SCC).^{3,4} However, multiple other malignant lesions can be found in the oral cavity such as sarcoma, minor salivary gland tumors, mucosal melanoma, lymphoma, or metastatic disease from nearly any site in the body.

Risk Factors for SCC of the Oral Cavity

The etiology of SCC of the oral cavity has been studied extensively. Numerous risk factors have been suggested as etiologic agents for the development of these malignancies. While no single causative agent can be attributed to the development of all oral cancers, several carcinogens have been identified, and of those tobacco and alcohol appear to have the greatest impact on malignancy development. Both extrinsic and intrinsic factors likely play a role in the development of SCC of the oral cavity.

The risk of oral cancer associated with tobacco use is noted to be 2 to 12 times higher than in the nonsmoking population, and 90% of individuals with oral cancer will have a smoking history.⁵⁻⁹ The

combination of various carcinogens within tobacco, combined with the heat, may lead to a variable number of genetic mutations in the epithelium of the upper aerodigestive tract. At some point these continued mutations, coupled with the patients' own inherent genetic susceptibility, expressed in the hetero- or homogeneity of certain tumor suppressor genes or oncogenes (*TP53*, *c-myc*), may lead to the development of a cell line capable of unregulated growth.

Alcohol in itself is not a recognized initiator in the development of oral SCC. However, the role of alcohol as a promoter in the development of oral cancer when coupled with the use of smoking tobacco has been shown.¹⁰ This may be related to the effects of contaminants in alcohol and its ability to solubilize carcinogens and enhance their penetration into oral mucosa.^{5,11}

A possible viral etiology has been demonstrated in oral cancers, especially by the human papilloma virus (HPV). The HPV subtypes 16 and 18, similar to those causing cervical cancer, have been implicated. Smith and colleagues showed that when individuals in his study had other risk factors adjusted, such as smoking, alcohol, and

age, the presence of HPV in the oral cavity was associated with a 3.7 times greater chance of cancer development than in the noninfected individual.¹² Other authors have noted a unique subset of characteristics in individuals that may develop SCC as a result of HPV infection, showing less association with tobacco or alcohol abuse, frequently involving the tonsils, and having an improved prognosis.¹³

The study of the tumor biology of SCC has exploded in the past decade. The accepted molecular theory concerning genetic alterations of SCC is that of a “multihit” tumorigenesis ultimately leading to unregulated cell growth and function.^{14,15} It is thought that multiple exogenous insults (tobacco, alcohol, viral) can lead to activation of oncogenes or inactivation of tumor suppressor genes. Oncogene dysregulation leads to a gain of function alteration, and transforming growth factor alpha (TGF- α) and eukaryotic initiation factor 4E (eIF4E) are two examples of well-studied genes that have proven up-regulation in SCC.¹⁶ Loss of tumor suppressor gene function requires loss of both normal alleles, which leads to the inactivation of the critical function of that gene. The most studied of the tumor suppressor genes are *TP53* and *P16*.^{15,17-19} No single gene alteration is responsible for carcinogenesis, but rather a host of altered genes contribute. Attempts have been made to use genes and their products to identify oncologically safe margins operatively with minimal success.²⁰ Gene therapy trials that target these specific genes hold better promise.

Premalignant Disease

Premalignant disease can be divided into that occurring as an isolated lesion or that associated with a condition. A precancerous lesion is defined as morphologically altered tissue in which the development of malignancy is more likely than with normal mucosa. A precancerous condition is a condition or generalized disease that does

not necessarily alter the appearance of the mucosa but may be associated with a greater risk for the development of cancer.²¹ Precancerous lesions are broadly classified as leukoplakia and erythroplakia.

Leukoplakia is defined as a white patch or plaque that cannot be characterized clinically or ascribed to any other pathologic disease.²² Leukoplakia cannot be scraped or rubbed off and is therefore primarily a diagnosis of exclusion. Lesions caused by lichen planus, white sponge nevus, nicotine stomatitis, or other plaque-causing diseases do not qualify as leukoplakia. Leukoplakia is strictly a clinical diagnosis and does not imply any specific histologic diagnosis. Leukoplakia is generally asymptomatic and clinically appears as a white or off-white lesion that may be flat, slightly elevated, rugated, or smooth (Figure 32-1). It may be found as isolated or multifocal lesions and may change in morphology over time. More than 70% of the time leukoplakia occurs on two or more surfaces and has a strong male predilection.^{23,24} A more aggressive variant exists and is referred to as proliferative verrucous leukoplakia (Figure 32-2). The lower lip vermilion, buccal mucosa, and gingiva account for most oral cavity leukoplakia; however, lesions found on the tongue and floor of the mouth account for most lesions exhibiting dysplasia or carcinoma.²³⁻²⁶ These relative frequencies change with different geographic locations and are based on local habits.

FIGURE 32-1 Typical appearance of floor-of-mouth leukoplakia.

FIGURE 32-2 Common presentation of proliferative verrucous variant of leukoplakia on gingiva.

The only consistent histology found in all leukoplakia is the presence of hyperkeratosis. The underlying epithelium may range from normal to invasive carcinoma. The true etiology for the development of leukoplakia is unknown; however, several causative factors have been proposed. Tobacco use, whether smoked or smokeless, is most closely associated with the development of leukoplakia, and more than 70% of patients with leukoplakia are smokers.²³ While several studies have shown elimination of tobacco use to be associated with resolution or decrease in the size of the lesion, others have shown poor improvement with its cessation.

Ultraviolet radiation to the lower lip is frequently observed in the development of lower lip vermilion leukoplakia. Individuals with chronic unprotected exposure to sunlight are at highest risk for development. These leukoplakia lesions are frequently associated with actinic cheilitis (Figure 32-3).²⁷

FIGURE 32-3 Actinic cheilitis of the lower lip secondary to chronic unprotected sun exposure.

Trauma is also associated with the development of leukoplakic lesions. Ill-fitting dentures, sharp edges on oral prostheses or teeth, or parafunctional oral habits with objects such as toothpicks can be associated with leukoplakia. Obvious traumatic lesions to the buccal mucosa such as the development of a linea alba are not considered leukoplakia.

The frequency of dysplasia and carcinoma within leukoplakia is most closely associated with the lesion's location and patient's habits. Waldron and Shafer in their study of 3,256 lesions submitted to their respective oral pathology departments as "leukoplakia" found that 43% of floor-of-mouth lesions and 24% of both tongue and lip lesions contained some degree of dysplasia or carcinoma.²⁵ Several studies have also looked at malignant transformation over time and found it to vary from 0.13 to 17.5%.^{23-26,28} The results of these studies vary according to suspected causes of the leukoplakia (geographic habits) and the length of follow-up or time to biopsy of the lesion. The malignant transformation of these lesions has been studied extensively by Silverman and colleagues.²³ They note that, while a definite rate of transformation cannot be stated, their 257 patients had a 17.5% transformation rate with an average follow-up time of 7.1 years. The second year of follow-up in their series exhibited the greatest rate of malignant transformation at 5%. If those lesions initially noted to be dysplastic on biopsy were followed, they had an even higher rate of malignant transformation, at 36.4%. Earlier studies by Silverman and colleagues found malignant transformation rates of 0.13% and 6%.^{26,28} The variability in transformation rates of most studies is attributed to differences in ethnicity, drinking alcohol and tobacco usage, location of the lesions, and duration of follow-up.

Erythroplakia is a red patch that cannot be scraped off or characterized clinically or ascribed to any other pathologic

disease (Figure 32-4). Almost all true erythroplakia demonstrates dysplasia, carcinoma in situ, or invasive carcinoma. Shafer and Waldron's review of biopsies submitted under this clinical diagnosis revealed that 51% were invasive SCC, 40% were carcinoma in situ or severe dysplasia, and 9% were mild to moderate dysplasia.²⁹ The most common sites of occurrence are the floor of the mouth and retromolar trigone. Lesions appear as bright red, are frequently "velvety" in appearance, and have a sharply demarcated border. The etiology of these lesions is unknown but thought to be the same as that for leukoplakia. Frequently these lesions are noted to be nonhomogeneous in appearance with adjacent or intralesional leukoplakia. When observed with this morphology, they are referred to as erythroplakia or "speckled erythroplakia" (Figure 32-5). These lesions also harbor an ominous potential as rates of malignant transformation have been noted of up to 23%.²³

Oral submucous fibrosis (OSF) is a precancerous condition seen predominantly in India and Southeast Asia. It is a chronic, progressive mucosal disorder most frequently associated with the habit of chewing betel quids; however, there is evidence that this lesion is multifactorial in nature with genetic, immunologic, nutritional, and autoimmune factors possibly involved.^{30,31} The condition is characterized by a mucosal rigidity that leads to trismus, odynophagia with spicy foods,

FIGURE 32-4 Typical appearance of erythroplakia located on left posterior soft palate.

FIGURE 32-5 Typical appearance of erythroplakia on labial and buccal mucosa.

and difficulty with speech and swallowing. Unlike tobacco pouch keratosis, OSF does not regress with the cessation of betel quid use. Longitudinal studies have shown a malignant transformation rate of 7.6% over a 17-year period.³²

Cervical Lymph Node Levels

The neck is divided into six "surgical levels" based on anatomic structures (Figure 32-6). Each anatomic area of the oral cavity has a predictable lymphatic drainage pattern to the over 300 lymph nodes in the

FIGURE 32-6 Lymph node levels of the neck. Levels I to VI are subdivided and described in text.

neck.³³ By grouping defined nodal groups into surgical levels, clinicians are afforded the ability to communicate with each other. It also allows clinicians to tailor their surgical management of the neck based on these known drainage patterns.

Level I includes the submental and submandibular nodal groups.

Level IA, the submental group, is bounded by the hyoid bone inferiorly, the mandibular symphysis superiorly, and the anterior bellies of the digastric muscles laterally.

Level IB, the submandibular group, is bounded by the posterior belly of the digastric inferiorly, the mandibular body superiorly, the anterior belly of the digastric muscle anteriorly, and the stylohyoid muscle posteriorly.^{34,35}

Level II includes upper jugular lymph nodes surrounding the internal jugular vein and adjacent spinal accessory nerve.

Level IIA is bounded inferiorly by a horizontal plane made by the inferior body of the hyoid bone, superiorly by the skull base, anteriorly by the stylohyoid muscle, and posteriorly by a vertical plane defined by the spinal accessory nerve.

Level IIB is bounded inferiorly by a horizontal plane made by the inferior body of the hyoid bone, superiorly by the skull base, anteriorly by a vertical plane defined by the spinal accessory nerve, and posteriorly by the lateral border of the sternocleidomastoid muscle (SCM).^{34,35}

Level III includes middle jugular lymph nodes surrounding the internal jugular vein. It is bounded inferiorly by a horizontal plane defined by the inferior border of the cricoid cartilage, superiorly by the horizontal plane defined by the inferior body of the hyoid bone, anteriorly by the lateral border of the sternohyoid musculature, and posteriorly by the lateral border of the SCM or sensory branches of the cervical plexus.^{34,35}

Level IV includes the lower jugular lymph nodes surrounding the internal jugular vein. It is bounded inferiorly by the

clavicle, superiorly by the horizontal plane created by the inferior border of the cricoid cartilage, anteriorly by the lateral border of the sternohyoid musculature, and posteriorly by the lateral border of the SCM or sensory branches of the cervical plexus.^{34,35}

Level V includes all the nodes in the posterior triangle, the spinal accessory and transverse cervical nodes, and all of the upper, middle, and lower jugular lymph nodes on the posterior aspect of the SCM.

Level VA is bounded inferiorly by the horizontal plane created by the inferior border of the cricoid cartilage, superiorly at the apex found at the convergence of the SCM and trapezius muscles, anteriorly by the posterior belly of the SCM or sensory branches of the cervical plexus, and posteriorly by the anterior belly of the trapezius muscle.

Level VB is bounded inferiorly by the clavicles, superiorly by the horizontal plane created by the lower border of the hyoid bone, anteriorly by the posterior belly of the SCM or sensory branches of the cervical plexus, and posteriorly by the anterior border of the trapezius muscle.^{34,35}

Level VI includes the pretracheal, paratracheal, and prelaryngeal or so-called Delphian lymph nodes. It is bounded inferiorly by the suprasternal notch, superiorly by the hyoid bone, and laterally by the common carotid arteries. This level is also known as the anterior compartment.^{34,35}

Clinical Correlation Based on Site

The boundaries of the oral cavity extend from the vermilioncutaneous junction of the lips to the junction of the hard and soft palate posterior-superiorly and to the line created by the circumvallate papilla posterior-inferiorly. Posterior-laterally the boundaries are represented by the anterior faucial pillars. The American Joint Committee on Cancer (AJCC) has divided the oral cavity into seven distinct anatomic locations from which primary lesions may develop.³⁶ The sites have defined bound-

aries, and in developing these sites the AJCC has attempted to produce a means of better studying and treating oral cancer.

Mucosal Lip

The lip begins at the junction of the vermilion border with the skin and includes only the vermilion surface or that portion of the lip that comes into contact with the opposing lip. It is well defined into an upper and lower lip joined at the commissures of the mouth.²⁶ It is supported by the orbicularis oris muscle and receives its blood supply from branches of the facial artery. Sensory innervation is provided by the mental nerve and motor function via branches of the facial nerve.

Mucosal lip cancers represent approximately 2 to 42% of oral cavity cancers.^{4,37-41} Mucosal lip cancer is seen almost exclusively in older white men as a result of chronic sun exposure (Figure 32-7). Its infrequent occurrence in dark-skinned races is further evidence of its etiology. Nodal metastasis in lip cancer is infrequent, 10% of lower lip cancers and 20% of cancers in the upper lip and commissure are found to metastasize to the nodes.⁴² Metastasis from the lower lip is to the submental, submandibular, and perifacial nodes (level I more commonly than level II). Preauricular, periparotid, and submandibular nodes drain cancers of the upper lip and commissure (level II more commonly than level I). Bilateral

FIGURE 32-7 Neglected carcinoma of the lower lip.

neck metastasis may develop if the lower lip lesion is near or has crossed the mid-line; however, the upper lip rarely exhibits crossover between right- and left-side lymphatics.⁴³

Buccal Mucosa

Buccal mucosa includes all the lining of the inner surface of the cheeks and lips from the line of contact of the opposing lips (mucovermilion junction) to the line of attachment of mucosa to the alveolar ridge (upper and lower) and pterygomandibular raphe.³⁶ The buccal mucosa is supported by the buccinator muscle posteriorly and the obicularis oris anteriorly. The vascular supply to the posterior aspect is derived from the buccal artery, a branch of the internal maxillary artery; innervation is from the buccal branches of the facial nerve along with the long buccal branch of the third division of the trigeminal nerve.

Carcinoma of the buccal mucosa represents 2 to 10% of all SCC of the oral cavity (Figure 32-8).^{4,37,38,44} In Central and Southeast Asia the use of “pan” (a combination of tobacco, betel nut, and lime) has been linked to buccal mucosa carcinoma and represents more than 40% of all oral cavity SCC.⁴⁵ First-echelon lymphatic drainage from the buccal mucosa is level I followed by level II.⁴⁶ Cervical metastases are observed in 10 to 27% of presenting patients.^{44,47,48}

Alveolar Ridge

The alveolar ridge mucosa may be divided into lower (mandibular) and upper (maxillary) components. The mucosa overlying the alveolar process of the mandible extends from the line of attachment of mucosa in the buccal gutter to the line of free mucosa of the floor of the mouth. Posteriorly it extends to the ascending ramus of the mandible.³⁶ The mucosa overlying the alveolar process of the maxilla extends from the line of attachment of mucosa in the upper gingival buccal gutter to the junction of the hard palate. Its pos-

FIGURE 32-8 Squamous cell carcinoma of the left buccal mucosa.

terior margin is the upper end of the pterygopalatine arch.³⁶

Alveolar ridge or gingival carcinoma represents 2 to 18% of oral cancers and occurs predominantly on the mandibular alveolus (64 to 76%).^{4,37-41,49,50} At diagnosis, approximately one-third of these tumors exhibit some bony involvement.^{50,51} Lymph node metastasis tends to occur more frequently in mandibular ridge tumors than in maxillary tumors. Nodal drainage is principally to levels I and II for both the maxillary and mandibular lesions and is found in 24 to 28% of patients at diagnosis.^{46,49-51} Alveolar ridge carcinomas are frequently insidious tumors masquerading as inflammatory lesions, periodontitis or gingivitis, tooth abscesses, or denture sores (Figure 32-9).

Retromolar Gingiva (Retromolar Trigone)

The retromolar gingiva is a triangular region of attached mucosa overlying the ascending ramus of the mandible from the

level of the posterior surface of the last molar tooth superiorly to the tuberosity of the maxilla. Laterally this area merges with buccal mucosa and medially is in continuity with the soft palate, anterior tonsillar pillar, and floor of the mouth.³⁶

Tumors of the retromolar trigone frequently involve adjacent anatomic sites at the time of diagnosis (Figure 32-10). Primary symptomatic complaints with these tumors are sore throat, otalgia, and trismus. Tumors of the retromolar trigone represent 2 to 6% of all oral cavity carcinomas.^{4,38,39} Lymphatic drainage from this area is predominantly to the submandibular nodes (level IB) and the upper jugulodigastric nodes (level II).^{46,52} Lesions of this region tend to be more aggressive in nature with regard to developing cervical metastasis, because 27 to 56% of individuals present with metastatic disease.⁵³⁻⁵⁵

Floor of the Mouth

The floor of the mouth is a semilunar space over the mylohyoid and hyoglossus muscles, extending from the inner surface of the lower alveolar ridge to the undersurface of the tongue. Its posterior boundary is the base of the anterior faucial pillar of the tonsil. It is divided by the frenulum of the tongue and contains the ostia of the submandibular and sublingual salivary glands.³⁶ Anatomically it consists of the

FIGURE 32-9 Biopsy-proven squamous cell carcinoma of the mandibular alveolar ridge resulting in erosion of underlying bone and loosening of dentition.

FIGURE 32-10 Ulcerative carcinoma of left retromolar trigone with extension towards the anterior tonsillar pillar.

unattached mucosa overlying the mylohyoid and hyoglossus muscles.

Carcinoma of the floor of the mouth represents 8 to 25% of oral cavity SCC, and several studies have shown a fairly dramatic increase in incidence (Figure 32-11).^{4,38-41} Two distinct lymphatic drainage systems have been identified in the floor of the mouth.⁵⁶ The superficial system drains bilaterally into the submandibular nodes (level I), while the deep system drains into the ipsilateral submandibular, upper and

FIGURE 32-11 Carcinoma of anterior floor of the mouth presents with induration, ulceration, and mild tongue fixation.

middle jugulodigastric nodes (levels I, II, and III). Studies have shown that nearly one-half of all patients presenting with a floor-of-mouth carcinoma will have metastatic disease at presentation.⁵⁷⁻⁵⁹ Shaha and colleagues demonstrated that 60% of individuals with metastatic disease will have multiple levels involved.⁵⁷

Hard Palate

The hard palate is between the upper alveolar ridge and the mucous membrane covering the palatine process of the maxillary bones. It extends from the inner surface of the posterior edge of the palatine bone and can be divided into a hard and soft component.³⁶ In the United States, only 25% of palatal SCC occurs in the hard palate with 75% occurring in the soft palate (anatomically a part of the oropharynx).⁶⁰⁻⁶² In India and Southeast Asia, where reverse smoking is popular, the proportion of hard palate lesions is greater.

The hard palate represents 3 to 6% of all oral cavity SCC (Figure 32-12).^{4,37-39} There is a paucity of lymphatics to the hard palate. Approximately 10 to 25% of individuals present with evidence of metastasis, generally to levels I and II.^{61,63} Hard palate lesions may also metastasize to retropharyngeal nodes or nodes that are not palpable on a clinical examination or readily removable with a traditional neck dissection. Nonhealing ulcers and poor-fitting dentures are common complaints

FIGURE 32-12 Carcinoma of the hard palate with extension to alveolar mucosa.

among individuals who develop disease at this site.

Anterior Two-Thirds of the Tongue (Oral Tongue)

The anterior two-thirds of the tongue is the freely mobile portion that extends anteriorly from the line of circumvallate papillae to the undersurface of the tongue at the junction of the floor of the mouth. It has four areas: the tip, the lateral borders, the dorsum, and the undersurface (nonvillous ventral surface of the tongue). The undersurface of the tongue is considered a separate category by the World Health Organization.³⁶ The tongue is entirely a muscular structure composed of the extrinsic muscles, the genioglossus, hyoglossus, styloglossus, and palatoglossus, as well as the intrinsic muscles of the tongue. Blood supply to the tongue is from the paired lingual, sublingual, and deep lingual arteries. The tongue receives motor innervation via the hypoglossal nerve and taste and sensation from lingual branches of the trigeminal nerve.

In the United States, SCC of the tongue is found mainly on the anterior two-thirds (75%), versus the posterior one-third (25%).⁶⁴ Tongue carcinoma represents 22 to 49% of all oral cancer diagnosed (Figure 32-13).^{4,37-41} Several epidemiologic reviews have shown the unfortunate trend of an increase in tongue cancer and an alarming increase in the

FIGURE 32-13 Carcinoma proliferating from ventral tongue to encompass full thickness of the tongue.

incidence of those diagnosed before 45 years of age.^{40,41,65-67} Lymphatic drainage of the oral tongue is principally to level II, followed by levels III and I.^{46,52} Carcinoma of the lateral border generally metastasizes ipsilaterally, but SCC of the tip or body of the tongue may exhibit bilateral metastases. Approximately 40% of patients have evidence of clinical node metastasis at the time of diagnosis.⁶⁸

Staging

The TNM system devised by the AJCC is designed to stratify cancer patients into different stages based on the characteristics of the primary tumor (T), regional lymph node metastasis (N), and distant metastasis (M). It is an attempt to help guide treatment and estimate patients' 5-year survivability. *T* refers to the primary lesion and is graded on greatest dimension and presence of adjacent tissue infiltration (Table 32-1). *N* refers to regional lymph node involvement and is graded on the presence of nodes, greatest dimension, and side of involvement in relation to the primary tumor (Table 32-2). *M* grades distant metastasis and is based simply on its presence (M1) or absence (M0). The AJCC staging system (Table 32-3) is designed for clinical use; however, the patient may be restaged based on final pathology after

Node	Description
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension

Adapted from Greene FL et al.^{35,36}

resection and designated with a *p* prefix (pTNM) or at autopsy with an *a* (aTNM). If synchronous tumors are found at presentation, the higher stage tumor should be used for stage designation, and an *m* suffix may be used to denote the multiple primary tumors (TmNM).^{36,69}

Assessment of Primary Lesion

Proper lesional assessment is based on a thorough clinical evaluation. Accurate

measurement of the primary lesion before biopsy is essential. Often, biopsied SCCs are referred without accurate measurements, leaving the treating surgeon in a difficult situation relative to properly assigning a T group. Additionally, postbiopsy inflammation could lead to over- or underestimates of the lesion's true dimensions.

A complete evaluation of all anatomic locations within the oral cavity must be performed by visual examination and palpation to detect any mucosal abnormality. The goal in evaluating the patient is to detect any abnormal tissue and assess the extent of disease. Patients may present with myriad complaints such as a nonhealing sore in the mouth, loosening of teeth, ill-fitting dental prosthesis, trismus, otalgia, or weight loss. Examination of the oral cavity should include removal of all dental appliances and use of a dental mirror for indirect evaluation of the nasopharynx and hypopharynx. Bimanual palpation is critical to assess any involvement of structures such as the deep musculature of the tongue, floor of the mouth, buccal mucosa, salivary structures, or bony mandibular

Tumor	Description
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4a*	Tumor invades adjacent structures (eg, through cortical bone, into deep [extrinsic] muscle of the tongue, maxillary sinus, skin of face) (resectable)
T4b	Tumor invades masticator space, pterygoid plates, or skull base or encases internal carotid artery (unresectable)

*Superficial erosion alone of bone or tooth socket by an alveolar primary is not sufficient to classify a tumor as T4.

structures. Assessment of the lateral tongue and posterior pharynx is assisted by anterior and lateral traction on the tongue with cotton gauze (Figure 32-14).

The AJCC describes the possible growth patterns of a tumor as endophytic, exophytic, or ulcerated.³⁶ These characteristics play no part in staging the primary tumor. While depth of invasion is not used to clinically stage the patient, several studies have shown that depth of invasion does play a prognostic role in the development of regional metastasis, especially in tongue and floor-of-mouth cancers.⁷⁰⁻⁷² The study performed by Spiro and coworkers at Memorial Sloan-Kettering Cancer Center looked at primary tumor thickness in relation to risk of cervical node metastasis in SCC of the tongue and floor of the mouth.⁷⁰ They found that patients with thin (< 2 mm) cancer of these respective areas had a failure rate of 1.9% and lymph node metastasis present in 7.5% of

patients versus patients whose primary tumor was thick (> 2 mm), who had a 45.6% failure rate and metastatic node disease was present in 38%. Rarely, primary tumors may be located in areas that are difficult to assess or may be painful to assess, requiring an evaluation under anesthesia along with panendoscopy.

Panendoscopy, or “triple endoscopy,” involves the use of a rigid bronchoscope, esophagoscope, and laryngoscope to sequentially examine and take biopsies, if required, from the aerodigestive tract. Warren and Gates first described the notion of synchronous and metachronous tumors in 1932.⁷³ A synchronous tumor is described as a second histologically confirmed malignancy. This malignancy must be distinct and geographically separated by normal non-neoplastic mucosa and not of metastatic origin from the index lesion. It must also be discovered at the time of initial tumor evaluation. If the second primary tumor is discovered at a later time it is considered a metachronous tumor.

Slaughter and colleagues described the concept of “field cancerization” secondary to the panmucosal effects of smoked tobacco irritants and alcohol.⁷⁴ This theory explains the relatively high prevalence of second primary malignancies in the upper aerodigestive tract and has been described on a molecular level.⁷⁵ Panendoscopy became the gold standard for discovering

FIGURE 32-14 Anterior manual traction of the tongue with the aid of a cotton gauze improves visualization of this lateral and ventral tongue mass.

an often asymptomatic synchronous lesion. McGuirt reported a synchronous primary lesion rate of 16% in his prospective study of 100 head and neck cancer patients.⁷⁶ The discovery of the synchronous lesions frequently led to an alteration in the treatment plan of the index lesion. Other reported incidences of synchronous primary tumors range from 2 to 9%.⁷⁷⁻⁸¹ Panendoscopy can be performed quickly and at a minimal price for the patient in terms of cost and added morbidity.

The availability of flexible endoscopes, especially nasopharyngoscopes, has led to their use in many institutions, along with the conversion to flexible bronchoscopes and esophagoscopes. Additionally with the advent of tomographic imaging, routine preoperative panendoscopy is currently undergoing reevaluation in many institutions. Many authors believe that the low yield of bronchoscopy compared with chest imaging should preclude its use, while others have called for selective endoscopy to investigate only symptom-driven complaints.⁸¹⁻⁸⁴ Should multiple primary tumors be discovered during patient evaluation, each lesion should be staged separately.

Assessment of Regional Metastasis

Evaluation of the neck is perhaps the most critical and difficult aspect of staging oral or any head and neck cancer. The presence of a single lymph node with metastatic disease reduces the patient's 5-year survival by 50%. In turn, the presence of extracapsular spread decreases this survival by another 50%.⁸⁵ A retrospective study by Snow and colleagues showed a surprisingly high rate of extracapsular tumor spread in even small lymph nodes. His analysis showed that lymph nodes greater than 3 cm had a 73.7% chance of extracapsular spread, 2 to 3 cm a 53.3% chance, 1 to 2 cm a 44.3%, and less than 1 cm a 28.8% chance.⁸⁶ Other studies have concurred with this high rate of extracapsular spread.^{87,88} These drastic

reductions in long-term survival underscore the importance of preoperative staging for an appropriate prognosis and treatment plan. It should be noted that staging depends not on specific lymph node level involvement, but rather on presence of nodes, size, number, and whether they are ipsilateral, contralateral, or bilateral in relation to the lesion.

Traditionally, the gold standard in staging the neck has been through digital palpation of all levels of the neck bilaterally. The neck has a large number of palpable structures and a large area to be surveyed for the presence of lymph nodes. While there is no correct order in which to evaluate the neck, each clinician should develop a sequence to use consistently to avoid missing any part of the examination. Observation of the neck is important to note any asymmetries or skin changes. Most clinicians prefer to palpate the neck standing behind the patient, simultaneously palpating each aspect of the neck. We find it helpful to break the neck down into muscular triangles and examine them sequentially from the submandibular triangle to the posterior triangle. Lymph node chains should be evaluated for the presence of palpable masses, noting their size, surgical neck level, and whether the mass is fixed or moveable. Bending the patient's head forward or slightly to the side will ease taut tissues of the neck allowing for better palpation. Other important palpable structures of the neck to be evaluated in the examination include the parotid gland, the thyroid gland, and the postauricular, occipital, and supraclavicular lymph node chains. The parotid gland should be evaluated for the presence of any palpable disease or masses and the thyroid gland for any nodule, masses, or thyromegaly. The trachea should be inspected for any deviation or fixation.

The past decade has seen a relatively high incidence of observer error.^{89,90} Deficiencies have been observed in both the ability to recognize the presence of a

clinically palpable node and also in the ability to assess its size. A study by Alderson and colleagues showed that both residents and staff involved in the treatment of head and neck malignancies consistently underestimated the size of smaller nodes, and accuracy of assessment was independent of experience.⁹⁰

With the advent of advanced imaging, both computed tomography (CT) and magnetic resonance imaging (MRI) have been used as adjuncts to the physical examination for both evaluating nodal disease and helping to delineate the nodes in relation to vital structures such as the carotid artery. Studies have shown that clinically negative tumor-positive nodes may be detected on CT or MRI in 7.5 to 19% of cases.⁹¹⁻⁹⁶

Computed Tomography

CT is generally performed preoperatively with intravenous contrast to help delineate vascular from lymph structures. The scan generally involves 3- to 5-mm slices from the skull base to the clavicles. Important radiographic markers for the presence of suspicious adenopathy include lymph node size, shape, and central necrosis. A lymph node is considered abnormal when it is greater than 1.5 cm in the jugulodigastric region or greater than 1 cm in other regions of the neck.^{92,96} Shape has been suggested as a criterion to help distinguish pathologic nodes. The shape of a normal or hyperplastic lymph node resembles a bean, as opposed to round or sphere-like metastatic nodes frequently present. Next to size, the most specific indicator of metastatic nodal disease on tomographic imaging is the presence of intranodal necrosis, independent of size and shape (Figure 32-15). Only an intranodal abscess or fatty hilar metaplasia can simulate central tumor necrosis.

Magnetic Resonance Imaging

MRI is another method of neck imaging that has gained popularity in the past decade. With superior soft tissue detail, one would expect better delineation of

FIGURE 32-15 Axial computed tomography scan with contrast demonstrates large right cervical node with criteria for regional metastasis.

lymph node pathology; however, the fat that surrounds the cervical lymph nodes can interfere with imaging detection. The T1-weighted, fat-suppressed contrast-enhanced image is perhaps the optimal sequence to evaluate cervical metastatic disease.^{92,97} MRI provides the distinct advantage of viewing the neck and primary tumor in planes not available by CT. Difficulty with the use of MRI concerns both the time and motionlessness required for an acceptable study to be performed. Individuals with oral cancer frequently have large lesions that may compromise the airway while supine for extended periods of time. When using MRI for evaluating the neck the same criteria concerning nodal size, shape, and central necrosis should be applied as when evaluating with CT.

Ultrasound

Ultrasound (US) evaluation of the neck has become increasingly popular in European countries. Sonography is relatively inexpensive and is tolerated well. It may be used as an initial study to help guide the clinician in deciding whether further imaging studies of the neck may be required. This is especially true in the clinically N0 neck. Sensitivity of sonography in the detection of cervical lymph node metastasis is 89 to 95%, and specificity is 80 to

95%.^{98–100} This specificity can be increased with the use of US-guided fine-needle aspiration.¹⁰¹ Criteria for the evaluation of potentially malignant cervical nodes with sonography also involve the assessment of nodal size, shape, and presence of central necrosis. Metastatic nodes are characteristically round to spherical in shape and are frequently hypoechoic. In the presence of extracapsular spread, loss of border definition is observed. Normal lymph nodes are frequently difficult to detect because of their high echogenicity mimicking that of the surrounding fatty tissue.

Positron Emission Tomography

The use of 2-¹⁸F-fluoro-2-deoxy-D-glucose (FDG) positron emission tomography (PET) relies on the enhanced metabolic activity of tumoral tissue in the body, of which increased glycolysis is usually the biochemical hallmark. FDG, a radiolabeled glucose analog, is preferentially taken up within tumor cells that exhibit increased glycolysis; they can be detected from the increased signaling in that tissue (Figure 32-16). This study is

FIGURE 32-16 Preoperative positron emission tomography scan demonstrates increased activity in right tongue and right neck at levels II and III.

unique in that it represents a functional imaging scan as opposed to a morphologic imaging scan. A prospective study by Adams and colleagues showed a higher sensitivity and specificity for FDG-PET (90%, 94%) compared with CT (82%, 85%) and MRI (80%, 79%).¹⁰² Several other studies have produced similar results.^{103–105} As with ultrasound, FDG-PET may have a unique role in the evaluation of the clinically N0 neck.¹⁰⁶ FDG-PET has found a place in the evaluation of an unknown primary with success rates reported from 10 to 60% in the identification of the index lesion.^{107–109}

Drawbacks to the use of FDG-PET for evaluation of the neck include the inability to differentiate between cancerous and reactive inflammatory lymph nodes and the poor anatomic delineation of the primary tumor and neck nodes in relation to surrounding structures, particularly those of a vascular nature.

Assessment of Distant Metastasis

Final evaluation of the oral cancer patient involves a work-up for possible distant metastasis. Although the percentage of individuals who present with an untreated primary tumor who already have distant metastasis is low, it is prudent to have thoroughly staged the individual for optimal treatment planning. Distant metastasis from the oral cavity most frequently involves the lung, followed by liver and bone. Therefore, routine posterior-anterior and lateral chest radiographs and the evaluation of liver function tests (LFTs) are considered the minimum metastatic work-up for head and neck cancer patients. Depending on abnormalities found in the chest radiograph or LFTs, locoregional extent of the disease, and degree of clinical suspicion, the surgeon may also choose to obtain a CT of the chest or abdomen and pelvis. Obtaining other studies such as bone scans should be symptom-driven. An added advantage of an FDG-PET study in the evaluation of

distant metastatic oral cancer is its whole body imaging of possible tumor spread.

The infrequency of distant metastasis was recognized early by Crile.¹¹⁰ Studies produced from the patient database at Memorial Sloan-Kettering Cancer Center have also shown relatively low rates in the eventual development of distant metastasis, ranging from 13% in individuals with floor-of-mouth cancer to 15% in patients with carcinoma of the tongue.^{57,111} As new therapies lead to better locoregional control of disease, we can expect to see a greater incidence of distant metastasis in long-term follow-up.

Diagnosis

A thorough clinical examination is the first line of defense in the detection of oral cancer. Prognosis is directly dependent on the tumor stage at diagnosis. Nearly one-half of all oral cancers are not detected until they are in advanced stages. This delay may be because symptoms may not develop until later in the disease process or the socioeconomic group most likely to develop oral cancer is unable to seek treatment until it has reached an advanced stage. Studies have shown that only 14% of adults in the United States have ever had an oral cancer examination.¹¹² A study by Holmes and colleagues showed that detection of oral and oropharyngeal SCC during non-symptom-driven examinations was associated with a lower stage at diagnosis.¹¹³ These detections occurred in the dental office, whether by a dentist, dental hygienist, or oral and maxillofacial surgeon.

Toluidine Blue

Oral cancer can have various clinical appearances, ranging from subtle mucosal color or texture changes to gross ulceration or a fungating lesion. These mucosal alterations are particularly difficult to assess in early cancers and dysplasia. It was recognized in the 1960s that toluidine blue stained malignant cells in vivo. Tolu-

idine blue is a metachromic dye that has been used as a nuclear stain. The dye uptake has been shown to aid in the early recognition and diagnosis of oral SCC.¹¹⁴ While the dye's exact mechanism of action is unknown, theories have been proposed that the dye selectively stains cells with increased deoxyribonucleic acid synthesis or quantitatively more nucleic acids than other cells.¹¹⁵ It has also been suggested that the dye binds to sulfated mucopolysaccharides, found in higher quantities in actively growing cells. Several studies have borne out toluidine blue's sensitivity (89 to 100%) and specificity (62 to 90%) for oral SCC.¹¹⁵⁻¹¹⁷ This specificity increases when a protocol is followed involving a second rinse 14 days after the initial application to allow for resolution of any inflammatory lesions that may be present. The sensitivity of toluidine blue in detecting dysplastic lesions is not as high as that for SCC. Sensitivity rates have been recorded ranging from 74 to 84.6%.^{115,117} These dysplastic lesions stain inconsistently, and toluidine blue cannot be used as reliably.

Toluidine blue is currently marketed as a commercially available kit. Our opinion is that its use should be limited to the screening of high-risk individuals, and assisting in directing biopsies from a large area of abnormal-appearing tissue. In the end, toluidine blue cannot be substituted for a thorough oral examination and biopsies when clinical suspicion is high.

Biopsy

Once a clinically suspicious lesion is identified in the oral cavity, tissue diagnosis must be obtained prior to rendering any treatment. This biopsy can usually be done in an office setting or rarely under general anesthesia with panendoscopy if the lesion is difficult to access and patient tolerance is low. The traditional biopsy, whether incisional or excisional (for small lesions), is the gold standard. It should be emphasized that an accurate dimension of the

lesion should be acquired prior to biopsy in order to properly stage the lesion. When faced with a large lesion, it is best to take several biopsies from different sites in an attempt to decrease any sampling error that might be read as dysplasia, necrosis, or inflammation.

Brush cytology has gained acceptance in the dental community as a safe, minimally invasive technique for use in the screening of clinically suspicious lesions.¹¹⁸ Brush cytology differs from exfoliate cytology in that it removes an entire transepithelial layer for cytologic evaluation as opposed to the sloughing surface layer of the mucosa. Commercially available kits exist that include a brush biopsy instrument, glass slide, and fixative. The suspicious lesion is sampled by rubbing or rotating the sampling brush against its surface until pinpoint bleeding at the biopsy site is obtained, indicating sampling to the basement membrane and an adequate specimen. This specimen is then transferred to the slide, fixed in the office, and sent to the corporation for evaluation by both a computer and oral cytopathologist. Brush biopsy results are classified as "negative" when no epithelial abnormality is noted, "positive" when definite cellular evidence of dysplasia or carcinoma is found, "atypical" when abnormal epithelial changes of uncertain diagnostic significance are observed, and "inadequate" when an incomplete transepithelial specimen was submitted. The largest study of brush cytology by Sciubba and colleagues found a sensitivity and specificity of 100%.¹¹⁹ However, as some authors have pointed out, a lack of investigation with scalpel biopsy of atypical results in "innocuous-appearing" lesions has resulted in a possible specificity exaggeration of this technique; other studies have borne this result out with reported sensitivities of approximately 90% but a specificity of only 3%.¹²⁰

Brush biopsies' best value may lie in the general dentist's hand where he or

she may encounter epithelial abnormalities on a daily basis and is reluctant to refer the patient for biopsy. It is our opinion that brush cytology is only a screening tool, and any atypical or positive results must be confirmed by an incisional biopsy. The same should be said about highly suspicious lesions read as "negative." If clinical suspicion remains high despite a negative cytology result, a biopsy should be obtained.

Conclusions

SCC of the oral cavity continues to be a common disease worldwide including in the United States. Despite research and advances in surgical and adjuvant therapy, long-term survival remains poor. It is a disease all clinicians will be faced with, and early recognition and diagnosis of premalignant and malignant disease is directly related to outcome. Proper staging of the primary lesion and neck with a thorough clinical examination and imaging is paramount to designing a successful treatment plan.

Oral Cancer Treatment

Jon D. Holmes, DMD, MD

Eric J. Dierks, DMD, MD

Oral cavity cancers account for 30% of head and neck cancers and represent a significant challenge to clinicians. Treatment requires multidisciplinary expertise and is complicated by the complex role that the oral cavity plays in speech, mastication, and swallowing. Oral squamous carcinomas account for 90% of malignancies affecting the oral cavity, and will be the focus of this chapter. Although discussion will be limited to the treatment of squamous cell cancers, oncologic principles outlined in this chapter can be applied to other malignancies affecting the oral cavity.¹⁻³

Regardless of advances in diagnosis and treatment, mortality from oral cancer has not changed significantly in the past 50 years. Approximately 50% of patients diagnosed with oral cancer will ultimately die of their disease.^{4,5} Early detection and appropriate treatment of cancers remain the most effective weapons against cancers of the oral cavity. Unfortunately public and professional awareness and knowledge of oral cancer is low. A recent editorial referred to oral cancer as “The Forgotten Disease.”⁶ Incidence and mortality for oral cancer is nearly double that of cancer of the cervix (30,300 vs 13,500 and 8,000 vs 4,400, respectively); yet few adults can remember their last oral cancer examination, whereas most women are aware of their last gynecologic examination and Pap smear.⁷ Patient knowledge of other cancers, such as skin, breast, and prostate, has

increased in recent years because of public awareness campaigns. Only recently, however, has oral cancer begun to receive some of the same attention. The American Cancer Society recommends a cancer-related check-up, including examination for cancers of the oral cavity, every 3 years for asymptomatic men and women aged 20 to 39 years and yearly for men and women aged 40 years and older.⁸ Although the oral cavity is readily accessible for examination, results of a study by Holmes and colleagues questioned whether health care professionals were screening for asymptomatic cancers.⁹ Additionally, smaller symptomatic cancers often went undetected in their study and were ultimately detected at a later stage. Interestingly all asymptomatic cancers were referred from dental practices, and the average clinical and pathologic stage of cancers referred from physician offices were statistically higher.⁹ This is unfortunate since the population at highest risk for development of an oral cancer is four to six times more likely to seek care from a physician than a dentist.^{10,11} Clearly there is a need for increasing the public’s awareness of oral cancer and improving screening for early oral cancers in order to improve outcomes regardless of treatment modality employed.

Histology

Just as the molecular events leading to the development of squamous cell carcinoma

are a multistep process, the histologic progression of benign mucosa to invasive cancer typically follows an orderly progression. Although squamous cell carcinoma is the most common, other variations require alterations in treatment.

Verrucous carcinoma is generally considered an uncommon variant of squamous cell carcinoma, representing only 5% of oral cancers.¹² It has a predilection for the buccal mucosa, and typically appears as a thick white cauliflower-like growth (Figure 33-1). The basement membrane is typically intact and the cells are very well differentiated. It is not uncommon to find focal areas of invasive squamous cell carcinoma within the excised specimen, and patients should be prepared for this eventuality. The prognosis is excellent following adequate excision.

FIGURE 33-1 Verrucous carcinoma of buccal mucosa with extension onto the adjacent maxillary alveolus.

Basaloid squamous cell carcinoma represents a rare aggressive form of squamous carcinoma. It affects males predominately, and is associated with a high rate of cervical and distant metastases.¹³ Histologically basaloid cells are arranged in nests or cords. Perineural invasion and a high mitotic index are common and coincide with its tendency to recurrence and worse prognosis, with a 38% mortality at 17-month follow-up.¹⁴ Given the aggressive nature of basaloid squamous cell carcinoma, elective treatment of the neck and postoperative radiotherapy with or without adjunct chemotherapy are probably indicated.

It is helpful to request from the pathologist a depth-of-invasion measurement on more superficial lesions, given its predictive value in regard to occult metastases, and determining the need for elective neck dissection (see discussion on elective neck dissection in this chapter). Depth of invasion will not influence treatment of deep indurated or fixed lesions. Slowly resorbing sutures, which will serve as a marker if an excisional biopsy is performed, is best if closure is required.

Management of Premalignant Lesions

Leukoplakia is defined as a predominately white lesion of the oral mucosa that cannot be characterized as any other definable lesion (Figure 33-2).¹⁵ Worldwide estimates of its prevalence range from 1.5 to

FIGURE 33-2 *Leukoplakia of the ventral tongue.*

2.6%.¹⁶ Lower socioeconomic status seems to be associated with higher prevalence.¹⁷ The potential for malignant transformation of oral leukoplakia to invasive squamous cell carcinoma is well recognized, and leukoplakia can be considered a precancerous lesion (ie, “a morphologically altered tissue in which cancer is more likely to occur than in its apparent normal counterpart”).¹⁵ Estimated rates of transformation, however, vary widely. This most likely relates to the heterogeneity of the lesions included in most studies. While homogeneous white leukoplakia has a relatively low risk, erythroleukoplakia has a high incidence of associated dysplasia, carcinoma in situ, and frank carcinoma. In their oft-quoted study of 257 patients followed for a mean of 8 years, Silverman and colleagues found transformation rates for leukoplakia to range from 6.5% for homogeneous lesions to 23.4% in erythroplasia.¹⁸ Lesions containing dysplasia had a transformation rate of 36.4%.¹⁸ The annual transformation rate in one population was less than 1%, which still demonstrated a 36-fold risk increase for squamous cell carcinoma in patients with oral leukoplakia over the population in general.¹⁹

Predicting which lesions will ultimately transform is currently not possible. Given its asymptomatic nature, the sole indication for treatment of leukoplakia is an attempt to prevent subsequent malignant transformation. Treatment modalities include excision, ablation, and chemoprevention. Unfortunately no treatment modality has been shown to prevent subsequent development of squamous cell carcinoma.

The first Cochrane review on therapy for leukoplakia did not find any reliable therapy to prevent the transformation of leukoplakia to oral squamous cell carcinoma.²⁰ Also, there were no effective preventive measures to halt the development of oral leukoplakia. No surgical procedures were included in this review because of the lack of randomized clinical trials evaluat-

ing surgical excision. Chemopreventive agents including retinoids, beta carotene, green tea, and bleomycin were evaluated. Retinoids held the most promise and were associated with resolution of lesions. The ultimate goal remains prevention of subsequent malignant transformation, and unfortunately none of the agents demonstrated this reliably. In addition associated side effects were problematic (see section “Chemoprevention” in this chapter).^{20,21}

Surgical excision remains an alternative for dealing with worrisome lesions. CO₂ laser excision has been used to treat widespread superficial lesions in an attempt to limit scarring and morbidity associated with large excisions. Laser ablation allows the destruction of large superficial lesions. It does not provide a histologic specimen, however, and biopsies from any areas of ulceration or erythroplasia are probably indicated prior to ablation. Unfortunately recurrence following laser excision or ablation is not uncommon, and it does not necessarily prevent malignant transformation.²²

Given the high rates of multiple lesions and their propensity to recur, photodynamic therapy (PDT) is gaining popularity as a potential method for dealing with multiple diffuse lesions. PDT relies on a complex interaction of a photosensitizing agent, which is preferentially concentrated in abnormal tissue, with light of various wavelengths, depending on the photosensitizer, to create necrosis through a nonthermal reaction. Tissue necrosis is mediated through the creation of singlet oxygen, a highly reactive species that induces cellular damage through several mechanisms. Advantages of PDT include minimal damage to surrounding tissues and no cumulative damage, which theoretically allows unlimited treatments. Given the propensity for these patients to develop multiple lesions, this is an important advantage over excision or ablation using traditional methods. Disadvantages include marked photosensitivity, especially

with regard to sun exposure, for variable lengths of time after the administration of the agent. Areas treated undergo healing through mucosalization with minimal or no scarring. Although a complete review of PDT is beyond the scope of this chapter, excellent reviews are available.^{23–25}

PDT has been used with some success in the endoscopic treatment of dysplastic Barrett's esophagitis to prevent its transformation to adenocarcinoma.²⁶ Similarly attempts have been made to treat diffuse oral leukoplakia with PDT with some success.²⁷ In addition to its role in the management of leukoplakia, initial trials of PDT applied to invasive squamous cell carcinoma of selected sites in the head and neck are being reported. Copper and colleagues reported on 25 patients with T1 and T2 lesions of the oral cavity and oropharynx treated with PDT. Complete remission was noted in 86% of lesions. Recurrences were salvaged with conventional therapy.²⁸ In addition to its application to mucosal lesions, interstitial delivery of light may allow treatment of more deeply situated tumors. Although results are promising, PDT for leukoplakia and oral cavity cancers remains investigational, and its role in the management of leukoplakia and squamous cell cancers of the head and neck awaits clarification.

Role of Panendoscopy in Treatment Planning

Once a histologic diagnosis of oral cancer has been made, a patient evaluation is initiated in an attempt to define the extent of the locoregional disease, as well as the existence of distant metastases. The discussion that was started with the patient when the biopsy was performed is now continued with the knowledge that a malignancy is present, but that continued work-up is necessary to define the extent of disease. Patients frequently feel a sense of urgency once a diagnosis of cancer is rendered. They want treatment initiated quickly. It is important to convey that cancer is not a

surgical emergency and that the growth rate of epithelial malignancies allows for an appropriate evaluation that must be completed prior to making treatment recommendations. It should also be remembered that there is a high incidence of depression in the head and neck cancer patient population. The level of family and community support should be gauged, and appropriate referrals should be made if deemed necessary. The patient's overall medical condition should also be assessed in preparation for any planned treatment. Aside from the standard history and physical examination, including head and neck examination, nasopharyngoscopy or indirect laryngoscopy in the office should be considered. This evaluation may be forgone if panendoscopy or "triple endoscopy" is planned to search for synchronous primary cancers.

Following McGuirt's 1982 study of panendoscopy, examination of the esophagus, larynx, and bronchus was considered mandatory in the work-up of the patient with cancer of the head and neck.²⁹ A mirror examination of the nasopharynx was also frequently included. McGuirt's finding of synchronous tumors in 16% of patients led most clinicians to include panendoscopy in their evaluation.²⁹ Recently its routine use has been called into question for a variety of reasons, including cost containment, improved imaging modalities, and lower rates of synchronous primary tumors of the head and neck than previously expected. Some clinicians still feel there is a role for an examination of the primary cancer under general anesthesia, along with panendoscopy. They argue that the ability to examine some larger primary cancers is compromised in the clinical setting because of patient discomfort, and that the panendoscopy affords the clinician an invaluable opportunity to examine the primary cancers without this constraint. Others argue that the low yield of bronchoscopy over chest radiographs and computed tomography (CT) scans and the

ability to perform an examination of the larynx with flexible nasopharyngoscopy mitigate against the usefulness of rigid laryngoscopy and bronchoscopy. Also, the majority of patients with cancer of the head and neck receive a flexible esophagoscopy along with placement of a percutaneous endoscopic gastrostomy tube. For these reasons panendoscopy should probably be symptom driven.³⁰

Choosing a Treatment

Once the initial evaluation, data collection, and staging are complete, a discussion regarding treatment is undertaken. The clinician and the patient are faced with deciding which treatment modality or combination offers not only the best chance for cure, but also quality of life. Quality-of-life issues are becoming increasingly important in treatment planning. Despite media hyperbole on cancer treatment "breakthroughs," cancer treatment still falls into three basic categories: surgery, radiation, or chemotherapy, or some combination thereof. Choosing the appropriate treatment relies on many factors, including the patient's medical condition as well as the modalities available to the clinician. Certain therapeutic modalities, such as neutron beam radiotherapy, may hold promise for certain tumors, but are limited in their availability. Although each will be discussed separately in the upcoming sections, most patients will ultimately receive more than one form of treatment.

Surgery

Surgery remains the cornerstone of most treatment regimens for oral cavity cancer. Surgery offers several advantages, including the harvest of a specimen for histopathologic analysis and the possibility of removing the cancer with one treatment modality at one session. For most stage I and stage II cancers of the oral cavity, surgical resection with frozen section analysis of the margins is advocated by most clinicians. Although primary radiation to

T1 and T2 lesions may offer similar disease control, the side effects of radiation to the oral cavity outweigh those of surgery in most situations. In addition, given the rate of second primary cancers in the head and neck cancer patient population, it is often better to hold radiation if possible in case it is needed in the future. The oral cancer patient population is prone to the development of second primary cancers and some would argue that radiation for borderline indications might be withheld for future use should the need arise. Reirradiation, although possible in some circumstances, is associated with a high degree of morbidity.

The importance of obtaining clear histologic margins has been a foundation for surgical treatment of oral cavity cancer and has been supported by several studies that have demonstrated decreased survival associated with positive margins, even if follow-up radiation is given. Unfortunately clear pathologic margins are not always an assurance of a good outcome. Field cancerization is a concept that was proposed by Slaughter and colleagues in 1953, after they reviewed resection specimens from the oral cavity and oropharynx. They found multiple foci of cancer in 11% of specimens. Areas of dysplasia also existed distant from the primary site.³¹ Additional studies have shown that margins that are clear histologically may still have cells at the margin that demonstrate premalignant changes, and this can be associated with recurrence. A recent study demonstrated that an altered *P53* gene existed in 52% of reviewed patients and that recurrence occurred in almost half of these patients.³² Other markers have been shown through molecular analysis to exist at margins that are clear histologically; specifically the proto-oncogene *eIF4E* has been shown to be associated with a decreased disease-free interval when present at the resection margin.³² In an interesting study Thomson performed biopsies in patients with unilateral squamous cell

carcinomas or premalignant lesions.³³ These biopsies were taken on the opposite side of the mouth in the same area as the contralateral cancer or premalignant lesion. These so-called “mirror image” biopsies revealed frank dysplasia or carcinoma in situ in 30% of patients.³³ This concept of “condemned mucosa” has caused clinicians to question the ability of surgeons to obtain clear margins in some cancers. Studies have clearly shown, however, a decreased local control and survival in patients with positive margins.

Jacobs and colleagues analyzed patients who had received postoperative radiation; patients with satisfactory margins suffered an 11% relapse rate, whereas patients with unsatisfactory margins relapsed 26% of the time.³⁴ This is most likely due to the inability of radiation therapy to deal with the increased tumor cell burden in some cases of final positive margins.³⁴ These studies have led some to investigate addition of brachytherapy to external beam postoperative radiation to patients with unsatisfactory margins, and to subsequently demonstrate improved survival in patients with positive margins who received this intensive radiation.³⁵ It is agreed by most that surgeons should strive for clear margins, given this impact of positive margins on survival. Excision with 1 to 1.5 cm of normal tissue beyond the obvious tumor edge is generally sufficient. Margins should then be harvested from either the specimen or the wound resection periphery depending on the surgeon’s preference. These thin strips are oriented for the pathologist using a specimen map (Figure 33-3). Mucosal margins as well as deep margin specimens are submitted; however, frozen-section analysis is accurate but not infallible. Indeed the role of frozen analysis of margins in oral cavity cancer has been heavily debated and its cost effectiveness called into question, leading some surgeons to abandon the practice. Although frozen-section analysis is highly accurate and has a high correla-

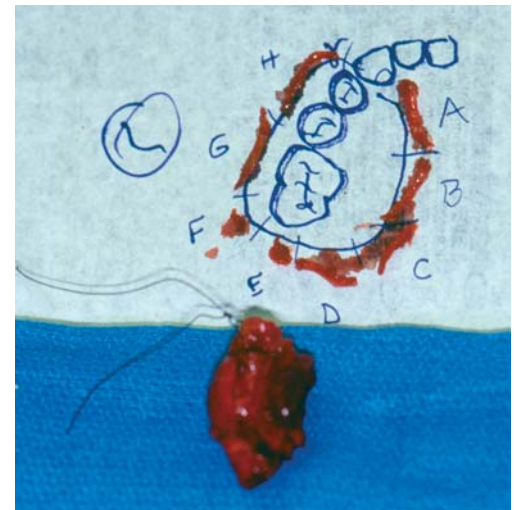

FIGURE 33-3 Specimen map for demonstration of the orientation of frozen section specimens to the pathologist.

tion with final histologic analysis of the submitted tissue samples, its ability to predict whether the entire tumor surface of the final specimen will be clear of close or involved margins is not as reliable. For this reason frozen sections appear to be more beneficial in smaller localized tumors.^{36–38}

On occasion a surgeon will be faced with a situation where the frozen margins were negative but the final processed specimen shows involvement of one or more margins. This phenomenon can have several explanations. First, sampling error can occur. Secondly, if the margins analyzed by frozen technique were taken from the tumor resection bed, then it might lie just beyond the cancerous margin. Also, tumor shrinkage of approximately 25 to 30% occurs when the tumor is removed from the body. Faced with this dilemma the surgeon has several options. Re-excision of a positive soft tissue margin is difficult and rarely productive. Wound closure or reconstruction of the defect distorts tissue, and it is frequently impossible to determine exactly where the positive margin was. For this reason a final positive margin may represent an indication for postoperative radiation therapy (see section “Radiation” below). Conversely clearance of cancer within bone with radiation is difficult

and recurrence rates are high, suggesting that patients with positive bone margins should be strongly considered for re-excision. Recent reports illustrate that pathologic margins that are positive on final analysis are more likely a reflection of the aggressiveness of the particular cancer than a reflection on the surgical procedure. Sutton and colleagues found that final positive margins had a high correlation with aggressive histologic parameters such as perineural and lymphovascular invasion.³⁹ Thus, the biologic aggressiveness suggested by positive margins may in itself account for the poorer outcome of patients with positive surgical margins, and be an indication for multimodality therapy instead of attempts at re-excision.

Surgery in patients with head and neck squamous cancer presents unique challenges that surgeons should be prepared to face. The following discussion offers an overview of some of the perioperative issues facing patients and surgeons. Subsequent sections will review surgical points pertinent to specific sites within the oral cavity.

Perioperative Issues in Oral Cavity Cancer Treatment

The decision to operate on a patient with head and neck cancer must involve consideration of potential complications. Studies have demonstrated that age itself is not associated with increased complications, but comorbidities are associated with increased complications and lengthy hospital stays. This is especially true regarding complex reconstructive efforts, such as vascularized tissue transfer.⁴⁰ Several factors deserve special attention in the patient undergoing surgery for a malignancy of the upper aerodigestive tract.

Airway If there is any doubt concerning the ability of a patient to maintain an airway in the perioperative period, a tracheotomy is advisable. A tracheotomy tube does not prevent aspiration, and paradoxi-

cally may actually increase its likelihood because of tethering of the trachea and impaired glottic closure. Tracheotomy is not without its own risks, and the nursing staff performing tracheotomy care must be well versed in suctioning and maintenance. Decanulation can generally be performed soon after edema has decreased.

Perioperative Antibiotics Operations on the oral cavity are considered “clean-contaminated,” and therefore, perioperative antibiotics are indicated. Several well-controlled studies have demonstrated that antibiotics started prior to the incision and continued for no more than 24 hours serve to minimize perioperative infections and emergence of resistant strains. First-generation cephalosporins and clindamycin represent the most commonly used prophylactic antibiotics in oral cancer surgery. Topical antimicrobials such as chlorhexidine and clindamycin rinses have also been shown to successfully reduce the incidence of infections.^{41,42}

Alcohol Withdrawal Many patients with oral cavity cancer will be dependent on alcohol. Alcohol withdrawal is common if precautions are not taken and can culminate in delirium tremens leading to cardiovascular collapse and death. Appropriate prophylaxis with benzodiazepines is recommended if the patient drinks daily. Lorazepam is commonly used because of its predictable onset and lack of active metabolites. Intravenous alcohol (5 to 10% alcohol with 5% dextrose in water) can be used in the postoperative period and slowly tapered as the patient recovers from surgery.

Deep Venous Thrombosis Patients who will be immobilized for a significant time during surgery or following surgery should receive prophylaxis for deep venous thrombosis. This prophylaxis most commonly takes the form of mechanical compression devices that cause endothelial cells to

release antithrombogenic factors and prevent stasis. It is important that these be placed and activated before surgery. Pharmacologic agents are generally reserved for known cases of thrombosis because of their propensity to cause bleeding in the postoperative setting. Low-molecular-weight heparin may be an option in this setting. If the patient has undergone microvascular reconstruction, aspirin or low-molecular-weight dextran may be indicated.

Fluid Management Most patients undergoing surgery for oral cavity cancers can be managed without invasive monitoring of fluid status. Colloids may be needed to prevent undue amounts of crystalloid leading to a significant increase in edema. Preoperative and daily weights can be used to track fluid status. In patients with compromised cardiovascular reserve or in those undergoing large resections and free-flap reconstruction, invasive monitoring with central venous monitoring or via a Swan-Ganz catheter may be necessary. Although uncommonly performed, patients requiring bilateral resection of the internal jugular veins will need fluid restriction.

Transfusion Opinions regarding the need for transfusion vary. In general a hematocrit less than 25 requires transfusion, and those between 25 and 30 may need transfusion based on clinical parameters.

Nutrition Many patients with head and neck cancer will present with decreased nutrition reserves. Even patients without weight loss are often faced with therapies that will leave them unable to maintain their nutrition. The ability to bypass the upper digestive tract during intense multimodality therapy by the endoscopic placement of a gastric feeding tube (percutaneous endoscopic gastrostomy or PEG tube) is invaluable. This procedure offers a minimally invasive “lifeline” for patients undergoing intensive therapy to the head

and neck. Placement of a PEG tube has become commonplace in head and neck cancer patients. Although rare there have been anecdotal reports of seeding squamous cell carcinoma to the abdominal wall if the PEG is placed prior to resection.⁴³ This complication, although rare, has led some surgeons to recommend placement in the postoperative period. Even if a PEG is placed, the patient should be encouraged to continue some oral intake, as the risk of esophageal stenosis increases if the patient completely stops oral alimentation during radiation treatment. This is especially true during combined chemoradiation protocols.

Complications of Surgery

Complications of surgical resection are many and vary directly with the patient's comorbidities, such as ischemic cardiac disease, chronic pulmonary disease, and alcoholism. Medical manifestations of preexisting chronic disease states, such as myocardial infarction, stroke, and pneumonia, can be precipitated by major surgery, a long general anesthetic, and a prolonged intensive care unit stay. Significant morbidity or death can be the result. Technical surgical complications, such as failure of reconstructive flaps, development of fistulas, and the other myriad problems that may require return to surgery for management, pale in significance to the greatest complication—locoregional recurrence of the cancer.

Radiation

A complete review of radiation physics and medicine is beyond the scope of this chapter, and excellent reviews on the topic are available.⁴⁴ Surgeons dealing with oral cancer should have an understanding of radiation therapy and its advantages and disadvantages. This entails a familiarity with radiation biology and the interaction of radiation with living tissue, as well as the biology of cell death. Cell death can be divided into two types: reproductive cell death, which results from damage to cel-

lular genetic material, or apoptosis, which is programmed cell death. Reproductive cell death can occur as a result of single DNA strand breaks, which are common and easier for the cell to repair, or double-strand breaks, which are more difficult for the cell to recover. Apoptosis occurs when a cell enters a programmed cell death mode as a result of damage. Radiation can cause either type of cell death and also slows cellular division. Classically radiation is discussed in terms of the four R's: repair, reoxygenation, redistribution, and regeneration.

Radiotherapy is primarily given by external beam using electromagnetic radiation or particulate components. X-rays and gamma rays represent photons. X-rays are produced by a man-made source and gamma rays are produced by radioactive decay, most commonly of cobalt 60. Particulate radiation using electrons plays an important role in head and neck cancer. Another form of particulate radiation is neutron radiotherapy, which may have a specific role in salivary gland malignancy.⁴⁵ Regardless of the source, radiation interacts with tissue to produce several types of damage to cells. The radiation particle-cell interaction may be either direct, or more commonly impact with H₂O molecules to create secondary particles that interact with cellular DNA. Absorbed dose is reported as a gray (Gy), which is one joule of absorbed dose per kilogram. Previously dose was reported as a rad, which was defined as 100 ergs absorbed per gram. One gray is equal to 100 rad and one centigray (cGy) equals one rad (1 cGy = 1 rad).

In the early to mid-twentieth century, radiation was given as orthovoltage (125 to 500 KeV). Currently radiation is delivered as megavoltage (> 1 MeV). Megavoltage results in more radiation delivered to deeper tissues with less superficial (skin) damage. In comparison a superficial radiograph unit (x-ray machine) delivers 30 to 125 KeV. Radiation therapy is typically

given in daily doses of 200 cGy, except in altered fractionation schedules.

Fractionation refers to the schedule on which the radiation dose is administered. Standard radiotherapy is administered daily, 5 days a week, with weekends off. In an effort to maximize damage to the more rapidly dividing tumor cells while sparing normal tissues as much as possible, fractionation schedules have been altered. Although used primarily in clinical trials, clinicians should be familiar with the advantages and disadvantages of other fractionation schedules because it is likely that their use will become more widespread. *Accelerated fractionation* refers to an overall reduction in treatment time accomplished by giving two or more daily-dose fractions of close to conventional size. *Hyperfractionation* implies that the overall treatment time is conventional or slightly reduced, but an increase in total dose is achieved by giving two or more small-dose fractions on each treatment day. Each of these regimens is associated with varying degrees of early and late toxicities. For example, some clinicians feel that long-term effects such as osteoradionecrosis are increased with hyperfractionated schedules, especially when combined with concomitant chemotherapy. This view is not universal, however, and as more experience is gained, questions regarding toxicity will be answered.^{46,47}

Aside from changes in radiation schedules, other facets of radiation delivery technique have undergone recent changes. Radiation is delivered to a specific target area that is limited by shielding (defined as radiation portals or "ports") that is placed to protect areas that are not suspected of harboring tumor or that are less tolerant of radiation (ie, the spinal cord). The radiation treatment plan is typically standardized for each subsite in the oral cavity. *Conformal radiation treatment* refers to more localized delivery of radiation to the suspect site. By linking CT images with the ability to manipulate the

radiation beams, radiation therapists are able to more accurately focus the radiation dose on the tumor bed and avoid adjacent uninvolved areas that may be more susceptible to radiation damage (Figure 33-4). There is still concern that highly conformal treatment plans may result in increased recurrence rates because of the more limited field of radiation. Intensity modulated radiotherapy is an example of a conformal treatment plan combined with varying radiation doses to limit the collateral damage to surrounding areas.^{48,49}

Brachytherapy or interstitial radiotherapy is administered by placing a radioactive source, typically radium (²²⁶Ra) or iridium (¹⁹²Ir), directly in the tumor mass using needles or loop catheters. In this manner radiation is delivered continuously. This does not allow the tumor cells to “repopulate” between fractions as in external beam therapy. Unfortunately cells native to the area cannot recover either, resulting in extensive radiation-induced fibrosis and osteoradionecrosis. This technique allows a higher total dose of radiation to be given to a primary site than does external beam because the radiation is placed directly in the tumor mass. Brachytherapy has devel-

FIGURE 33-4 Three-dimensional conformal mapping of postoperative radiotherapy for esthesioneuroblastoma of the olfactory bulb. Globes and optic nerves are depicted to ensure minimal radiation damage to these structures.

oped a reputation for creating chronic wounds and may lead to osteoradionecrosis when used adjacent to the mandible. Its current use is generally limited to treatment of tongue or tongue base primaries, and is usually combined with external beam radiation. Brachytherapy has also been advocated for treatment of close or positive margins following surgical excision.³⁵ Brachytherapy patients may require a tracheotomy for airway control because of airway compromise from edema. Wound healing is also severely compromised. Some clinicians have recommended only limited biopsies in the treated area if recurrence is suspected because chronic nonhealing wounds can develop.^{50,51}

Radiation can be administered with curative intent in the preoperative setting or as an attempt to shrink a tumor presurgically (neoadjuvant). When the primary tumor is to be treated with radiation, the clinician must also consider elective radiation of the neck for control of occult metastases. Because of its dependence on oxygen for effectiveness, bulky neck disease with its attendant hypoxic core should probably be treated with neck dissection, either before radiation or as a planned procedure within 4 weeks of completion of radiation. Early-stage oral cavity cancer (T1 or T2) responds equally well to radiation or surgery. The morbidity of radiation and the inability to use it again in the case of a second primary cancer or recurrent disease makes surgery a more attractive modality in most situations. Larger tumors (T3 and T4) generally respond poorly to radiation alone. Preoperative radiation given in an attempt to shrink larger tumors is hampered by the fact that tumors do not shrink concentrically. Viable islands of tumor cells can be left beyond the new clinically evident margins. In theory surgeons are committed to excising to the original margins, something that seldom happens in clinical practice.

The primary role for radiation in oral cavity cancer is in the postoperative setting

when there is potential for persistent disease. Clinical protocols vary among institutions, but there are accepted indications for postoperative radiation therapy:

- Two or more lymph nodes containing metastatic disease in a neck dissection (many clinicians contend that one positive node is an indication)
- Extracapsular extension (ECS) of cancer beyond the confines of a node
- Poor histologic factors: extensive perineural or perivascular invasion, positive (close) soft tissue margins
- Large (T3 or T4) primary cancers

Reports have found ECS to be associated with decreased survival: disease limited to the node was associated with a 70% survival, whereas ECS was associated with a 27% survival at 5 years.⁵² Million and colleagues found that 35% of patients with clinically negative necks converted to positive if the primary cancer was treated with surgery alone.⁵³ This dropped to 5% if radiation therapy was added. Even microscopic evidence of extracapsular extension is associated with a higher rate of recurrence and death.⁵⁴ The decision to add radiation treatment must be made with a clear understanding of the morbidity of its use.

In advanced disease, clinicians are faced with a choice of preoperative or postoperative radiation treatment. Planned preoperative radiation treatment is rarely used but may lower the probability of positive margins and may allow smaller surgery (controversial). Lower doses of radiation are required because of the improved oxygenation in areas not disturbed by surgery. Postoperative radiation treatment allows easier surgery and better healing in tissues not disturbed by radiation-induced fibrosis. Frozen-section analysis of margins is easier in this setting, and surgery allows improved treatment planning based on final pathology. Postoperative radiation therapy remains the mainstay in most cases of resectable cancers of the oral cavity. A study by the Radiation Therapy Oncology Group,

RTOG 73-03, compared 50 Gy preoperative radiotherapy to 60 Gy postoperative radiotherapy. The 10-year follow-up demonstrated no survival advantage to either regimen, but postoperative radiation treatment demonstrated superior locoregional control.⁵⁵ How much is enough? Results from an MD Anderson Cancer Center (University of Texas, USA) study showed that 54 Gy was needed in the postoperative setting, and 57.6 Gy was needed if extracapsular extension was present.⁵⁶

Timing of initiation of radiation therapy following surgery is controversial. Vikram demonstrated a clear survival advantage in patients whose radiation therapy was started within 6 weeks of surgery.⁵⁷ For this reason reconstructive options that led to reliable healing in this amount of time were advocated.⁵⁷ A more recent study failed to replicate Vikram's earlier findings, leading some to challenge the supposed impact of timing on ultimate outcome. Other studies have reported improved outcomes when postoperative radiation begins within 6 weeks and ends within 100 days of surgery for oral cavity squamous cancers.^{58,59}

The future direction for radiation treatment may include the development of effective radioprotectants and radiosensitizers. Radioprotectants, such as amifostine, are given in an attempt to protect normal tissues. Amifostine was developed by the military as a possible protection from nuclear attack and has recently been applied to head and neck cancer patients to protect salivary gland function during radiation therapy.⁶⁰ Xerostomia is a long-term problem that has a significant effect on patients treated with radiation therapy to the head and neck, with 64% of patients reporting moderate to severe permanent xerostomia.⁶¹ Decreased incidence of candidiasis, a frequent side effect observed in patients with radiation-induced xerostomia, has been used as an end point in amifostine therapy used for its protective effect on salivary gland function.⁶² Its use is asso-

ciated with side effects, such as hypotension, and some patients do not tolerate it. It is costly and there remains some fear that its radioprotective effects might extend to the cancer cells as well, resulting in higher recurrence rates. Radiosensitizers are chemotherapeutic agents that enhance that effectiveness of radiation (see section "Chemotherapy" below).

Chemotherapy

Until 1991 the role of chemotherapy in head and neck cancer was limited to its use in the management of recurrent and/or metastatic disease. A landmark study that changed our view of chemotherapy was reported by the Cooperative Studies Program of the Department of Veterans Affairs Laryngeal Cancer Study Group who reported a multi-institutional trial on patients with advanced laryngeal cancer.⁶³ Their study demonstrated larynx preservation and equivalent survival among patients who received induction chemotherapy followed by radiation, as opposed to traditional laryngectomy and postoperative radiation.⁶³ Although criticized by some for its lack of a radiation-only control group, the results fostered a renewed interest in use of chemotherapy in the management of advanced head and neck malignancy, including squamous cell carcinoma of the oral cavity. Several reviews are available on the evolving role of chemotherapy in head and neck cancer. The following summarizes the basics of chemotherapy in oral cavity cancer and discusses several potential future applications.

Prior to analyzing the results of chemotherapy in oral cavity cancer, an understanding of the basic biology of chemotherapy and the associated terminology is necessary. In many ways chemotherapy for cancer is conceptually similar to chemotherapy for infections; however, the immune system in general is not inherently competent to destroy the cancer. Chemotherapeutic agents kill a constant fraction of cancer cells leaving

behind a certain amount of resistant cells. These resistant cells subsequently divide and the tumor mass once again increases. In infectious diseases the body's immune system aids in the destruction of the decreased burden of cells, whereas in cancer the patient usually does not have an immune system that can deal with the rogue cell line. Similar to infections with resistant strains, multidrug protocols have been developed to counter the development of resistant cell lines in cancer. Principles of chemotherapy have been developed to overcome the development of resistant cell lines such as the use of multiple agents that have demonstrated independent activity against the cancer type, the combination of drugs with differing toxicities to allow maximum dosing of each agent, and the maintenance of short intervals between dosing agents while allowing adequate recovery of normal tissues. Solid tumor growth is governed by Gompertzian kinetics, which means that growth slows as tumor bulk increases. Since chemotherapeutic agents are most effective against cells undergoing replication, smaller and faster growing tumors are more susceptible.⁶⁴

Assessment of the literature regarding chemotherapy is complicated if one does not understand the definitions of complete response, partial response, stable disease, and progression. Each of these is determined by the sum of the product of the perpendicular diameters of all measurable tumors. Measurements are obtained at the beginning of treatment and at completion.

- Complete response: Defined as the disappearance of all evidence of disease
- Partial response: At least a 50% reduction in size as defined by the formula above
- Stable disease: Less than a 50% reduction in tumor size
- Progression: An increase of 25% or appearance of new lesions

An important point to remember is that tumor regression must only last for 4 weeks. It is understandable, therefore, that reports of a complete response often have little impact on improved survival. The response rate represents the total percent of patients achieving complete and partial responses. An additional problem with chemotherapy trials is patient selection bias. Increasingly the role of comorbidities in ultimate outcome and the impact of performance status on survival are being recognized as important contributors to survival in head and neck cancer (see discussion below). Performance status is typically reported using the Karnofsky performance status (PS), which rates patients on a scale of 0 (death) to 100 (normal, no evidence of disease) or the Eastern Cooperative Oncology Group scale, which rates patients on a scale of PS 0 (fully active) to PS 5 (death).^{65,66} Most clinical trials require a certain PS to qualify, leading to enrollment of healthier patients and improved outcomes.

Timing of chemotherapy has been the subject of much investigation. Again, definitions are the key to understanding and interpretation of results of clinical trials. *Palliative chemotherapy* is given to patients with incurable disease to temporarily reduce tumor volume in the hope of improving quality of life and lengthening survival. This is typically the arena that serves as a testing ground for new therapeutic agents. *Adjuvant chemotherapy* is given to patients who have undergone treatment of their primary cancer site with surgery and/or radiation. Goals of treatment include elimination of occult disease, especially distant metastases. As the patient no longer has visible or palpable tumor with which to gauge response, agents must be selected that have proven activity against the cancer type. *Neoadjuvant chemotherapy* (also known as *induction chemotherapy*) is given to patients prior to definitive treatment of the primary cancer site.⁶⁴ This tactic is generally

chosen in an attempt to decrease the size of the primary cancer to make definitive treatment possible. For example, a tumor deemed unresectable may be “downstaged” by neoadjuvant chemotherapy to a resectable tumor. As stated earlier tumors do not shrink concentrically and islands of tumor may remain beyond the visible margin. An additional advantage to neoadjuvant therapy is the ability to evaluate response. Squamous cell carcinomas represent a heterozygous population even within the same tumor. Some will be exquisitely responsive to a particular regimen, whereas others will not. Medical oncologists can tailor their treatment more accurately if visible or palpable tumor is available to evaluate response. The biggest criticism of neoadjuvant therapy is that it delays the definitive treatment of the primary cancer. Local failure is still the biggest cause of death in oral cavity cancer, and delaying treatment of the primary site increases the difficulty of obtaining control of the primary cancer. In addition initial chemotherapy can theoretically select more hardy cell lines that are resistant to all therapy. Indeed critics of the Department of Veterans Affairs Laryngeal Cancer Study Group larynx trial contend that neoadjuvant chemotherapy simply selected out less aggressive cancers that would respond to radiation treatment. Currently the role of chemotherapy that has generated the most interest is combination with radiation treatment for an “organ sparing” approach. Chemotherapy in combination with radiation treatment can be given in a sequential or a concurrent strategy. Concurrent therapy takes advantage of the radiosensitization of certain drugs and avoids delay in treating the primary cancer site. The downside is a marked increase in side effects and toxicity that can lead to breaks in radiation treatment, which have been shown to be associated with a decrease in local control. In an attempt to control some of these toxicities, chemotherapy is usually given at

the beginning of radiation treatment and frequently at the completion of radiation. Sometimes radiation therapy is interrupted (split-course radiation) on purpose, and chemotherapy is given. Again, radiation breaks are considered to be associated with decreased control and are therefore not recommended.

Chemotherapeutic agents are under constant development and a complete discussion of available agents is beyond the scope of this chapter. Several principles deserve mention. In general drugs can be divided into cell cycle-specific and noncell cycle-specific agents, depending on whether the particular agent requires that the target cell be in a certain phase (G₀, S, G₁, or mitosis) to be effective. Agents can also be categorized based on their principle mode of action. Antimetabolites, such as methotrexate and 5-fluorouracil, block development of certain metabolites critical for cell metabolism. 5-Fluorouracil is a fluoridated pyrimidine analog that inhibits thymidylate synthetase, blocking the generation of thymidine, which is necessary for DNA synthesis. It is frequently used in the treatment of head and neck squamous cell carcinoma. Typically it is combined with other agents, and it is a radiosensitizer. Methotrexate, an analog of folic acid, blocks conversion of dihydrofolate to tetrahydrofolic acid, which is a precursor of thymidylic acid and purine. This results in an interruption of DNA, RNA, and protein synthesis. Once a standard for head and neck squamous cell carcinoma, methotrexate is now typically only used for palliation. Its side effect profile and ability to be administered intramuscularly on an outpatient basis make it a good option for this purpose. Cisplatin and carboplatin are alkylating agents that form cross-links in DNA and arrest cell division. Cisplatin is more effective in squamous cell cancer but is associated with more renal and neurologic side effects than carboplatin. Other agents used less frequently in head and neck squamous cell cancer

include paclitaxel, which stabilizes microtubular formation and arrests cells in G₂, and bleomycin, which creates DNA breaks. Agents under development include flavopiridol, a cyclin-dependent kinase inhibitor that has been shown to induce apoptosis (programmed cell death) in squamous cell cancer lines in vitro, and for which a phase 1 trial is underway.^{67,68}

Standard therapy for resectable disease remains surgery followed by radiotherapy, if indicated. To date, induction chemotherapy followed by surgery has not shown a survival benefit in oral cavity cancer. The question of adding chemotherapy in the postoperative setting remains unanswered. Currently no study has shown definitive improvement. Cooper and colleagues reported on the results of the RTOG 95-01/Intergroup phase 3 trial that evaluated concurrent chemoradiotherapy in postoperative treatment of high-risk squamous cell carcinoma of the head and neck, defined as multiple lymph nodes involved, extracapsular disease, and positive margins. The locoregional control and overall 2-year survival were not improved significantly, and the small improvement in disease-free survival was at the expense of a significant increase in toxicity.⁶⁹ Adding chemotherapy following surgery and radiation has been shown to decrease the incidence of distant metastases, but this has not been associated with improved survival. At this point chemotherapy in the postoperative setting is not indicated except in cases of known metastatic disease, and its use outside of clinical trials should probably be discouraged.⁷⁰⁻⁷²

Currently the role for chemotherapy in oral cavity cancer is limited to use in unresectable disease in which it is combined with radiation treatment, metastatic disease, or recurrence. Organ preservation (not to be confused with organ function) through the use of concurrent chemoradiation protocols has received much attention. Meta-analyses by El-Sayed and Nelson, and Munro have demonstrated that

concurrent treatment is better than neoadjuvant therapy. Locoregional control and survival were improved in advanced head and neck cancers.^{73,74}

In an attempt to avoid the systemic effects of chemotherapy, investigators have attempted to deliver agents topically, as well as intratumorally with both intra-arterial injections and intratumoral depot forms via polymers and gels (see section in this chapter on recurrent tumors). A novel form of concurrent chemoradiation is the intra-arterial cisplatin and radiotherapy (RAD-PLAT) protocol popularized by researchers at the University of California, San Diego, and University of Tennessee at Memphis, which has shown promise for advanced cancers with bulky primary cancers and nodal disease.⁷⁵ Treatment involves supradose cisplatin delivered directly into feeder vessels of the tumor bed by microarterial catheters placed under angiography. Sodium thiosulfate, which is a neutralizing agent for cisplatin, is administered systemically, allowing doses five times larger than standard protocols. Results of patients with T4 N2-3 disease treated with the protocol revealed 4-year local control of 84%, disease-specific survival of 46%, and overall survival of 29%.⁷⁵ Unfortunately, the protocol is associated with significant toxicity, including death. Use of the RADPLAT protocol is currently limited to centers that have gained familiarity with the technique and management of the toxicities associated with it. Most of these concurrent chemoradiation protocols involved oropharyngeal and hypopharyngeal cancers, and are plagued by noncompliance because of toxicity and side effects. Mucositis is intense and placement of a PEG tube is usually mandatory.⁷⁵

Other novel techniques for minimizing the systemic side effects of chemotherapeutic regimens are under development, including the PDT discussed above under the management of leukoplakia.

Trials of chemotherapy limited to the oral cavity are few. At this time the clearest

indication for chemotherapy in oral cancer is in metastatic and recurrent disease. The most commonly used chemotherapeutic regimen for metastatic or recurrent oral cavity squamous cell carcinoma involves combinations of cisplatin or carboplatin and 5-fluorouracil. Median survival rates of 5 to 7 months and 1-year survival of 20% demonstrate the need for improved regimens. Investigations continue to define a role for chemotherapy in advanced squamous cell carcinomas of the oral cavity. Unfortunately early responses to chemotherapy have not demonstrated improvement in overall survival and only modest gains in median survival time.⁷⁶

Current research in chemotherapeutic agents focuses on agents that bind to specific receptors in an attempt to limit effects to target cells. Similar to the hormonal therapy used in breast and prostate cancers, investigators are experimenting with agents such as epidermal growth factor inhibitors.⁷⁷ Gene therapy that targets known alterations in head and neck squamous cell cancer lines, such as *TP53*, is also an area of growing research.⁷⁸ Restoration of these altered genes, possibly through viral vectors, holds promise in certain populations.⁷⁹ A recent review by Milas and colleagues at the MD Anderson Cancer Center offers insight into the current state of chemotherapy in head and neck cancer, as well as newer chemotherapeutic agents on the horizon.⁸⁰

Chemoprevention

An additional area of intensive research is development of chemoprevention agents, which are defined as agents that reverse or suppress premalignant carcinogenic progression to invasive malignancy (see section "Management of Premalignant Lesions," above). The role of such agents would be twofold: (1) to treat premalignant lesions to prevent their evolution to invasive carcinoma, and (2) to prevent development of second primary squamous cell cancers in patients who have

already undergone treatment of cancer. Given its accessibility to clinical observation, leukoplakia has been used to monitor responsiveness to certain chemoprevention agents in clinical trials. Of the agents evaluated, including retinoids, beta carotene, and vitamin E derivatives, retinoids have demonstrated the most efficacy in eliminating leukoplakia. It is important to note, however, that reversal of these lesions has not been demonstrated to reduce the risk of developing cancer, and the lesions soon return after cessation of treatment. 13-*Cis*-retinoic acid, which is more commonly used to treat acne, has been studied extensively in both the treatment of premalignant lesions and in the prevention of second primary cancers. It may act through the up-regulation of a distinct retinoic acid receptor, RAR- β , whose down-regulation is associated with development of head and neck cancer. Results of trials to date have been mixed. Although effective in eliminating leukoplakia, side effects limit its use, and lesions return after discontinuing the drug. Secondary primary tumors occur in 4 to 7% of patients treated for head and neck squamous cancer and are the major concern-related cause of death in early-stage cancer. The prevention of these tumors is therefore important. Studies of 13-*cis*-retinoic acid have shown decreased incidence of second primary cancer but no effect on primary disease recurrence. This suggests that retinoids may prevent cancerous development in damaged cells but will not treat fully transformed cancer cells. Also, overall survival was not affected. Required doses of retinoids have side effects, including mucocutaneous toxicity (peeling and cheilitis) and elevation of liver function tests. Development of second-generation retinoids may attenuate some of these side effects. One study demonstrated a worrisome increased incidence of primary lung cancer in patients treated with beta carotene.^{81,82} In addition, Wang and colleagues recently reported on

a novel tretinoin biofilm that allows sustained topical delivery to the oral cavity.⁸³

Investigators continue to search for chemotherapeutic agents with more acceptable side effect profiles. One of these agents is the Bowman-Birk inhibitor, a protein derived from soybeans that has shown clinical activity against leukoplakia without the attendant side effects of retinoids.⁸⁴ Nonsteroidal anti-inflammatory drugs have also been investigated since chemoprevention activity was found in some cyclooxygenase-2 (COX-2) inhibitors. COX-2 influences several steps in the development of malignancies, such as apoptosis, angiogenesis, invasiveness, and immune surveillance.^{85,86} COX-2 expression has been noted in high-risk premalignant lesions.⁸⁷ In addition to their potential role in chemoprevention, COX-2 inhibitors hold promise in the treatment of invasive squamous cell carcinomas.⁸⁸ Although chemoprevention offers hope for patients at high risk for development of second primary cancers and treatment of patients with high-risk lesions (see discussion on premalignant lesions above), its use is currently restricted to clinical trials and off-label use. Further work is needed to establish a safe and effective chemopreventive regimen.

Special Treatment Considerations by Site

The Lip

Although classified as an oral cancer, squamous cell carcinomas of the lip typically follow a different clinical course than those of oral mucosal cancers. The primary etiologic agent, sun exposure, is different from oral cancers, and the location of lip cancers usually leads to earlier discovery. The behavior of squamous cell cancers of the vermilion border is usually intermediate between squamous cell carcinoma of the skin and that of the mucosa. The vast majority arise on the lower lip where sun exposure is

greatest. Most lip cancers are treated by surgical resection using 0.5 to 1.0 cm margins and frozen-section control. Although often referred to as a “wedge” resection, the actual specimen more closely resembles a shield with parallel sides and a tapering base. “Wedge” excisions may be combined with a vermilionectomy or “lip shave” procedure, removing vermilion that has suffered extensive actinic damage or contains carcinoma in situ (Figure 33-5). CO₂ laser ablation of the surface of the lip is also useful as an alternative to vermilionectomy for diffuse actinic changes. Squamous cell carcinoma of the lip shares with squamous cell carcinoma of other cutaneous sites a potential for perineural invasion. A large perineural tumor deposition along the inferior alveolar nerve, several years after a lip cancer, can be mistaken for primary intraosseous carcinoma (Figure 33-6).

Neck dissection is usually not indicated for lip cancer unless there is clinical evidence of lymph node involvement by examination or imaging. Cancers of the upper lip and commissure can metastasize to the parotid lymph nodes, and superficial parotidectomy may be required if there are clinically enlarged nodes. Some larger lesions can be treated with radiation alone if surgical resection will result in unacceptable compromise in appearance and function.

Five-year survival for lip cancer is good for early-stage disease (90% for stages I and II).^{89,90}

FIGURE 33-5 Vermilionectomy combined with wedge resection of lip cancer associated with diffuse actinic changes across the remainder of the lip.

FIGURE 33-6 Apparent intraosseous squamous cell carcinoma arising from perineural spread of a previous lip carcinoma. Review of the original lip resection specimen demonstrated perineural invasion.

Buccal Mucosa

Buccal squamous cell carcinomas represent approximately 10% of oral cavity cancers in the United States compared to 41% in India. Squamous cell carcinomas of the buccal mucosa can be deceptive in their clinical course. Because of the intimacy to the buccal space and deeper structures, cancers that penetrate the buccinator muscle can be difficult to eradicate (Figure 33-7). Patients may present with involvement of the pterygoid space posteriorly or the parotid gland laterally. Extension either superiorly or inferiorly can lead to invasion of the maxillary alveolus or mandibular alveolus respectively. These cancers often arise in wide areas of damaged mucosa, and adequate excision of these lesions often results in complex defects of the cheek that can be difficult to reconstruct. Primary radiation may be an option for smaller lesions. Although up to 50% of patients with buccal squamous cell carcinoma can present with neck metastases, the rate of occult disease in the neck is around 10%.⁹¹ As with other oral cancer sites elective treatment of the neck with radiation or surgery is indicated in T3 or T4 lesions. Consideration should also be given to elective treatment of the neck in deep T1 (> 4 mm) and larger T2 lesions. Vikram and Farr concluded that combined therapy for large lesions with surgery and radiation offered the best chance for cure.⁹²

Two-year overall survival rates for early-stage disease treated with a variety of treatment modalities range from 83 to 100%. Stage III survival rate is 41% and stage IV is 15%. Available survival statistics, however, are often not accurate because of the inclusion of verrucous carcinoma in some of the published reports.

Diaz and colleagues at the MD Anderson Cancer Center reported on 119 consecutive patients with buccal squamous cell carcinomas, the majority of which were treated with surgery followed by radiation if indicated (positive margins, nodal involvement).⁹³ Five-year survival rates for patients with stages I, II, III, and IV disease were 78%, 66%, 62%, and 50% respectively. The significant impact of nodal involvement was noted. Diaz and colleagues found 5-year survival rates of 69% with nodal involvement, which decreased to 24% in cases with extracapsular extension.⁹³

Retromolar Trigone

Given their proximity to the pterygomandibular space, tonsillar pillars, mandible, and tongue base, squamous cell carcinomas of the retromolar trigone (RMT) can behave in a more aggressive fashion, like an oropharyngeal primary cancer (Figure 33-8). Smaller lesions are amenable to wide local excision with or without a marginal mandibulectomy depending on the proximity to the bone (see discussion below). Larger lesions may invade the pterygomandibular space and extend cephalad towards the skull base. Such tumors require segmental composite resections with neck dissection. Significant trismus can be an indication of pterygoid involvement and may make radiation treatment with or without concomitant chemotherapy a better option than surgery. Elective neck radiotherapy or elective neck dissection with a selective neck dissection should be considered in T2 or greater lesions. As with other sites a depth of invasion greater than 4 mm in T1

FIGURE 33-7 Squamous cell carcinoma of the buccal mucosa, deeply invading through the buccinator muscle.

lesions may be an indication for elective treatment of the neck.

Kowalski and colleagues reported on 114 RMT cases treated with surgery with or without radiation and found 5-year survivals of 80% (T1), 57.8% (T2), 46.5% (T3), and 65.3% (T4).⁹⁴ Overall 5-year survival was 55.3%. They recommended adjunctive radiation in stages III and IV.⁹⁴ In an excellent review of the management of RMT cancers, Genden and colleagues also suggested that the addition of preoperative or postoperative radiation confers a survival advantage.⁹⁵

FIGURE 33-8 Squamous cell carcinoma of the retromolar trigone.

The Tongue

The oral tongue, that portion anterior to the circumvallate papillae, is the most common location for intraoral squamous cell carcinomas. They typically present as painless indurated ulcerations. If pain is present it is usually due to secondary infection. The behavior and treatment of oral tongue cancers is sufficiently different than that of posterior tongue lesions (oropharyngeal tongue or tongue base) to allow clinicians to determine the epicenter of the tumor and classify it correctly. This may be challenging in the case of larger cancers. The oral tongue poses significant challenges to clinicians. Seemingly small lesions can metastasize early and recur after treatment. Control rates for small lesions of the tongue (60 to 80%) are poorer than those of similar size in other oral cavity subsites. There are minimal barriers in the tongue to tumor invasion, and there is frequent invasion into adjacent or deeper structures at presentation. Although more commonly associated with oropharyngeal primary cancers, referred otalgia is not uncommon for cancers of the oral tongue, and limitation of tongue mobility with resultant dysarthria is associated with invasion of the deeper musculature. Magnetic resonance imaging (MRI) can be useful in evaluating the depth of invasion (Figure 33-9). Treatment of tongue lesions should be aggressive, and strong consideration for elective treatment of the neck should be given in all cases except for the most superficial lesions (< 2 mm). Although Fakih and colleagues were not able to demonstrate a survival advantage in patients who underwent an elective neck dissection versus a watch-and-wait policy, they did demonstrate that deeper lesions were associated with a significant rate of cervical metastases.⁹⁶ Up to 10 to 12% of tongue cancers with metastases to the neck can demonstrate “skip” metastases to level IV. Consideration should be given to extending the neck dis-

section to include level IV.⁹⁷ Postoperative radiation should be considered in situations where multiple frozen-section specimens were sent before obtaining clear margins, perineural invasion, microvascular or microlymphatic invasion, or other worrisome findings that are present.

Smaller superficial tumors are amenable to wide local excision and reconstruction via primary closure, split-thickness skin grafting, or healing by secondary intention. Larger tumors are reconstructed with vascularized tissue transfer, and mandibulotomy may be needed for adequate access to large or posterior lesions. Radial forearm or lateral arm microvascular free flaps allow excellent mobility and little bulk (Figure 33-10). Unilateral or bilateral pedicled nasolabial flaps can occasionally be used for anterior tongue lesions. Large oral tongue cancers that cross the midline present the surgeon with a difficult choice. If resection is chosen it is often better to tailor the radial forearm flap smaller than the resected area to allow the remaining tongue musculature less bulk to move during excursions (Figure 33-11). Near total glossectomy (resection of the oral tongue with only tongue base remaining) almost always results in high morbidity and is associated with a high incidence of aspiration that may ultimately require laryngectomy for aspiration control. Treatment with external beam radiation alone is associated with unacceptable failure rates. In this setting consideration should be given to organ-sparing protocols with concomitant chemoradiation therapy if surgery will be associated with unacceptable morbidity. Brachytherapy combined with external beam radiation is the treatment of choice at some centers. Technical expertise is required, and most patients require tracheotomy for airway control.

Tongue base tumors, although actually an oropharyngeal subsite and not considered an oral subsite, are discussed here for completeness. The tongue base allows tumors to grow silently, and diagnosis at an

FIGURE 33-9 Enhanced, T2-weighted magnetic resonance imaging of a tongue showing right tongue tumor deeply invading tongue musculature.

early stage is the exception rather than the rule. Most small (T1 and some T2) lesions should be treated with combined therapy, typically surgery plus radiation treatment. Larger tumors are typically treated with an organ-sparing approach using chemoradiation therapy or external beam therapy, sometimes combined with brachytherapy. Results with external beam alone have been disappointing. Reconstruction of smaller posterior tongue defects is best accomplished by radial forearm or lateral arm flaps, if primary closure or healing by secondary intention is inappropriate. Larger

FIGURE 33-10 Radial forearm flap used to reconstruct large tongue defect with nearly normal speech and swallowing.

FIGURE 33-11 A, Large deeply infiltrative squamous cell carcinoma of the lateral tongue. B, Radial forearm flap tailored to the size of the resection, not the apparent size of the defect.

excisions (75% to total) typically are reconstructed with a free rectus flap.⁹⁸

Most treatment failures of the oral tongue involve locoregional recurrence. Second primary cancer rates are high (30%) and this also contributes to treatment failure and death. Three-year survival for T1 and T2 lesions is 70 to 80%, but this decreases to 15 to 30% in patients with lymph node metastases.^{99,100} Some clinicians have reported that tongue squamous cell carcinoma arising in young patients may represent a more aggressive subset and warrant more aggressive therapy. Overall survival for younger patients is actually similar to those of older patients with the same stage because of their lack of intercurrent illnesses. It was found, however, that oral tongue cancers in younger women did behave more aggressively and were associated with higher recurrence rates. This subset may warrant more aggressive initial therapy.^{101,102}

Floor of Mouth

The floor of mouth (FOM) is the second most common location for oral cavity squamous cell cancers (Figure 33-12). FOM cancers can extend along the ventral tongue and cause fixation. In addition FOM tumors can become fixed to the mandible or extend into level I of the neck. McGuirt and colleagues have demonstrated improved outcome with elective treatment of the neck, and elective treatment of

the neck should be considered in all but the smallest thin lesions (< 3 mm).¹⁰³ Sagittal mandibulectomy may be considered in tumors that abut the mandible without evidence of invasion (see discussion below). Small primary cancers can be equally treated with surgery or radiation, although surgery is the choice of most clinicians. Anterior lesions may require sialodochoplasty to reroute the submandibular ducts if the submandibular gland is not removed by ipsilateral neck dissection.

Smaller FOM defects can be closed primarily or left to heal by secondary intention. A partial closure of the defect will often suffice. Larger FOM defects, particularly those that include mylohyoid resection, benefit from a bulkier reconstruction, such as a vascularized radial forearm flap or bilateral nasolabial flaps placed in a one- or two-stage operation.

Local recurrence remains a problem with FOM squamous cancers, and results in high rates of locoregional failure. Five-year survival rates are 64 to 80% (stage I), 61 to 84% (stage II), 28 to 68% (stage III), and 6 to 36% (stage IV).¹⁰⁴

Alveolus and Gingiva

Gingival squamous cell cancers represent a unique subset in oral cavity cancers that arise on the attached gingiva and that should be differentiated from those that arise on the unattached mucosa of the

alveolus. Occult neck metastasis is rare, and elective treatment of the neck is not necessary in smaller lesions. Larger lesions may require partial maxillectomy, or marginal or segmental mandibulectomy, if bone invasion is suspected. Indications and variations on mandibulectomy are discussed below. In general control rates are excellent for gingival primary cancers if treated with adequate margins.

Alveolar cancer arises from the unattached mucosa of the alveolar ridge and has a different clinical behavior than gingival carcinomas. It requires more aggressive therapy and more extensive resection of bone.

Most anterior and some posterior maxillectomies for alveolar and gingival squamous cells can be accomplished via a transoral approach using techniques of orthognathic surgery (Figure 33-13).¹⁰⁵ The pterygoid plates require removal only if there is evidence of invasion through the posterior maxilla. Posterior extension may indicate the need for a transfacial (Weber-Fergusson) approach for adequate exposure. Reconstruction of maxillary defects can be accomplished with local flaps, such as the temporoparietal fascial or temporalis muscle flap, or free-flap reconstruction. The complex nature of maxillary defects and the bulk of some of the flaps, however, often leave a less-than-satisfactory result. Prosthetic obturation of the defect

FIGURE 33-12 Advanced squamous cell carcinoma of the anterior floor of the mouth.

FIGURE 33-13 *Le Fort I island approach to a posterior maxillary tumor, without Weber-Fergusson incision.*

offers several advantages, including a simpler operation, easier early detection of recurrence, and replacement of teeth.

Most maxillary alveolus and gingival squamous cells that invade the sinus involve the infrastructure lying below Ohngren's line, an artificial line that runs from the medial canthus to the angle of the mandible and separates the maxillary sinus into an infra- and supra-structure. Defects arising from cancers resected below this line are easily reconstructed with obturators. Cancers that require true total maxillectomy (resection of one of the paired maxillas, including the orbital floor) tend to require flap reconstruction. If dura mater is exposed as part of a skull base resection, flap coverage is advisable.

Overall 5-year survival for alveolar ridge carcinoma is 50 to 65% for both the upper and lower alveolar ridge. Poor outcome is associated with advanced stage, perineural spread, and positive margins. Adjunctive radiation is recommended if nodal metastases, perineural spread, or positive margins are present.¹⁰⁶

The Palate

Squamous cell cancers of the palate, hard and soft, are rare. The soft palate is considered an oropharyngeal subsite (Figure

33-14). Cancers arising from the hard palate may extend onto the soft palate and vice versa. The periosteum of the palate acts as a significant barrier, and smaller lesions can be treated with wide local excision. Healing by secondary intention under a protective stent secured to the palate is a viable reconstructive option if the palatal bony structure is not removed. Oral-nasal communications in the hard palate can be treated with an obturator or a local flap, such as an anteriorly based midline tongue flap. Oral-nasal fistulas in the soft palate are best treated with temporary obturation, as the majority will close spontaneously. Occult cervical metastases are rare among hard palate cancers (10 to 25%), and elective treatment of the neck is generally not indicated except in T3 or T4 lesions.^{107,108} Also, metastases may occur to the retropharyngeal nodes, and consideration should be given to irradiation of the neck to include this area if suspected.

Management of the Mandible in Oral Cavity Cancer

Management of the mandible in oral cavity cancer has been the subject of much controversy. In the past the mandible was routinely sacrificed in the treatment of FOM and tongue cancers, as it was felt that the regional lymphatics coursed through the mandibular periosteum, necessitating an in-continuity resection of the tongue, FOM, mandible, and neck dissection (Commando's operation). The morbidity of this approach was felt necessary to eradicate in-transit metastases, a belief that was likely based on mistranslation by McGregor of an article published by Polya and von Navratil in 1902, in which they actually recommended removal of the periosteum or rim of mandible and not a segment.¹⁰⁹

Marchetta and colleagues subsequently demonstrated that lymphatics did not flow through the mandible, and that the periosteum of the mandible actually served as a barrier to invasion.¹¹⁰ It was found that squamous cell carcinoma inva-

sion occurs most commonly through the periodontal ligament in the dentate mandible and through the porous occlusal surface of the edentulous mandible.¹¹⁰ O'Brien and colleagues also demonstrated that an inflammatory front preceded cancer that stimulated subperiosteal resorption and the creation of bony clefts that allowed cancer to invade the cortex.¹¹¹ Once the cortex was invaded, the inferior alveolar canal was usually involved, especially in edentulous mandibles.^{111,112} This finding has led to surgeons advocating preservation of mandibular continuity through the use of a marginal mandibulectomy, in cases without obvious bony involvement. These principles apply only to the nonirradiated mandible. Cancer invasion of a previously irradiated mandible occurs through multiple sites. The clinical and radiographic evaluations of mandibular involvement, however, are frequently inaccurate. Clinical findings such as impairment of inferior alveolar nerve function or fixation of the tumor to the mandible raise the index of suspicion. The history of an extraction of a tooth in an area of a cancer may suggest local mandibular invasion. Although used by some, bone scans are cumbersome to obtain and interpret accurately. A high-quality panoramic radiograph is probably the most commonly used tool to decide on mandibular resection versus segmental resection. CT scanning using DentaScan

FIGURE 33-14 *Squamous cell carcinoma of the right soft palate invading posteriorly to involve the anterior pole of the tonsil.*

software has also been used, although recent studies have shown that an MRI demonstrating enhancement of the marrow signal was a better predictor of mandibular involvement. Also, newer techniques that modulate the magnetic field in an attempt to examine changes in the bone marrow hold promise for evaluating mandibular involvement. Tumor invasion into the marrow space is accompanied by a lower intermediate signal. A strong bright marrow signal associated with normal marrow fat underlying the dark cortex typically excludes mandibular involvement.³⁸

At this time the most accurate assessment of mandibular involvement occurs at the time of surgery when the surgeon can inspect the bone. In addition, some surgeons send periosteum for frozen-section analysis, whereas others submit cancellous scrapings for frozen analysis.¹¹³ Once a decision has been made to perform a marginal mandibulectomy, the surgeon has several choices for osteotomy design. Some surgeons advocate rim mandibulectomy, preserving at least a 1 cm inferior border, whereas others advocate a sagittal marginal mandibulectomy or a variation thereof.¹¹⁴ An important point is the avoidance of right angles in the osteotomy design that serve as stress risers and may lead to fracture. We prefer an osteotomy that begins in the sigmoid notch and sweeps inferiorly and anteriorly for lesions located in the posterior mandible (Figure 33-15). It is important to note that the thick cortical bone along the posterior ramus is rarely involved, even when the mandible is invaded, and it can usually be preserved and serves as an area for plating. Edentulous mandibles are generally not candidates for marginal resection although this is not an absolute rule. Wax and colleagues, and Shah have published excellent reviews of the topic of segmental and marginal resection, and the reader is directed to their reviews for a more in-depth discussion.^{115,116} If the surgeon is

FIGURE 33-15 Outline of marginal mandibulectomy suitable for resection of tumors of the retro-molar trigone and posterior maxillary alveolus.

anticipating a marginal resection, and a segmental resection becomes indicated based on operative findings, he or she is faced with a surgery for which both surgeon and patient might not be prepared. Frank discussions before surgery help prepare the patient and their family for this eventuality. Mention should be made of the possible return to the operating room if final pathologic analysis reveals an unexpected amount of bone involvement

necessitating a segmental resection and more elaborate reconstruction.

Splitting the mandible, or mandibulotomy, is often necessary for access to large cancers, especially of the posterior tongue (Figure 33-16). Technical refinement of mandibulotomy helps avoid complications. Mucosal incisions should not be placed directly overlying the proposed osteotomy site. Division of the mandible at the parasymphysis or symphysis is preferred over an osteotomy in the body region. If the mandibular osteotomy is being performed for access to the tongue, the cut should be made anterior to the mental nerve to preserve it. Preadaptation of plates will allow reestablishment of the preoperative occlusion and contour.

Management of the Cervical Lymph Nodes in Oral Cavity Squamous Cancer

Management of the regional lymphatics is a consideration in any cancer. The ability of a cancer to metastasize most commonly manifests itself by growth of cancer in lymph nodes. Surgical treatment of the neck is justified for two reasons: the removal of gross disease in patients with

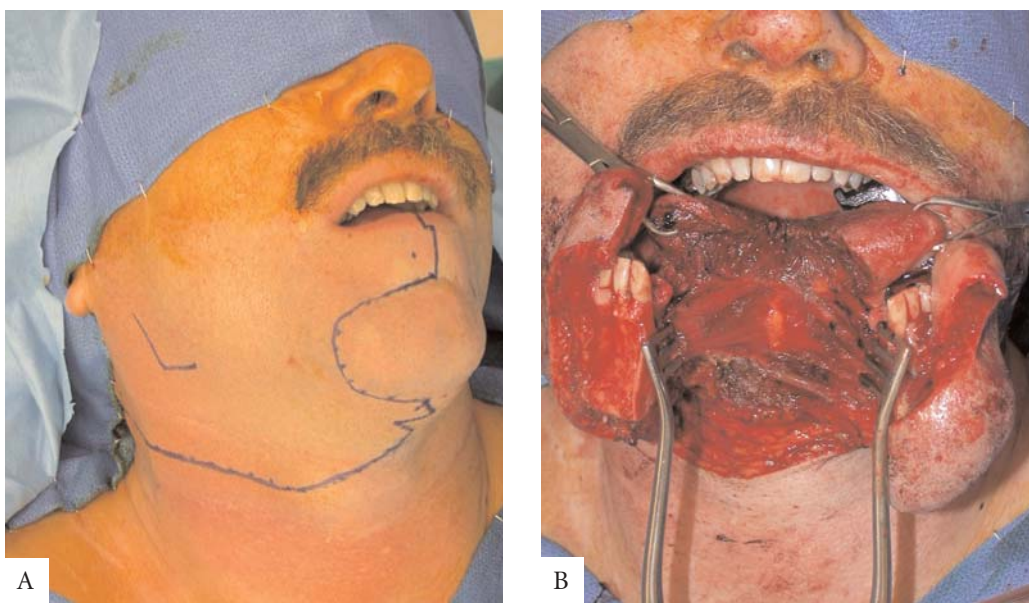

FIGURE 33-16 A, Outline of incision for lip-splitting approach to the posterior oral cavity and oropharynx. B, Midline division of the tongue following midline mandibulotomy.

clinical evidence of nodal involvement (therapeutic neck dissection) or a high enough index of suspicion of occult cervical metastases to justify an elective neck dissection (END). Some surgeons would also suggest that unreliable patients should undergo END as follow-up may be irregular. Excluding the hard palate and lip, approximately 30% of patients with oral cavity cancer will present with cervical metastases.¹¹⁷ The decision to treat the N0 neck is based on the probability of nodal involvement. Evaluation of the neck for cervical metastases remains a critical component of the evaluation of the patient with oral cavity cancer. Manual palpation is regarded as the first step in this process and is usually accomplished before biopsy to avoid postbiopsy inflammatory nodal enlargement. In most necks a lymph node must be at least 1 cm in diameter to be palpable. The accuracy and reliability of palpation is low, with an overall error of approximately 30% in several studies.¹¹⁸ Imaging modalities including CT, MRI, ultrasonography, and positron emission tomography (PET) have become increasingly important in the evaluation for cervical metastases and in guiding therapy.

A CT scan with contrast from the skull base to clavicles has become the most common imaging modality used for detection of cervical metastases (Figure 33-17). Specific criteria for nodal metastases, including node size greater than 1 cm (except the jugulodigastric node, which must be greater than 1.5 cm), central necrosis, and morphology (round instead of oval) have increased sensitivity to over 90%.¹¹⁹ MRI neck evaluation has gained popularity in recent years, and is typically used if the primary site is being imaged with MRI, such as for a tongue cancer. CT and MRI, in that order, are the most widely used imaging modalities for detection of occult metastases in the United States.

The characteristics of the primary tumor may also predict metastases. Spiro and colleagues demonstrated that depth of

invasion in tongue cancer was a reliable predictor of lymph node metastases in cancer of the oral tongue.¹²⁰ They found that cancers with 2 to 8 mm depth of invasion had a significantly higher rate of lymph node metastases than those with invasion of less than 2 mm (25.7% vs 7.5%). Depth of invasion greater than 8 mm was associated with a 41% rate of occult metastasis. Tumor thickness less than 2 mm has been associated with a 13% incidence of lymph node metastases and 3% would ultimately succumb to their disease, whereas greater than 9 mm of invasion was associated with a 65% incidence of lymph node metastases and 35% would die of their disease.^{120,121} O-charoenrat and colleagues also demonstrated an increased risk of cervical metastasis in tongue cancers with a depth of invasion greater than 5 mm, and correlated this with poor outcome even in early stage (I and II) tongue cancers.¹²² Similar results were reported by Kurokawa and colleagues, who found that depth greater than 4 mm was associated with an increased risk for development of late cervical metastases in patients with moderately differentiated squamous cell cancers of the tongue, and diminished overall survival.¹²³ This has led to recommendations that even in the absence of evidence of lymph node metastases, the neck should receive elective treatment (either elective neck dissection or irradiation) for thicker primary tumors. Other investigators have suggested that depth of invasion be added to the staging of oral squamous cell carcinomas. Aside from depth, clinicians have looked at other characteristics such as DNA aneuploidy and histologic grade. At this time applications of this technology have not been adopted in the routine clinical setting.

Two additional imaging modalities used for evaluating nodal metastases deserve mention. Ultrasonography and PET with fluorodeoxyglucose are gaining in popularity for initial staging and follow-up staging of patients with head and neck can-

FIGURE 33-17 Computed tomography scan with contrast showing peripheral rim enhancement and central lucency of lymph node harboring metastatic squamous cell carcinoma.

cer. Although not commonly used in the United States, ultrasonography has been used in outpatient clinics for evaluation of oral cancer patients in Europe for some time. Ultrasonography criteria for malignant changes include nodal size and changes in echogenicity, central necrosis that will lead to an echogenic hilum, and a hypoechoic periphery. Its ability to improve on manual palpation of cervical lymphadenopathy has led to its increased use in the United States. It can also help to evaluate carotid or jugular invasion. When performed by an experienced clinician and combined with aspiration cytology, ultrasonography is very accurate.¹²⁴ Knappe and colleagues reported a sensitivity of 89.2% and a specificity of 98.1% in 56 patients who underwent preoperative ultrasound-guided fine-needle aspiration followed by elective or therapeutic neck dissections.¹²⁵

Recently PET has become increasingly popular in the staging and follow-up of patients with head and neck squamous cell carcinoma. By identifying areas of high glucose uptake, PET scans allow clinicians to identify potential metastases in the preoperative work-up (Figure 33-18). Presence of distant metastases may influence the choice of initial treatment. The role of PET scans in the evaluation of occult cervical metastases

FIGURE 33-18 Positron emission tomography scan showing recurrent cancer in the left neck with three mediastinal metastases. Note the heavy physiologic uptake in the brain, heart, kidneys, and bladder.

is limited by the need for at least 5 to 10 mm³ of tumor for detection. Their role in the work-up of patients with cervical metastases and unknown primaries continues to be explored.¹²⁶ PET is also used to examine patients who have undergone chemoradiotherapy for recurrent disease.¹²⁷ These patients are notorious for their difficulty in examination secondary to extensive changes in the soft tissue. It is recommended that at least 3 months pass prior to obtaining a PET scan because of the persistent inflammation associated with radiation and the tumoricidal effects that persist after radiation is completed. It should also be remembered that current technology requires that a focus of squamous cell carcinoma be several millimeters to be detected.¹²⁸ In the past it was stated that distant metastases were a late finding in head and neck cancer patients and most patients succumbed to locoregional disease. It was felt that less than 1% of head and neck cancer patients had distant disease at presentation. As the use of PET scanning in the initial evaluation of patients

with oral cavity cancers becomes more widespread, detection of distant metastases at the initial evaluation may become more common. One result of these improvements in detection of distant disease is *stage migration*. In other words, as our ability to detect distant disease improves, more patients are staged higher. This does not mean that patients are being diagnosed later in the course of their disease than in the past but simply that our diagnostic abilities have improved.

Neck Dissection in Oral Cavity Squamous Cell Cancer

The goals of neck dissection are to remove gross disease in patients with clinical evidence of nodal involvement (therapeutic neck dissection) or to remove occult metastases in patients whose tumor characteristics make one suspicious of occult cervical metastases (elective neck dissection or END). The importance of treating the cervical lymph nodes was stressed by Crile in his landmark 1906 paper, and was later popularized by Martin and colleagues.^{129,130} Generations of surgeons were trained in the classic radical neck dissection (Figure 33-19). Improved understanding of the regional lymphatic flow and nodal basins at risk for metastases from different primary locations has led to an increasing number of modifications of the standard radical neck dissection. The resultant, often misused, terminology of neck dissection was standardized by the American Academy of Otolaryngology's Committee for Head and Neck Surgery and Oncology in 1991.¹³¹ Revisions were proposed in 2002 to improve communication among clinicians.¹³² These proposed changes were primarily in regard to the selective neck dissections, and specific names such as supraomohyoid neck dissection were eliminated in favor of the phrase "selective neck dissection" followed in parentheses by the levels removed. The definitions pertinent to oral cavity cancer are listed below:

FIGURE 33-19 Standard radical neck dissection of the right neck. Note the communication with the oral cavity where an oral cancer has also been resected.

- Radical neck dissection: Refers to the removal of all ipsilateral cervical lymph node groups extending from the inferior border of the mandible to the clavicle, from the lateral border of the sternohyoid muscle, hyoid bone, and contralateral anterior belly of the digastric muscle medially, to the anterior border of the trapezius. Included are levels I through V. This entails the removal of three important nonlymphatic structures—the internal jugular vein, the sternocleidomastoid muscle, and the spinal accessory nerve.
- Modified radical neck dissection: Refers to removal of the same lymph node levels (I through V) as the radical neck dissection, but with preservation of the spinal accessory nerve, the internal jugular vein, or the sternocleidomastoid muscle. The structures preserved should be named. Some authors propose subdividing the modified neck dissection into 3 types:

Type I preserves the spinal accessory nerve.

Type II preserves the spinal accessory nerve and the sternocleidomastoid muscle.

Type III preserves the spinal accessory nerve, the sternocleidomastoid muscle, and the internal jugular vein.

- Selective neck dissection: Refers to the preservation of one or more lymph node groups normally removed in a radical neck dissection. In the 1991 classification scheme there were several “named” selective neck dissections. For example, the supraomohyoid neck dissection removed the lymph nodes from levels I to III (Figure 33-20). The subsequent proposed modification in 2001 sought to eliminate these “named” dissections. The committee proposed that selective neck dissections be named for the cancer that the surgeon was treating and to name the node groups removed. For example, a selective neck dissection for oral cavity cancer would encompass those node groups most at risk (levels I to III) and be referred to as a selective neck dissection (levels I to III).
- Extended neck dissection: Refers to the removal of one or more additional lymph node groups, nonlymphatic structures, or both, not encompassed

FIGURE 33-20 Supraomohyoid neck dissection, or selective neck dissection, levels I to III. The sternocleidomastoid muscle, nerve XI, and internal jugular vein are preserved.

by a radical neck dissection. For example, mediastinal nodes or nonlymphatic structures such as the carotid artery or hypoglossal nerve.

It is important to remember that classification schemes are continually changing, and as science evolves the indications for different dissections will certainly change. For an oral cavity primary without evidence of lymph node metastases, a selective neck dissection removing lymph nodes from levels I to III is the generally accepted procedure. Shah and colleagues demonstrated supraomohyoid neck dissection to eradicate occult metastatic disease in 95% of patients.¹³³ Some surgeons, however, advocate including level IV (extended supraomohyoid neck dissection) to decrease the risk, however small, of missed occult metastases. Extension on the left side does entail an increased risk to the thoracic duct and attendant chyle leak.⁹⁸ Modifications of neck dissections have been made in an attempt to prevent the morbidity of radical neck dissection (Figure 33-21). Preservation of the spinal accessory nerve decreases the incidence of painful shoulder syndrome. Extensive skeletonization of the nerve, however, can result in significant dysfunction even if the nerve is preserved (Figure 33-22). Several studies have suggested that dissection of level IIb (above the nerve) is unnecessary in the clinically negative neck because of the low incidence of metastases in this area (1.6%), and is recommended only if bulky disease is present in level IIa.¹³⁴

If there is clinical evidence of lymph node metastases, controversy exists over the proper type of neck dissection (see section “Therapeutic Neck Dissection,” below). The application of supraomohyoid neck dissection to the N positive neck (therapeutic neck dissection) has yielded mixed results.¹³⁵ Previous studies have demonstrated that patients undergoing selective neck dissections for N0 necks have a higher rate of recurrence in the

FIGURE 33-21 Denervation of a patient's left trapezius following sacrifice of spinal accessory nerve during radical neck dissection.

neck if positive nodes are ultimately found in the pathologic specimen. This can be improved by the addition of postoperative radiation treatment.¹³⁶ The question remains as to whether this is due to the type of neck dissection or simply the biology of the tumor.^{137,138} Most surgeons advocate some form of neck dissection if there is demonstrable evidence of metastatic disease in the neck, and a diminishing number of surgeons maintain that the evidence of lymph node metastases is justification for nothing less than a standard radical neck dissection.

FIGURE 33-22 Dissection and skeletonization of spinal accessory nerve can produce shoulder dysfunction even if nerve is preserved.

Another controversy regarding the evolution of neck dissection concerns the concept of in-continuity versus discontinuous neck dissections. In the past it was considered mandatory to remove the primary tumor in direct continuity with the neck dissection, in one specimen. Work by Spiro and Strong found no adverse impact on survival when neck dissection was performed in a discontinuous manner. Bias might have occurred, however, as smaller lesions were in the discontinuity group.¹³⁹ A study by Leemans and colleagues found worse outcomes in stage II cancer of the tongue with discontinuous neck dissection, with local recurrence rates of 19.1% versus 5.3% and a 5-year survival of 63% versus 80%.¹⁴⁰ Most surgeons prefer an in-continuity approach if technically feasible, without the resection of obviously uninvolved structures such as the mandible.

The controversy surrounding elective neck dissection versus elective neck irradiation (without neck dissection) continues. Advantages of surgery include the production of a surgical specimen that guides the need for further treatment. If no lymph nodes are identified, radiation can be held. The possibility of future second, third, or even fourth primary cancer arising in this at-risk population makes reserving radiation attractive. A comprehensive discussion of the management of cervical lymph nodes in head and neck cancer is beyond the scope of this chapter. Three excellent reviews are available and recommended.^{117,141,142} Although several studies have failed to demonstrate a survival advantage in patients who undergo elective neck dissection versus careful follow-up and therapeutic neck dissection if a metastasis develops, most surgeons would agree that the morbidity associated with a selective neck dissection is minimal and would have a low threshold for performing it.

Sentinel Node Biopsy

As the evolution toward less invasive surgical modalities proceeds, dissection of the

N0 neck (staging neck dissection or elective neck dissection) is becoming increasingly limited. The sentinel node technique, first popularized for melanoma, has been investigated for use in head and neck cancer.^{143,144} Theoretically it allows the identification and removal of the first-echelon lymph node ("sentinel node") that would first receive metastases from a given site. The technique involves injecting the area surrounding the primary site with a radioactive-labeled material, ^{99m}Tc-sulfur colloid. Various molecular weights can be chosen depending on the transit time desired. A radiograph is then taken to identify and locate the sentinel node. The patient is then taken to the operating room where the surgeon may inject isosulfan blue dye around the primary tumor site. The dye will also drain to the sentinel node and stain it blue, assisting the surgeon in identification during surgery (Figure 33-23). The surgeon will also use a gamma detection probe counterprobe to identify the node with the highest concentration of radioactive colloid. The node is then removed, and if it is histologically positive, further treatment such as radiation may be indicated. In melanoma, sentinel node biopsy has a reported sensitivity of 82 to 100%, and very few false-negatives.^{145,146}

The technique has been investigated in the head and neck with varying results. Problems with the application of the sentinel node technique to squamous cell cancer of the oral cavity relate to the rich lymphatic drainage with possible bilateral drainage as well as the complex anatomy in the neck, leading to difficulty in dissecting out a single node. In addition close proximity of the sentinel node to the primary cancer, for example, an FOM primary cancer and submental node, can lead to the accumulation of colloid around the primary cancer, which obscures the sentinel node. The rich lymphovascular network can also lead to drainage to several nodes. Cevantos and colleagues used the sentinel node technique in 18 oral cavity cancers

with N0 necks.¹⁴⁷ They compared sentinel node biopsy to CT images and PET images by obtaining a CT and PET followed by sentinel node biopsy and neck dissection. They found 10 true-positives, 6 positive nodes identified on frozen section, 2 positive nodes on evaluation of permanent pathologic specimens, and 2 on immunoperoxidase staining for cytokeratin. In 6 specimens, the sentinel node was the only positive node. They also found 7 true-negatives and 1 false-negative. In 1 case the sentinel node identified by the radioactive colloid did not contain cancer, but another cervical node did. They also found that tumor in the node can lead to obstruction and redirection of lymphatic flow.¹⁴⁷ Pitman and colleagues further demonstrated the use of the sentinel node biopsy technique for the N0 neck.¹⁴⁸ Hyde and colleagues reported on 19 patients whose radiographic and clinical test results on their necks were negative and who underwent sentinel lymph node biopsy and PET scanning followed by conventional neck dissection.¹⁴⁹ In 15 of the 19 patients the sentinel node as well as the remaining nodes were negative. In 3 of the 19 patients the sentinel node was positive along with other nodes. In 1 patient the sentinel node was negative, but another node removed in the neck dissection was positive. The node was located close to the primary cancer, which often leads to difficulty discriminating activity due to the tumor and that of adjacent nodes. Interestingly PET failed to

FIGURE 33-23 Sentinel node biopsy. Note the dark staining of the sentinel node.

reveal cancer in the 4 patients with subsequently identified cervical metastasis (see discussion on PET scanning, above).¹⁴⁹ In the future the sentinel node biopsy may become the operative procedure of choice for dealing with the N0 neck. In an excellent review Pitman and colleagues concluded that sentinel lymph node biopsy remains an experimental technique in head and neck cancers and has not become a standard of care.¹⁵⁰

Therapeutic Neck Dissection

Patients presenting with nodal disease will usually undergo some type of therapeutic neck dissection, the nature of which varies with surgeon's preference. Some surgeons will treat all patients with suspected cervical metastases with a radical neck dissection. Most consider a modified radical neck dissection adequate, removing the internal jugular vein or sternocleidomastoid muscle if indicated. There is some evidence that selective neck dissection may be adequate for the N positive neck in certain carefully selected patient populations (see discussion of selective neck dissections, above). Anderson and colleagues reported the results of three academic centers in which patients with previously untreated clinically and pathologically N positive necks underwent neck dissection.¹⁵¹ They reported a regional control rate of 94.3%. Their results were comparable to patients undergoing more extensive neck dissections.¹⁵¹ Patients presenting with massive nodal disease who are going to be treated with chemoradiation therapy or combination of brachytherapy and external beam therapy can present a challenge to surgeons who are faced with the option of surgery before or following radiation. Not infrequently surgeons are faced with complete clinical resolution of disease and the prospects of a neck dissection in a heavily irradiated field. There is some variation in approaches to this dilemma. Some surgeons recommend pretreatment neck dissection to remove bulky disease, whereas

others plan a neck dissection 4 to 6 weeks after treatment regardless of response. Still others recommend a CT scan at 4 weeks and CT-guided biopsy of any suspicious nodes. This is followed by neck dissection if the node biopsy is positive for cancer. McHam and colleagues found that clinical factors did not predict patients with residual disease following chemoradiation therapy and recommended neck dissection in all patients initially seen with N2 to N3 disease.¹⁵² This recommendation was made in light of a 26 to 35% complication rate in patients undergoing neck dissections following chemoradiation therapy.¹⁵² The role of PET scanning in this situation is unclear, but patients with recurrent cancer following multimodality therapy typically have a poor outcome, making salvage surgery an unattractive alternative.

Surgical management of cervical lymph node metastasis, both occult and evident, continues to evolve. It is clear that metastases are an indication of aggressiveness and portend a poorer prognosis. Once the cancer has developed the necessary genetic mutations to break free and colonize independent of the primary tumor, the chance of cure with single modality therapy diminishes. In his presidential address to the New England Surgical Society, Blake Cady referred to "... lymph node metastases as the speedometers of the oncologic vehicle, not the engine. Indicators, not governors of survival."¹⁵³ Clearly the role for the radical neck dissection has diminished greatly over the past few decades, as less invasive surgical techniques for dealing with the cervical lymphatics have gained popularity. This trend will likely continue, as the role of surgery in the control of metastatic disease is better defined.¹⁵⁴⁻¹⁵⁶

Recurrence and Follow-Up Surveillance

In 1984 Vikram and colleagues published a series of reports that discussed patterns of failure in patients treated with multi-

modality therapy for head and neck cancer.¹⁵⁷⁻¹⁵⁹ This classic series of articles outlined failure characteristics at the local site, neck, distant sites, as well as development of second malignant neoplasms in patients treated at Memorial Sloan-Kettering Cancer Center, NY, USA.^{136,157-159} Ninety percent of patients who will suffer a recurrence of oral cavity cancer will do so in the first 2 years. For this reason patients are placed in a structured follow-up. Stage at recurrence is the most important predictor of survival, with stage I at recurrence associated with a median survival of 24.3 months and a disease-free survival at 2 years of 73%, whereas stage IV recurrence was associated with a median survival of 9.3 months and a 2-year disease-free survival of 22%.¹⁶⁰ Follow-up protocols vary widely and are intended to detect recurrences early. De Visscher and Manni suggested the following¹⁶¹:

1. Every 2 months for 1 year
2. Every 3 months for year 2
3. Every 4 months for year 3
4. Every 6 months for years 4 and 5
5. Then yearly

Despite this and other suggested follow-up protocols, the follow-up schedule must be tailored to the individual patient and must take into account the patient's likelihood of having a recurrence, possible continuation of smoking or other habits, ability to travel and keep appointments, and the potential availability of local medical or dental care that might assist in follow-up surveillance. Follow-up appointments include an update of patient history and review of systems as well as clinical examination for recurrence or detection of new primaries. Questions raised by physical examination should prompt an appropriate imaging study, rebiopsy, or examination under anesthesia. Caution should be used, however, in performing biopsies in patients who have received intensive multimodality therapy, such as RADPLAT, brachytherapy, or hyperfractionated radiation schedules

combined with chemotherapy. Extensive biopsy wounds are notorious for slow healing and can lead to chronic wounds.

Appropriate imaging, including a baseline CT or MRI at the completion of multimodality therapy, is invaluable. The role of PET scanning in follow-up continues to evolve.

Failure at the primary cancer site will ultimately occur in approximately 20% of patients, and regional recurrence in the neck will occur in 10%. Death from distant metastases is rare, occurring in only about 1 to 4% of cases in which locoregional control is maintained. An unfortunate consequence of improved control at the primary cancer site with multimodality therapy is an increasing incidence of distant metastases. In addition to recurrences, prospective studies have demonstrated that second primary cancers develop at a rate of 4 to 7% annually in patients who have had a head and neck squamous cancer. Second primary cancers are the leading cause of death among patients who have undergone treatment for early-stage oral cancers.^{136,157-159}

The ability of a cancer to metastasize depends on the development of a series of genetic mutations, allowing for cells to disseminate from the primary tumor, arrest in the microcirculation, extravagate, infiltrate into stroma, and survive and proliferate as a new colony. Surveillance for distant metastases therefore becomes an important component of the follow-up evaluation. The lungs are the most common site for distant metastases, followed by the liver and bone. Yearly or biannual chest radiographs allow for detection of lung metastases, the most common distant site metastasized for oral cavity cancer, and primary lung cancers, which are not uncommon in the population at risk for oral cancer.¹⁶² Given the current unavailability of an effective treatment regimen, however, some authors have questioned the use of annual or semiannual chest radiographs.¹⁶³ PET scanning may prove

to be a more valuable alternative for detection of distant disease. Yearly lab work to include liver function studies is also recommended. In patients who have received radiation as part of their treatment, periodic thyroid function tests are helpful, as many will ultimately become hypothyroid with attendant fatigue and decreased wound healing ability.

Collins stated that patients with head and neck cancer are probably never cured, and that it is better to consider that the host-tumor relationship has been durably altered in favor of the host.¹⁶⁴ It is important to realize that approximately one-third of patients with presumed localized disease will relapse and die of cancer. In advanced head and neck squamous cell carcinoma 20 to 30% will survive, 40 to 60% of patients will suffer locoregional recurrence, and 20 to 30% will succumb to distant metastases. Hence the majority of treatment failures remain recurrence of locoregional disease.¹⁶⁴ Patients with recurrent disease are restaged, which requires a similar evaluation as the original. Panendoscopy and examination under anesthesia take on greater importance when a clinician is faced with examination of tissue scarred and distorted by previous surgery and radiation. Distant metastases should be ruled out to the extent possible prior to deciding on aggressive re-treatment. If the patient does have recurrence that is confined to the locoregional area, treatment decisions are limited by previous therapy. Reirradiation protocols exist but are accompanied by significant morbidity.¹⁶⁵ Intensive reirradiation and chemotherapy protocols are being investigated and show some promise.¹⁶⁶ The morbidity of such treatments is significant, and their use should be restricted to clinical trials at this time. Surgical salvage remains the primary option, but the extent of salvage surgery must be considerably broader than might initially be considered. Goodwin reported on the outcome of salvage surgery for recurrent head and neck

cancers, and found benefit in stages I and II.¹⁶⁰ Success was limited in more advanced disease.¹⁶⁰ Clearly defined goals should be established between surgeon and patient for salvage surgery. Is the operation for cure or palliation? Palliative surgery should be undertaken very cautiously as surgical complications may greatly overshadow the palliative goals. Patients and their families must have realistic expectations as well as understand that there is no benefit from repeated surgical intervention for recalcitrant cancer.

Patients with inoperable cancer pose a unique challenge to the clinician. As cure is no longer a realistic option, treatment modalities to prolong life and improve quality of life assume a higher priority. Pain control becomes a significant issue in patients with recurrent head and neck cancer. Long-acting sustained release formulations such as transdermal narcotic patches combined with short-acting narcotics for breakthrough pain are typically required. Rhizotomy is an option for intractable pain. Pain control can be a goal of palliative chemotherapy or radiotherapy. Novel methods for the targeted delivery of chemotherapeutic agents into the tumor are under development. A combination of cisplatin and epinephrine gel injected into recurrent tumors demonstrated significant palliation without significant side effects in most.¹⁶⁷ Wound management becomes an important issue, and dealing with large malodorous wounds can be taxing on patients and families. Patients presenting with advanced head and neck cancer will typically survive 6 to 12 months without treatment, and patients with end-stage head and neck cancer will have a median survival of 101 days.¹⁶⁴

There is a natural tendency for clinicians to avoid the dying patient. There is a reluctance to face a disease whose biology has resisted their best efforts and whose treatment has left patients debilitated and frequently deformed. While

family members and clinicians are discussing further treatment options, patients are frequently simply concerned with pain control and the effects of massive doses of narcotics on bowel function. Frank, thoughtful discussions must be held with the patients and their families regarding end-of-life issues and will help surgeons deal with these very real concerns. Hospice provides an excellent resource, and once enrolled most families are appreciative of the support offered by these professionals in end-of-life care.

In this era of improved treatment modalities for local and regional disease, clinicians are finding that factors unrelated to the primary cancer and beyond their control are influencing survival. It is becoming increasingly evident that factors affecting outcome in oral cancer patients are multiple and may relate more to patient characteristics than the cancer itself or the treatment they receive. Researchers are finding that genetic factors of the primary cancer have an impact on the response of the particular tumor to any treatment.¹⁶⁸ High expression of epidermal growth factor receptors is associated with poor outcome, and may indicate the need for more intensive multimodality therapy. Alterations in *TP53* have been associated with recurrence in squamous cell cancer of the head and neck that was refractory to radiation treatment. Future treatments may include restoration of *TP53* function.¹⁶⁹

Importantly studies are also demonstrating that comorbidities and performance status predict survival independent of stage at diagnosis. Performance status has been shown to be a predictor of survival independent of tumor, regional nodes, and metastasis (TNM) stage. Many head and neck cancer patients suffer other medical problems related to tobacco and alcohol use, and these can result in decreased overall survival despite cancer-specific survival. Ribeiro and colleagues found that daily alcohol consumption,

smoking, poor body mass index, and other comorbidities had an independent impact on prognosis.¹⁷⁰ As discussed earlier there may indeed be a more aggressive form of squamous cell carcinoma that affects younger patients, but data from the National Cancer Data Base indicate that younger patients have a survival advantage that is most likely related to their lack of comorbidities.¹⁷¹ Frequently 5- and 10-year survival curves are impacted more by these comorbidities than the tumor characteristics recorded in the TNM system (see discussion below).¹⁷² The TNM staging system will continue to undergo revisions to enhance its use.

Future Treatments

In the future, biologic markers hold out promise as the key to treatment of head and neck squamous cancers. Serving as potential targets for gene therapy, biologic markers may also determine appropriate treatment strategies and may select which patients should be treated with surgery, radiation treatment, chemotherapy, or combination treatment. Certain subpopulations of squamous cancers, those with high levels of *TP53* expression and low levels of the marker Ki-67 for example, have higher relapse rates following initial therapy. These patients may benefit from more aggressive combination treatments.^{168,169}

Every few years a new cancer therapy is heralded as the end of cancer surgery. For the present, surgery will continue to play the key role in management of oral cavity cancers, and surgeons must be knowledgeable in all diagnostic and treatment modalities as they continue their captainship of the oral cancer team. The surgeons treating oral cancer, regardless of their discipline, must learn from the contributions and mistakes of their forebears and add the benefit of their own training and experience. They must then use their knowledge base and the input of other treating colleagues to synthesize a plan of treatment tailored to the patient who sits

before them. They must interact effectively with colleagues of other disciplines with the patient's benefit their foremost concern. They must execute the surgical components of the treatment plan with accuracy and skill. They must be supportive to their patients and their patients' families at a time of great stress in their lives and must not turn away from adversity or complication. They must accept the fact that not all patients can be cured. They should derive inspiration from those who survive and satisfaction from those who might succumb in a way made more favorable by the surgeon's input.

Lip Cancer

James W. Sikes Jr, DMD, MD

G. E. Ghali, DDS, MD

Lip cancer, one of the most common cancers of the head and neck region, is one of the most easily diagnosed, with generally a good prognosis. In some individuals, lip cancer may behave aggressively, manifested by recurrence or mortality in up to 15% of patients.¹⁻⁴ The most common malignancy of the lip is squamous cell carcinoma, whereas basal cell carcinoma accounts for only 1% of all lip carcinomas.⁴⁻⁶ Other malignancies of the lip have been reported but are less common.^{7,8}

Epidemiology and Etiology

The incidence of lip cancer varies throughout the world, resulting in 30% of all malignant tumors of the oral cavity in certain regions. In the sunbelt region of the United States, lip cancer is the most common cancer of the oral cavity, and its incidence is second only to skin malignancy of the head and neck. Australia, northern Spain, and Newfoundland have a reported annual incidence ranging from 11 to 50 cases per 100,000 population.⁹

In the United States, the incidence of lip cancer is 1.8 per 100,000 population, with the state of Utah having the highest regional rate of almost 12 cases per 100,000.¹⁰ Generally, the behavior of lip cancer resembles skin cancer more than carcinoma of mucosal origin in the oral cavity proper. The lower lip is the most common site for lip cancer (88 to 98%), with only 2 to 7% arising from the upper

lip and 4% at the oral commissures.^{1,4-6,11-13} The most common age at diagnosis is 54 to 65 years.⁴ Although a condition seen in middle age, lip cancer occasionally occurs in patients under age 30 years.¹⁴ Lip cancer has a predilection for men, with men to women ratios ranging from 35:1 to 6:1, depending on the location of the lesion.⁴

The etiology of lip cancer is incompletely understood at present. Several factors have been associated with lip cancer development, but direct cause and effect has not been proven. Approximately one-third of patients with lip cancer have outdoor occupations, suggesting that sun exposure may be an etiologic factor. Because of its prominence, the lower lip is at a higher risk for exposure to the sun, compared with the upper lip. Hence, this results in the discrepancy in the distribution between upper and lower lip cancers.^{15,16} Carcinoma of the lip principally affects those individuals with fair skin complexions. The prevalence of lip cancer is at least 10 times higher in whites than in those with darker skin and is extremely rare among Blacks.^{11,17} Although it has never been proven, darker-skinned individuals are believed to have a protective pigment in the vermilion of the lips that provides protection from solar injury.¹⁰

Multiple factors have been linked to lip cancer, including tobacco use, pipe smoking, thermal injury, lip trauma, poor oral

hygiene, exposure to chemicals, mechanical irritants, immunosuppression, and chronic infections.^{11-13,16,18-23} Several case series have reported that a large proportion of lip cancer patients regularly use tobacco, indicating that tobacco use is etiologically associated with lip cancer development.^{5,11,15,19,24-28} In 1984, Douglass and Gammon reassessed the epidemiology of oral cancer and declared that there was insufficient proof for declaring tobacco as an etiologic factor in the development of lip cancer.¹⁰ Additional case-controlled studies concluded that no statistically significant relation exists between tobacco exposure and lip carcinoma.^{29,30} The smoking of cigars and pipes is often considered an important etiologic factor; however, no convincing evidence exists that supports a causal relationship between tobacco use and developing lip carcinoma. Cigar and pipe smoking today, at best, are likely responsible for only a small fraction of lip cancers. Because alcohol and tobacco exposure—the two factors most strongly associated with developing oral carcinoma—seem to have limited influence on the developing lip carcinoma, the most consistently associated factor with lip cancer appears to be prolonged and cumulative exposure to ultraviolet radiation from sunlight.^{4,18-20, 24, 29, 31}

Anatomic Considerations

Embryologically, the upper lip forms by fusing the two maxillary processes with a

central median nasal process (Figure 34-1). As a result, a central midline mass with two larger lateral segments is formed. The separation of the lateral segments by this central midline mass makes metastasis from upper lip cancers to the contralateral neck exceedingly rare. Conversely, the lower lip, formed by fusion in the midline of two mandibular processes, is at an increased risk for contralateral neck metastasis, particularly with lesions near the midline. The lateral and superior borders of the upper lip are well defined at the nasolabial creases bilaterally and at the nasal base superiorly. The inferior border of the lower lip is defined along the transversely oriented labiomental crease.

The formal definition of lip cancer, established by the American Joint Committee on Cancer for the purpose of staging lip cancer, describes the lip as “beginning at the junction of the vermilion border with the skin and including only the vermilion surface or that portion of the lip that comes into contact with the opposing lip. It is well

defined into an upper and lower lip joined at the commissures of the mouth.”³² This definition focuses on the unique epithelial surface of the lip vermilion and excludes cancers that arise from the adjacent skin or labial mucosa. In statistical reporting, cancers of the lip are commonly grouped with those of the oral cavity, because the lip is defined as part of the oral cavity by the American Joint Committee on Cancer.^{9,32}

Lymphatic drainage of the lower lip originates as an interconnecting network of lymph vessels beneath the submucosa of the vermilion.³³ It subsequently gives rise to five or six lymphatic collecting trunks that eventually terminate into regional lymph nodes. The lymphatic trunks of the central one-third of the lower lip typically drain into the submental lymph nodes. The trunks that arise from each lateral one-third of the lower lip typically drain into the ipsilateral submandibular lymph nodes. In certain individuals, the lymphatic trunks from the central one-third of the lip may drain to the submandibular lymph nodes on either side.

Cervical metastasis from lip cancer occurs in fewer than 10% of patients with cancer of the lower lip and in up to 20% in cancer of the upper lip and commissure.⁵ In the upper lip, crossover of lymphatic drainage between the right and left halves typically does not occur.³³ The upper lip also possesses five or six collecting trunks on each side of the midline that originate as delicate lymphatic vessels in the submucosa of the vermilion. The trunks ultimately terminate in the submandibular lymph nodes but occasionally also drain to the ipsilateral preauricular or infraauricular parotid lymph nodes. Metastasis that results from cancer of the lip most commonly involves the submandibular and submental lymph nodes (level 1).^{34–36} Metastasis to level II of the jugular chain rarely occurs. Cancer involving the upper lip may occasionally metastasize to the parotid lymph nodes, but contralateral metastasis is unusual for cancers of the

upper lip that do not cross the midline and for lower lip cancers that do not involve the central one-third of the lower lip.

Metastasis from the lower lip is primarily to the submental, submandibular, and perifacial nodes. Metastasis is found in the submandibular lymph nodes in about 80 to 90% of patients with metastasis from cancer of the lower lip.^{5,37} Although the upper lip is responsible for fewer than 10% of lip cancer cases, its pattern of metastasis is fairly predictable, with the submandibular and parotid lymph node groups being most commonly involved.³⁸ Carcinoma of the commissure and upper lip spreads to the preauricular, periparotid, and submandibular nodes. Bilateral metastasis may develop if the lesion is near or has crossed the midline of the lip. Crossover between the lymphatics of the right and left sides of the upper lip rarely occurs.⁴

Cervical metastasis occurs late in the course of lip cancer in fewer than 10% of patients with cancer of the lower lip and up to 20% in cancer of the upper lip and commissure.⁵ Lymph node metastasis to the upper jugular digastric chain is seen in only about 15% of all patients who have lymph node metastasis and is almost always seen in conjunction with ipsilateral submandibular metastasis.^{5,37}

Management

Evaluation

Because carcinomas of the lip occur on a highly visible and constantly exposed region of the body, a relatively early diagnosis is often feasible. The clinical presentation of lip carcinomas is quite characteristic, generally presenting as an exophytic or ulcerated lesion on the vermilion border, along with variable degrees of infiltration of the underlying musculature or invasion of the overlying skin or labial mucosa (Figure 34-2). Well-differentiated squamous cell carcinomas are often associated with hyperkeratosis and leukoplakia of the vermilion border of the lip. Any lip lesion that

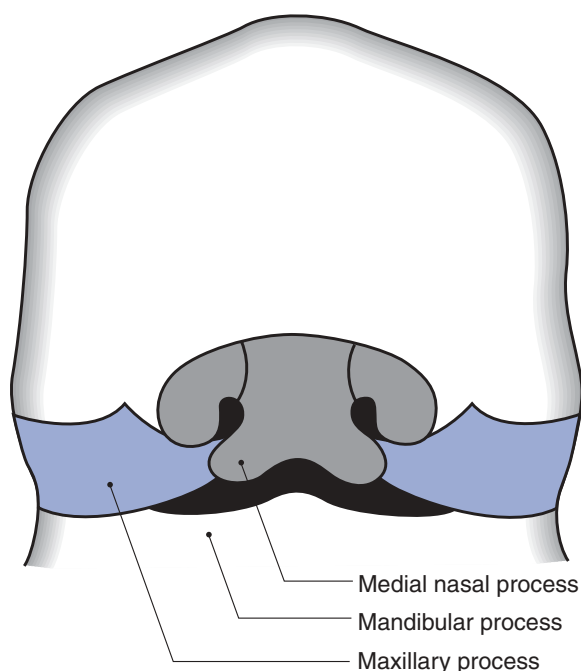

FIGURE 34-1 Developing upper lip, receiving contributions from a central medial nasal process and bilateral maxillary processes. Developing lower lip receiving contributions solely from bilateral mandibular processes.

FIGURE 34-2 Typical presentation of a large exophytic squamous cell carcinoma of the lower lip.

the clinician views as a possible malignancy should undergo an incisional biopsy that includes both a portion of the lip lesion and a small portion of normal appearing tissue at the margin. The factors that should be considered in planning surgical resection and reconstruction of the lips include the tumor stage, lip subsite of origin, patient preference, and the histopathologic type and grade of the tumor.

Staging of lip cancers is similar to that employed for tumors of the oral cavity (Table 34-1).³² Tumors less than 2 cm in greatest dimension are staged as T1, whereas massive tumors with invasion of deep soft tissues, adjacent bone, or overlying skin are staged as T4 (Table 34-2).

Stage	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
Stage IV	T3	N1	M0
	T4a	N0	M0
	T4a	N1	M0
	T1	N2	M0
Stage IVB	T2	N2	M0
	T3	N2	M0
	T4a	N2	M0
Stage IVC	Any T	N3	M0
	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

Radiographic evaluation of tumors detected at an early stage that involve the lip is generally unnecessary. On the other hand, advanced tumors that adhere to or invade the adjacent mandible require further radiologic evaluation. Detailed studies of the mandible, including panoramic radiographs and computed tomography scans, may be necessary to delineate the extent of the bony invasion, as well as any involvement of the inferior alveolar canal. Melanomas and squamous cell carcinomas are known to be neurotropic and may spread along the inferior alveolar nerve via the mental foramen.³⁹⁻⁴¹ Patients who complain of numbness or paresthesia warrant further radiologic evaluation.

Surgical Treatment

The ultimate goal of lip cancer management is long-term control of the carcinoma

with preservation of the competency and esthetics of the perioral region. Although external beam irradiation or surgical excision can control small primary tumors of the lip equally well, surgery is quicker and leaves little esthetic or functional impairment. Larger lip cancers require planned surgical resection, with reconstruction in most cases. In the past 100 years, clinicians have employed many methods to manage lip cancer. Some of the less effective methods have included direct applications of caustic agents, such as hydrochloric acid, arsenic paste, or nitric acid. In addition, laser surgery, electrocoagulation, and cryotherapy have been advocated by some. However, the two modalities that have been the most thoroughly evaluated and that have undergone the test of time are surgery and radiation therapy. These two techniques yield excellent results for very early

Table 34-2 Tumor Node Metastasis System for Lip Cancer

T = Tumor Size	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	< 2 cm
T2	> 2 cm and ≤ 4 cm
T3	> 4 cm
T4	Tumor invades through cortical bone inferior alveolar nerve, floor of mouth, or skin of face (ie, chin or nose)
N = Nodal Metastasis (regional)	
NX	Regional lymph nodes cannot be assessed
N0	No regional nodes palpable
N1	Single ipsilateral node < 3 cm
N2	Metastasis in a single ipsilateral lymph node, > 3 cm but ≤ 6 cm; or in multiple ipsilateral lymph nodes, none > 6 cm; or in bilateral or contralateral lymph nodes, none > 6 cm
N2a	Single ipsilateral node > 3 cm but ≤ 6 cm
N2b	Multiple ipsilateral nodes ≤ 6 cm
N2c	Bilateral or contralateral nodes ≤ 6 cm
N3	Node > 6 cm
M = Distant Metastasis	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

lip cancers, and surgery is the most common treatment selected for managing lip carcinoma of any size, particularly the larger T3 and T4 tumors.

The determination of an adequate surgical margin around a lip cancer is somewhat nebulous, and few objective data have been gathered to substantiate any recommendations for adequate excision margins. The size of the primary lesion is the most common factor that we use to determine the extent of the marginal excision. Larger cancers have typically mandated wider margins than have smaller cancers. Based on these general guidelines, a minimum of 8 to 10 mm of normal tissue around a lip cancer is recommended to facilitate its complete removal.^{2,11,25,42-44} Smaller lip cancers, less than 1 cm in greatest dimension, can often be managed with slightly smaller margins of 5 mm.⁴⁴ In our experience, the locally advanced T4 squamous cell carcinomas of the lip are optimally treated with a slightly larger margin of approximately 15 to 20 mm.

The lip shave, or vermillionectomy procedure, is ideal for those situations wherein areas of leukoplakia, actinic cheilitis, or carcinoma in situ involve the vermillion of the lips (Figure 34-3).⁴⁵⁻⁵⁴ These premalignant conditions require treatment but not complete full-thickness excision of the lip. This operation involves partial or entire excision of the lip vermillion. The vermillionectomy may also be used, in conjunction with a full-

FIGURE 34-3 Actinic cheilitis involving the vermillion of the lower lip.

thickness lip excision, in individuals possessing invasive lip carcinoma and premalignant vermillion changes. Following the vermillionectomy, the residual defect is primarily closed with labial mucosal advancement flaps.

In situations with invasive lesions, the lip shave procedure is contraindicated, and full-thickness excision of the involved portion of the lip is the traditional procedure for management. The most commonly selected configuration of lip excision is a V, W, or a shield (Figure 34-4). The defects resulting from the V and W excisions can easily be closed primarily with no additional mobilization of adjacent tissues (Figure 34-5). The rectangular form of excision, however, requires advancement of laterally based lip flaps to achieve a satisfactory closure. These forms of excision are selected purely on the basis of cosmetic and functional considerations for all T1 and most T2 lip carcinomas.

Invasion of the mandible, involvement of the mental or inferior alveolar nerve, tumor sizes of T3 or greater, or associated regional lymph node metastasis generally necessitate a more aggressive resection. Aggressive treatment requires an excision and reconstruction that is more complex than the standard full-thickness V or W excision, and will be discussed in detail in the following section on lip reconstruction. Include a marginal mandibulectomy with the resection of lip cancers that approximate the alveolar ridge or outer labial cortex of the mandible. Likewise, for rare lesions that actually demonstrate radiographic invasion of the mandible, include a segmental mandibulectomy in the treatment plan.

Lip Reconstruction

Lip reconstruction following surgical excision of cancer should reestablish the function and appearance of the lip. The key to functional restoration is the reconstitution of the orbicularis oris muscle. Primary surgical restoration of the orbicularis

FIGURE 34-4 The proposed incisions for a shield excision of lower lip are delineated.

muscle following resections that exceed two-thirds to three-quarters of the lip length will create microstomia.

Defects of the vermillion resulting from a lip shave procedure are generally restored with labial mucosal advancement flaps.⁵⁵⁻⁵⁷ The labial mucosal flap develops by creating a plane between the minor salivary glands and the inner surface of the orbicularis oris muscle. This flap may be mobilized into the buccal vestibule if necessary. The flap is secured to the anterior cutaneous margin of the excision to create a new vermillion cutaneous border (Figure 34-6). Other less commonly used flaps for vermillion reconstruction after a lip shave include cross-lip buccal mucosa flaps and tongue flaps.⁵⁷⁻⁵⁹

Closure may be achieved primarily when a full-thickness excision of the upper or lower lip results in a defect of up to one-third of the lip length (Figure 34-7). The

FIGURE 34-5 Primary closure of a W excision of the lower lip.

FIGURE 34-6 A, Actinic cheilitis of the lower lip with atypia noted on biopsy. B, Completed excision of the lower lip vermilion. C, Complete undermining of the mucosa and removal of adjacent minor salivary glands help prevent rolling of the lower lip and mucocele formation, respectively. D, Mucosal advancement and primary closure of the surgical defect has been completed. E, Early postoperative results following the lip shave procedure.

V-shaped excision design is most commonly used when a primary closure is anticipated. Typically, the apex of the V is placed at or slightly above the nasolabial fold or labiomental crease.^{55-58,60-62} A minimum of a three-layered closure comprising mucosa, muscle, and skin is necessary to avoid unesthetic notching of the lip as the scar matures.

Lip cancers that extend more deeply into the lip substructure but still involve a superficial length of vermilion that would otherwise produce a defect may be closed primarily via the W-shaped modification of the V configuration (Figure 34-8). This excision uses an M-plasty in place of the single apex of the V. A three-layered closure of the defect, with careful attention to detail in the reconstruction of the orbicularis oris muscle layer is achieved (see Figure 34-5).

The need to reconstruct lip defects greater than one-third of the lip length led

to the development of various circumoral flap advancement techniques.^{56-58,60,62-64} The most popular of these techniques includes the Karapandzic reconstruction flap (Figure 34-9). This flap consists of a transfer of the remaining lip tissue to reconstitute the lips and mouth opening. The Karapandzic flap uses release incisions within the labiomental crease, extending around the region of the oral commissures and continuing superiorly within the nasolabial creases bilaterally. Combining sharp and blunt dissection

FIGURE 34-8 A, Typical presentation of squamous cell carcinoma of the right lower lip. B, W excision of the lesion sparing the right commissure.

FIGURE 34-9 A, Defects greater than one-third of the lip may require circumoral flaps, such as the Karapandzic flap depicted by this schematic. B, Schematic depicting the closure of the Karapandzic flap. C, Esthetic postoperative results of a Karapandzic flap can be achieved. Note the recurrence of the lesion in the midline.

separates the orbicularis muscles from the surrounding facial expression muscles. Neurovascular structures are preserved and transposed medially, along with the flap, and intraoral buccal mucosal release incisions are often necessary.

For this reason, the Karapandzic flap is ideally suited in situations where two-thirds to three-quarters, or more, of the lower lip is resected, particularly when the resection is centrally located and leaves the lateral ends near the commissures intact. The incisions for elevation of the Karapandzic flap require mobilization of the skin and subcutaneous tissues that are superficial to the orbicularis oris muscle and mucosa and deep to the orbicularis oris muscle. At the same time, the muscle itself must be kept intact, with its nerve and blood supply preserved as tissues are rotated and sutured medially.

Among other reconstructive options for the lip, the cross-lip flaps are particularly useful in repairing moderate lip defects of one-third the length of one lip.^{60,65-67} These techniques transfer a full-thickness segment of lip tissue into a defect on the opposite lip. Estlander and Abbe developed the most commonly used cross-lip flap repair techniques.^{66,67} The Abbe flap, as originally described, transfers

tissue from the lower lip to a defect in the central component of the upper lip. It is, however, most often used to reconstruct lower lip defects by transferring tissue from the upper lip (Figure 34-10). The Estlander flap was used to reconstruct defects of the upper or lower lip in a single stage by transferring lip tissue around the

oral commissure (Figure 34-11). All cross-lip flaps are generally referred to as Abbe-Estlander type flaps.

The principle of the Abbe-Estlander flap repair is that the width of the base of the triangular flap is one-half that of the width of the base of the triangular surgical defect. The vertical length of the flap

FIGURE 34-10 A drawing of the two-stage Abbe flap, demonstrating the cross-lip transfer that is divided at approximately 3 weeks postoperatively.

FIGURE 34-11 A schematic drawing of the one-stage Estlander flap with the classic rounding of the commissure region.

FIGURE 34-12 In the cross-lip flap, the transfer portion in most cases need only be 50% as large as the defect. Care should be taken to prevent injury to the superior labial artery.

should match that of the defect. The cross-lip flap includes and depends on a small pedicle that carries the labial artery from the donor lip.

Generally, mark out the flap on the upper lip on the same side as the planned excision (Figure 34-12). Make a skin incision at the previously marked outline of the Abbe-Estlander flap on the lateral aspect of the upper lip. The lateral incision is deepened through both the musculature and the mucosa, extending from the vermilion border up to the apex of the flap. With extreme caution, perform an incision along the medial margin of the flap, beginning at the apex of the flap and working toward the vermilion border to avoid injury to the labial artery. As mobilization of the flap toward the vermilion border proceeds, separate the musculature of the upper lip bluntly with a hemostat, and divide a little at a time small segments of the muscle fibers with scissors. Once the labial artery is identified, under direct vision, divide the other attachments of the musculature of the upper lip around the labial artery, while keeping the mucosa of the vermilion border intact. In addition, to allow flap rotation, divide the intraoral labial mucosa on the medial aspect of the flap, from the apex of the flap toward the lip. Rotate the flap 180° to fill the surgical defect in the lower lip.

FIGURE 34-13 Typical appearance of the cross-lip transfer flap at the time of suture removal, demonstrated in this lower to upper lip transfer.

Inset of the flap begins by accurate approximation of the vermilion edges of the flap and the lower lip, followed by careful multilayered closure. Bring the vascular pedicle across the open mouth, and perform the second-stage release 3 weeks later (Figure 34-13). Preoperatively, instruct the patient to avoid trauma to this intervening pedicle during the immediate postoperative period.

When one commissure of the lip must be sacrificed along with the excision of the lip cancer, then employ a nonbridged Estlander flap (Figure 34-14). This flap is cre-

FIGURE 34-14 At times an extension into the labiomental crease may aid in closure of the defect, as seen marked during this cross-lip transfer flap.

ated as a single-stage procedure without the need for secondary pedicle division. The downside of this type of flap is the development of a somewhat unnatural, rounded commissure. The Abbe-Estlander flap can be used in reverse when a lesion of the upper lip is excised by elevating the flap from the lower lip. Alternatively, a cheek advancement flap with Burow's triangle is often useful for repairing lateral defects of the upper lip (Figure 34-15).

Several techniques designed for lip defects are too extensive for reconstruction using the Karapandzic or Abbe-Estlander techniques.⁶⁸⁻⁷⁰ These techniques use adjacent cheek tissue in the form of laterally based advancement flaps. In the Bernard flap, the lower lip may be excised in its entirety, along with soft tissues of the mental region, and the resulting defect is closed by lateral cheek flaps to form a new lower lip (Figure 34-16). To set back the commissure and to reduce the incidence of a "fish-mouth" deformity, excise triangles of the skin from both sides of the upper lip. Preserve the mucous membrane to help form a new vermilion border. Excise the triangular wedges of skin from the nasolabial crease on both sides, subsequent to excision of the primary tumor. The base of this triangular excision extends from the commissure of the

FIGURE 34-15 In situations that do not require reconstruction of the vermilion surface of the lip, a cutaneous advancement flap may be appropriate, as in this case with Burow's triangles to aid in advancement.

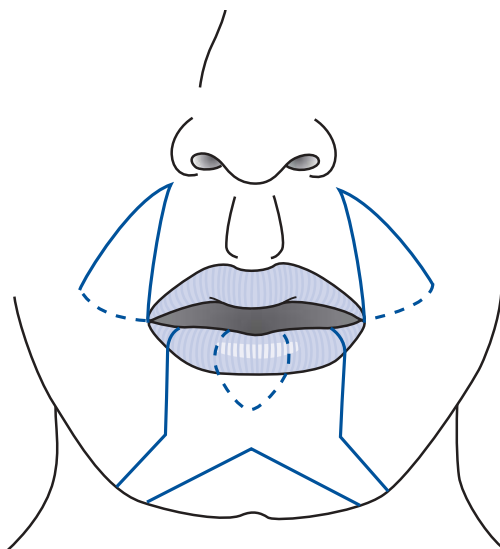

FIGURE 34-16 In situations requiring complete excision of the lower lip, the Bernard flap may provide a means for reconstruction with circumoral tissues, depicted in this schematic drawing.

mouth, up to the nasolabial crease, depending on the width of the cheek flap to be mobilized (Figure 34-17A). After excising the triangular wedges, incise the mucosae from their inner aspect, except for the base, and shift the triangular flaps of the upper lip mucosa medially, along with the flaps (Figure 34-17B). Make a counter incision in the lower mucogingival sulcus bilaterally, and mobilize both cheek flaps medially. Perform a closure of the lip musculature on both sides with interrupted sutures. The triangular wedges of the mucosa from the upper lip are everted and rolled inferiorly to provide a new vermilion surface. Mucosal closure is completed inferiorly in the mucogingival sulcus (Figure 34-17C and D).

The main advantage of the Bernard flap is its ability to reconstruct almost the whole lower lip in a single-stage procedure. The main disadvantage is reducing the size of the orifice and creating a so-called permanent smile deformity of the lips, most often produced in edentulous individuals.

The reconstruction of more massive defects that include total lip excision, as well as excising the adjacent floor of the mouth, skin, or mandible, requires the use

of distant flaps, such as the deltopectoral or pectoralis major myocutaneous flap. Alternatively, use free vascularized composite flaps to reconstruct these large defects. A free flap that has recently shown to be particularly useful is the composite radial forearm-palmaris longus free flap.^{71,72}

Cervical Lymphadenectomy

Patients with early cancer of the lip (stages I and II) do not generally need elective treatment of the cervical lymph nodes, because the rate of occult metastasis is low. The risk for cervical metastasis increases with poorly differentiated cancer, recurrent cancer, or with cancer that extends into the labial mucosa or that invades the mandible. Given the infrequency with which stage I and stage II lip cancers spread to regional lymph nodes, elective treatment of the neck is not always required. One report indicated that there was delayed cervical metastasis between 35 and 40% from lip cancer tumors 2 to 4 cm

in size.⁴ This report confirms a much larger rate of metastasis than that usually seen in clinical practice.

With advanced disease (stages III and IV), elective neck dissection of levels I through III is recommended (Figure 34-18). Thus, even if the patient has no palpable adenopathy (N0 neck), the clinician should still use elective radiation therapy or elective neck node dissection in managing patients, owing to the high rate of microscopic lymph node metastasis in these patients. In patients with lesions of the upper lip, commissure, or both, include a superficial parotidectomy. Clinically apparent lymph nodes require either radiation therapy or neck dissection for N1 nodes and combined therapy (neck dissection and radiation) for N2 and N3 nodes.⁷³

Treatment Results

The cure rate for T1 and T2 lip cancers without regional metastasis is greater than 90% with surgery or radiation.^{4,48} The

C, Closure of the wound includes the mucosal layer, orbicularis oris layer, dermal layer, and the skin closure. D, Postoperative follow-up at 1 year demonstrates no recurrence and good esthetic results.

FIGURE 34-18 Diagram depicting the levels of the neck. a = level one; b = level two; c = level three; d = level four; e = level five; f = level six.

5-year determinate survival is approximately 80%.¹ The cure rates for cancer of the lips suggest a better prognosis than for other cancers of the oral cavity. Cancer involving the oral commissure is more aggressive, with a 5-year cure rate ranging between 34 and 50%. Cancers that include areas larger than 2 cm have cure rates of < 80%, and those that invade deep enough to involve the mandible have a cure rate of < 50%.^{4,74} The primary cause of failure is local recurrence, rather than regional node metastasis. Other adverse prognostic factors include poor histologic grade, tumor thickness > 6 mm, desmoplasia, stromal sclerosis, muscular invasion, and perineural invasion.⁷⁵⁻⁷⁷ Angiogenesis has not been shown to have prognostic significance.⁷⁸ While *TP53* mutations are seen in 50% of lip cancers, the clinical significance of this observation is unknown.⁷⁹

Generally, elective lymph node dissection in the N0 neck is reserved for advanced stage disease (stage III and stage IV).^{74,80} About 5 to 10% of patients with lip cancer will develop evidence of

nodal involvement.^{1,81,82} Without question, the presence of cervical lymph node metastasis affects survival. The average 5-year survival for patients with cervical metastasis of lip carcinoma is approximately 50%, with a range of 29 to 68%. Recurrence rates in the neck after treatment of regional metastasis are 40% for N1 disease and up to 100% for N3 disease.¹ The risk of developing a metachronous lip cancer is estimated at about 20% by 10 years follow-up.⁸³

Conclusions

Lip cancer accounts for a significant percentage of all head and neck malignancies in the United States. Lip cancer arises from the lower lip in nearly 90% of cases. Etiologic factors associated with lip cancer include sun exposure, alcohol, and tobacco abuse. Commissure involvement is an adverse prognostic factor. Regional cervical lymph node metastasis is directly related to a poor prognosis. With overall cure rates of 80 to 90%, lip cancers have a more favorable prognosis than most other head and neck cancers.

Salivary Gland Disease and Tumors

Robert A. Ord, MD, DDS, MS

Alex E. Pazoki, MD, DDS

The salivary glands consist of three major paired glands (the parotid, submandibular, and sublingual) as well as numerous minor salivary glands, situated mostly in the oral cavity but also found in the pharynx, larynx, trachea, and sinuses. In the oral cavity 700 to 900 minor salivary glands are found, the majority of which are located at the junction of the hard and soft palates. These glands produce saliva, which functions as a lubricant for speech and swallowing, assists taste, has antibacterial and immunologic properties, and contains digestive enzymes. The salivary glands are affected by many different disease processes, some of which are surgical in nature while others have a medical basis. Surgical diseases include tumors, stones, and cysts, whereas medical diseases include viral infections, autoimmune diseases, and sarcoidosis. This chapter will concentrate on the salivary gland diseases that are of most interest to the surgeon.

Tumors

Tumors of the salivary glands show a wide variety of pathologic types varying from benign to highly malignant. Salivary cancers are comparatively rare and comprise 3% of head and neck cancers, which in turn account for 3% of all malignancies.

These neoplasms will be discussed according to their histopathologic diagno-

sis and the surgical principles dictated by the site of the tumor.

Histopathology

The large variety of tumors that occur in the salivary glands make an exhaustive list of all types impossible in a chapter of this length. The most common epithelial salivary gland tumors will be reviewed in order to illustrate the fundamentals of management of salivary neoplasia.

Benign Tumors *Pleomorphic Adenoma*

The pleomorphic adenoma is the most common benign salivary tumor at all sites. Approximately 80% of all pleomorphic adenomas (PSAs) occur in the parotid, and despite their slow growth they can become extremely large if neglected. This tumor is thought to arise from both salivary ducts and myoepithelial cells and is a true “mixed tumor.” Because of its derivation, histologically, many different patterns can occur, from cellular, glandular, and myxoid types to cartilagenous and even ossified forms. These features can be seen in different areas of the same tumor, accounting for its name, *pleomorphic* (Greek for *many forms*). The important feature from a surgical standpoint is the presence of a “pseudo capsule,” which contains outgrowths or pseudopodia of the

tumor. Attempts at “enucleation” of the tumor from within its “capsule” will inevitably leave viable tumor cell nests and predispose the patient to multifocal recurrence. Some authorities believe that younger patients with pleomorphic adenomas have a higher chance of tumor recurrence and increased growth during pregnancy. Malignant change is rare and usually takes place in long-standing tumors, the most common type being carcinoma ex pleomorphic adenoma. Prognosis will depend on the type of malignancy and involvement of the capsule. Rarely, malignant change in both elements of the pleomorphic adenoma (ductal and myoepithelial) will occur giving rise to the carcinosarcoma or true mixed malignant (biphasic) pleomorphic adenoma. On rare occasions, an apparently histologically benign tumor will metastasize into the so-called benign metastasizing pleomorphic adenoma.

Warthin’s Tumors This benign tumor is almost exclusively found in the parotid. It occurs mostly in men and is more common in smokers. It is thought to derive from salivary duct cells that are entrapped in lymph nodes during embryonic development. The tumor consists of large cystic spaces with a surrounding columnar epithelium and a

stroma of lymphocytes. Surgically these tumors may be multiple in one parotid gland or bilateral, or involve lymph nodes adjacent to the parotid gland.^{1,2}

Hemangi endothelioma In children the most common cause of parotid mass is a hemangioma or hemangi endothelioma.³ These are benign tumors that may appear soon after birth and grow rapidly. Usually, conservative treatment while waiting for involution is recommended.

Malignant Tumors Mucoepidermoid Carcinoma Mucoepidermoid carcinoma (MEC) is the most common malignant salivary gland neoplasm in both adults and children, and the most common salivary gland cancer of the parotid and minor salivary glands. This tumor can be of low grade or high grade depending on its histology. Low-grade MECs have multiple macrocysts and abundant mucus-producing cells. High-grade varieties have multiple squamous cells and very few mucus-producing cells or cysts, and mucicarmine or periodic acid–Schiff stains may be needed to identify intracellular mucus to characterize this tumor. There are three cell types of MEC: mucus producing, intermediate, and squamous. The respective ratio of mucus-producing cells to squamous cells will determine the clinical aggressiveness of the tumor (see above). Low-grade MECs can be very slow growing and nonmetastasizing, and can generally behave like a benign tumor. High-grade MECs can exhibit aggressive growth and invasion resulting in widespread metastasis and death. High-grade tumors usually show increased pleomorphism and meiotic figures. High-grade lesions may metastasize to cervical lymph nodes or spread hematogenously to the lung, liver, and bone.

Adenoid Cystic Carcinoma Although this tumor is very slow growing, its relentless course, with repeated recurrence and metastasis via the blood stream, gives low 20-year

survival rates.⁴ Adenoid cystic carcinoma is the most common malignancy of the submandibular gland and is the second most common salivary gland cancer overall. Three histologic types are seen: tubular, cribriform (the classic “Swiss cheese” pattern), and solid. The solid type has the worst prognosis, especially when areas of necrosis are present. The infiltrative nature of this lesion and the frequency of perineural involvement with spread along the nerve mandate wide resection margins. Perineural spread is a bad prognostic sign for both local recurrence and distant metastasis. Clinical and radiologic examination of this tumor frequently underestimate its true extent, and follow-up of 15 to 20 years is required as late recurrences occur.

Low-Grade Polymorphous Adenocarcinoma Low-grade polymorphous adenocarcinoma occurs almost exclusively in the minor salivary glands and is second only to mucoepidermoid carcinoma at these sites. It arises from terminal duct cells and is characterized by cytologically bland monotonous cells that can assume many different patterns (glandular, cribriform, and lobular) within the same tumor. Characteristically “Indian file” cells and perineural involvement are seen. Although this tumor behaves in a very low-grade manner, local recurrence will occur with inadequate excision.⁵ The important pathologic features seen from the surgeon’s viewpoint are frequent misdiagnosed on initial biopsy, due to the different patterns that may be sampled. Common misdiagnoses are adenoid cystic carcinoma, pleomorphic adenoma, and malignant pleomorphic adenoma. It is also important to be aware that the frequent presence of perineural involvement does not lead to a worse prognosis, as is the case for adenoid cystic carcinoma.

Site of Tumor

Parotid Gland The surgical principles of treating parotid tumors are dictated by the histopathology of the tumor and the

need to preserve the facial nerve. Diagnostic imaging with computed tomography (CT) or magnetic resonance (MR) is desirable for superficial lobe tumors but is essential for suspected deep-lobe neoplasms, especially those with a parapharyngeal component. Since 80% of parotid tumors are benign and 80% of these are pleomorphic adenomas, a solitary mass in the parotid with no features of malignancy is most likely a PSA. Open biopsy of such a mass is therefore contraindicated as this will rupture the “capsule” and “seed” the PSA, increasing the complexity of subsequent surgery and chances of recurrence. Fine-needle aspiration biopsy (FNAB) for cytology is the preferred method of diagnosis.⁶ Clinically only one-third of malignant tumors will have symptoms or signs of malignancy, such as pain, ulceration of skin, facial nerve palsy, or metastatic cervical nodes.⁷ Thus virtually all parotid tumors will initially be treated as benign unless FNAB shows definite malignancy or there is clinical evidence of malignancy (Figure 35-1). The majority of tumors occur in the superficial lobe, and superficial lobectomy with preservation of the facial nerve has been the standard operation for many years. Recent minor modifications have included the use of a face-lift incision, the use of the superficial musculoaponeurotic system to prevent Frey’s syndrome, the use of flaps or alloplasts to augment defects, and the suggestion that “capsular dissection” without the need to remove the entire superficial parotid may be sufficient.^{8–10} Superficial lobectomy is suitable for benign and low-grade malignant tumors, and even in high-grade malignancies only branches of the nerve that are actually infiltrated will be sacrificed. If the nerve or portions of it have to be resected, immediate grafting is recommended. In deep-lobe tumors a total parotidectomy is performed, with the superficial lobe being dissected first to expose the nerve. Good margins with

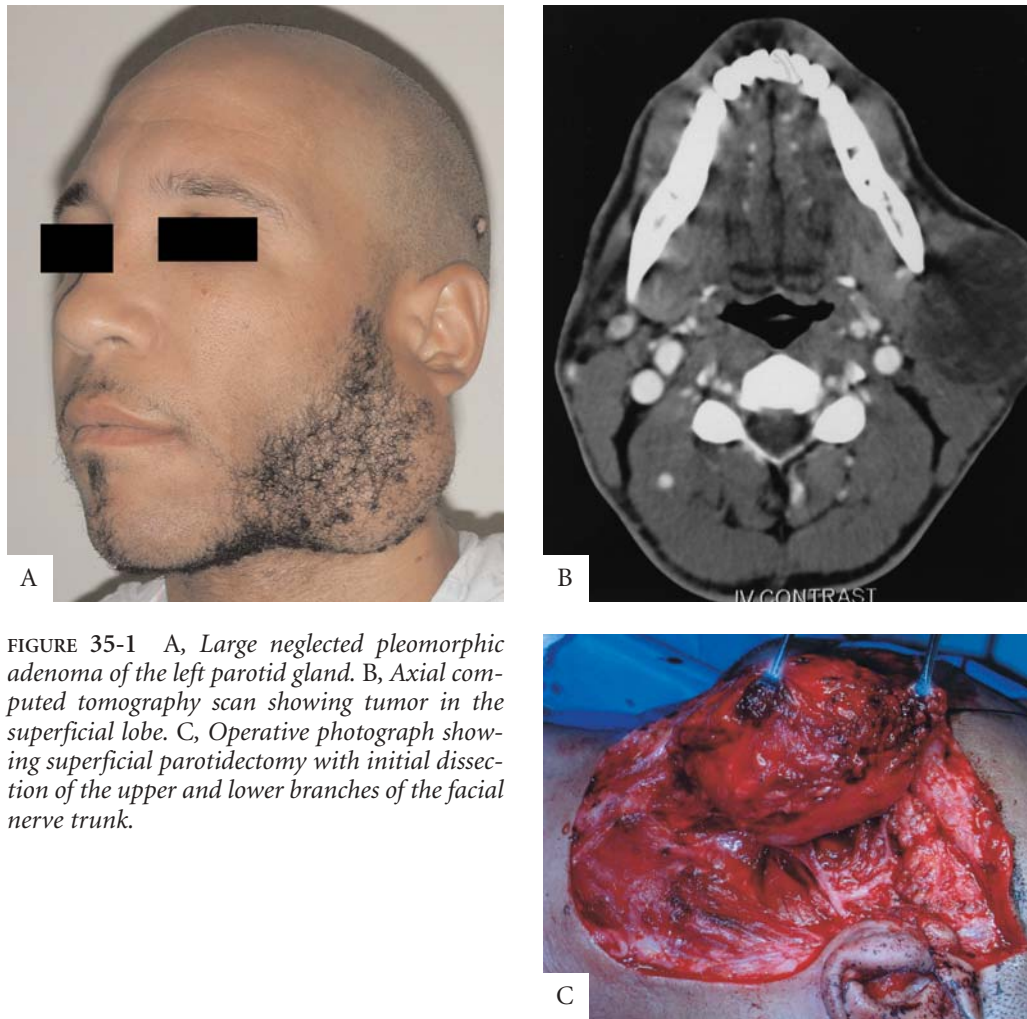

FIGURE 35-1 A, Large neglected pleomorphic adenoma of the left parotid gland. B, Axial computed tomography scan showing tumor in the superficial lobe. C, Operative photograph showing superficial parotidectomy with initial dissection of the upper and lower branches of the facial nerve trunk.

surrounding normal salivary gland tissue are more difficult to obtain on deep-lobe tumors, which tend to be large as they are often detected late. In high-grade tumors, surrounding tissues such as skin, masseter, and mandible may require sacrifice, as dictated by the need to obtain clear margins. In these instances consideration should be given to neck dissection. Where clinically positive nodes are present, a modified radical neck dissection is usually the operation of choice.¹¹ Where the patient is N0 clinically, but at high risk for occult nodal disease, a selective neck dissection of levels I to IV or levels II to IV is indicated. In high-grade tumors postoperative radiation therapy is usually indicated. Chemotherapy has not been shown to convey a survival benefit for these lesions.

Submandibular Gland In suspected submandibular neoplasms, CT imaging, MR imaging, and FNAB are all useful in the diagnostic work-up. Fifty percent of tumors will be malignant, adenoid cystic carcinoma being the most common. In benign neoplasms (PSAs) removal of the submandibular gland with an extracapsular dissection of the tumor and 2 to 3 mm of surrounding soft tissue is sufficient. For malignant tumors the minimum resection will be an en bloc removal of level I. If indicated the overlying platysma superficially and the mylohyoid muscle deeply will be excised. In most malignant tumors with N0 necks, the cervical incision necessary for removal of level I will dictate extending this to a supraomohyoid neck removing levels I to III. The adenoid cystic carcinoma does not usually metastasize via the lym-

phatics; instead it spreads hematogenously and neck dissection may not be indicated. The mandibular branches of the facial, lingual, and hypoglossal nerves are all in close relation to the submandibular gland. If these nerves appear to be involved by cancer, they should be traced until the nerve appears normal. After resection, frozen sections should be sent from the cut nerve trunk to confirm clearance, although “skip” lesions do occur. Radiation may be useful postoperatively.

Minor Salivary Glands *The Palate* The majority of minor salivary gland tumors occur at the junction of the hard and soft palates. In this location 50% are malignant, the most common being low-grade mucoepidermoid carcinoma followed by low-grade polymorphous adenocarcinoma. Coronal and axial CT scans with bony windows are helpful to demonstrate bone destruction and involvement of the sinuses or nasal cavity. Biopsy through the middle of the lesion is indicated as the overlying mucosa will be excised.¹² In PSA, excision with a 5 mm margin is adequate. The periosteum is a good deep margin if the bone is uninvolved, as is usually the case with PSA (Figure 35-2). In low-grade lesions a 1 cm margin and similar approach

FIGURE 35-2 Large pleomorphic adenoma of the right palate.

are used. Local flap reconstruction or the use of a palatal plate with subsequent secondary healing by granulation is used for reconstruction. Where bone invasion has occurred, as in adenoid cystic carcinoma or high-grade tumors, a partial maxillectomy will be required. In the case of adenoid cystic carcinoma, attention must be given to the greater palatine nerve, with frozen section clearance obtained. Cranial extension, orbital involvement, and infiltration posteriorly into the pterygoids will increase the extent of surgery and its morbidity, with a decrease in survival (Figure 35-3). Reconstruction is usually with an obturator, although primary maxillary reconstruction has been revisited with the development of interosseous implants and composite microvascular free flaps.

The Retromolar Fossa Although this is a relatively unusual site for minor salivary gland tumors, virtually 100% are malignant and are low-grade mucoepidermoid carcinomas. The surgeon should be aware that a cystic soft tissue mass distal to the third molar, with or without radiographic mandibular involvement, is unlikely to be a mucocele, and incisional biopsy should be undertaken to confirm the diagnosis.

FIGURE 35-3 Recurrent low-grade polymorphous adenocarcinoma of the palate postmaxillectomy with invasion of the orbital floor and orbital fat.

Intrabony Tumors Although intrabony (central) salivary gland tumors are rare, the vast majority are malignant low-grade mucoepidermoid carcinomas.¹³ These are mostly seen in the third molar region of the mandible and are frequently multilocular. The tumors are often diagnosed radiologically as ameloblastomas, or odontogenic keratocysts. Resection with a 1 cm margin and sacrifice of the inferior alveolar nerve and overlying soft tissue in areas of perforation are required. Neck dissection is usually not necessary, but if the neck has been opened widely for mandibular resection a supraomohyoid neck dissection can be undertaken. A reconstruction plate is placed and either primary reconstruction with a fibular or deep circumflex iliac artery microvascular flap or secondary posterior iliac crest corticocancellous reconstruction may be used.

Other Intraoral Sites Interestingly, the proportion of benign to malignant tumors varies according to site, with virtually all upper lip tumors being benign and a higher proportion of lower lip tumors being malignant. Salivary gland neoplasms of the tongue and buccal mucosa tend to be malignant and require wide soft tissue dissection to obtain margins.

The Sublingual Gland Less than 1% of all salivary gland tumors occur in the sublingual gland but almost 100% are malignant. Surgical approach will be dictated by the histology and required access for margins. In most cases we have preferred a lip split and mandibulectomy to allow good visualization of the tumor, direct examination of the mandibular lingual cortical plate, and the ability to trace back the lingual nerve when necessary.

Obstructive Disease

Obstruction to the salivary glands is usually seen in the submandibular and parotid glands. It may be due to calcified stones

(most common in the submandibular gland) or mucous plugs (most common in the parotid) or strictures of the duct. Stone formation is classically due to stasis of flow, infection, and alteration of the duct contents. Calcified stones are formed by the precipitation of calcium salts around a nidus of mucous plugs, epithelial cells, or microorganisms. Approximately 80% of sialoliths occur in the submandibular gland.¹⁴ Microliths in the minor salivary glands have been described.

As calcified sialoliths increase in size they may give rise to symptoms, especially when they are present in the duct. Classically the patient reports pain and swelling when eating or drinking or sometimes even from the smell of food (Figure 35-4). Examination of the gland may show a tender swelling with inability to milk saliva from the duct orifice.

Plain radiography is used to demonstrate calcified stones, the lower occlusal film for the submandibular gland, and an occlusal or periapical dental film held in the cheek for the parotid. Lateral oblique mandibular films or panoramic radiographs will show parotid duct stones and calcified stones in the hilum or glandular substance of the submandibular gland. CT

FIGURE 35-4 Right submandibular gland swelling and sialadenitis secondary to an obstructing sialolith.

scans and ultrasonography have also been used. When a noncalcified (mucous plug) obstruction is suspected, sialography may demonstrate a filling defect (Figure 35-5). Acute infection should be managed with antibiotics prior to sialography. Treatment of the stone will depend on its location.

Submandibular Gland

Anterior Duct If the stone is palpable in the anterior floor of the mouth close to the orifice of Wharton's duct, an intraoral approach may be used. Although the anterior duct is traditionally regarded as a line between the first molars, the floor of the mouth slopes downward following the mylohyoid muscle as the premolars are reached, and technical difficulty is increased as the stone is more distal (Figure 35-6). Initially a suture is passed

FIGURE 35-5 A, Sialogram showing a large calcified stone in the hilum, with dilated intraglandular ducts. Note the filling defect at the proximal duct from the mucous plug (arrow). B, The filling defect is confirmed by this sialogram to be at the terminal duct (arrow).

behind the sialolith around Wharton's duct to use as a traction suture, tenting the duct upward and preventing posterior displacement of the stone during surgical manipulation. An incision in line with the duct is made through the mucosa and dissection carried down to the duct. This is opened in its long axis allowing removal of the stone. The posterior suture is removed and the gland is milked or explored with a lacrimal probe to find other stones. The duct is sutured open to the edges of the mucosa (fish tailed) to prevent stricture.

Posterior Duct Stones in the posterior submandibular duct are much more technically difficult to remove intraorally, requiring general anesthesia, excellent light, and retraction, as well as the help of an assistant to push the gland upward into the mouth from extraorally. Even so, irritating bleeding can occur and the lingual nerve must be visualized and protected (see Figure 35-6).

Stones in the Hilum or Gland

When the stone is below the posterior edge of the mylohyoid muscle, removal of the gland is necessary. Although intraoral submandibular gland excision has been described, the potential for bleeding from branches of the facial vein and artery and possible scarring of the anterior pole of the gland to the mylohyoid muscle can make this a technically challenging and hazardous procedure.¹⁵ We believe that the conventional cervical approach gives the best access and is the safest procedure.

Under general anesthesia an approximately 5 cm incision is made over the submandibular gland at 1½- to 2-finger breadths below the mandible. This incision should be parallel to the neck skin creases, not to the lower border of the mandible (Figure 35-7). The platysma is sectioned and the inferior pole of the submandibular gland visualized. The gland is exposed by subcapsular dissection at the inferior posterior pole. Blunt finger dissection will release

the deep surface of the gland. The authors do not routinely tie the facial artery and vein at this stage as these can usually be dissected off the gland, although clipping

FIGURE 35-6 Lateral oblique radiograph of the mandible showing the entire Wharton's duct occupied by calcified sialolith. Note how the stone passes inferiorly and deeply, the farther posteriorly it is placed (arrows).

FIGURE 35-7 A, Incision for submandibular gland excision parallel to the neck crease. B, Submandibular gland mobilized and retracted through the wound. The arrow points to the lingual nerve in the superior part of the wound.

multiple arterial branches to the gland can be tedious. The anterior pole of the submandibular gland is mobilized off the mylohyoid muscle, and in cases of chronic sialadenitis, sharp dissection may be necessary due to dense fibrosis. The superior pole of the gland is dissected in a subcapsular plane and the gland mobilized posteriorly. The posterior edge of the mylohyoid muscle is retracted to expose the lingual nerve and the branch to the gland is tied and sectioned (see Figure 35-7B). The submandibular duct is dissected superiorly into the floor of the mouth as far as possible, tied, sectioned, and the gland removed.

Parotid Gland

Most obstructive symptoms in the parotid gland are associated with noncalcified stones or mucous plugs. Although these can sometimes be removed with tweezers following duct dilatation or “milked” from the duct, they often cause repeated bouts of pain and swelling. Sialography is helpful in evaluating the extent of damage to the ductal architecture. Sialograms may show changes varying from mild sialectasis to gross dilatation of Stensen’s duct with loss of secondary and tertiary ducts (Figure 35-8). Sialograms are frequently helpful symptomatically, with cure or

improvement in many patients. In advanced cases with no improvement, parotidectomy may be required.

Stones in the Terminal Duct Radiographically opaque stones at Stensen’s papilla can be managed intraorally in a similar manner to those of the anterior portion of Wharton’s duct. Following placement of a posterior traction suture, the duct is opened with an incision running in the long axis of the duct.

Stones in the Posterior Duct When the stone involves the extraglandular portion of the duct lateral to the buccinator muscle, both intraoral and extraoral approaches are described.^{16,17} The intraoral approach involves a Y-shaped mucosal incision, dissection through the buccinator muscle, and the use of a traction suture to pull the duct into the mouth. The extraoral approach requires the duct to be displaced laterally with a finger placed in the mouth, with blunt dissection down to the stone, avoiding the facial nerve.

Parotid Gland Stones Stones at the hilum of the gland or intraglandular stones usually require a parotidectomy if they are symptomatic. The facial nerve

dissection may be challenging due to extensive fibrosis (Figure 35-9).

Nonsurgical Approaches

Miniature endoscopes have been used to visualize sialoliths and remove them with baskets.¹⁸ Lithotripsy has also been attempted either via endoscopes (intracorporeal) or extracorporeally. Intracorporeal lithotripsy uses shock waves produced by lasers, electrohydraulic sources, or a pneumbalistic source. In a review of 6 series of extracorporeal lithotripsy ranging from 33 to 104 stones, Escudier reported a stone-free range of 18.2 to 52.9% with residual fragments occurring in 47.1 to 81.8% of cases.¹⁹

Mucocele and Ranulas

Mucocele are mostly due to extravasation of mucus from a salivary gland, although a few are true retention phenomena. The most common site is the lower lip, due to trauma (usually following an accidental bite in a child). Mucoceles are simple to treat and they should not recur if the underlying damaged minor salivary gland has been removed. Following a vertical incision through the mucosa over the mucocele, a number of minor salivary glands are usually identified. As it may be impossible

FIGURE 35-8 Sialogram showing gross destruction of the parotid ductal architecture with dilatation of the glandular ducts into large mucus-filled sacs.

FIGURE 35-9 A, Computed tomography scan showing a large parotid stone at the hilum of the gland. B, Parotid duct opened to show the sialolith in situ, following parotidectomy.

FIGURE 35-10 Large ranula overlapping the occlusal plane in a 10-year-old boy.

to identify the damaged gland, all these minor glands should be removed before carefully suturing the mucosal incision.

Ranulas are large retention phenomena that occur in the floor of the mouth in relation to the sublingual gland. They may be large enough to elevate the tongue and interfere with speech and swallowing (Figure 35-10). Where dehiscence in the mylohyoid muscle occurs, the mucus can drain into the submandibular space as a “plunging ranula.” The treatment of ranulas has been reviewed at length in a classic paper by Catone.²⁰ He concluded that definitive therapy was removal of the sublingual gland. Several large series have been reported comparing sublingual gland excision with so-called marsupialization, demonstrating 100% cure for gland excision and 43 to 63% cure for marsupialization.^{21,22}

Despite this evidence some authorities still plead the case for marsupialization or “marsupialization with packing,” which they claim has a lower recurrence rate of 10 to 12%.²³ We subscribe to the view that

ranulas should be treated by sublingual gland excision.

An intraoral approach is made with an incision along the axis of the gland lateral to the ductal orifices. The submandibular duct is identified, either by dissection or following cannulation with a lacrimal probe. The gland is dissected in a subcapsular plane with meticulous hemostasis. At its posterior pole the lingual nerve is identified as it crosses the duct and is preserved. The sublingual gland is dissected from anteriorly, and the final excision is the posterior pole after visualizing the lingual nerve.

Management of Mucosal and Related Dermatologic Disorders

Michael W. Finkelstein, DDS, MS

Steven D. Vincent, DDS, MS

Fungal Disease of the Oral Cavity

Fungal diseases of the oral cavity can be classified as superficial or deep in relation to the primary tissue(s) involved in the infection. Most oral fungal infections are opportunistic in nature. Persons living in geographic areas endemic to one or more of these fungi may show immunologic reactivity to the surface antigens without having historic features of active disease. The deep fungi usually infect the lungs before dissemination to other organ systems, including the oral cavity. Deep fungal diseases, including histoplasmosis, coccidioidomycosis, blastomycosis, and cryptococcosis, present clinically as chronic proliferative ulcerated granulomatous tissue lesions that may be single or multiple and painful or asymptomatic. They may simulate clinical features of a malignant neoplasm.

Candidosis

Although numerous deep and superficial fungal diseases can involve the oral cavity, candidosis is by far the most common. The term *candidosis* is the correct nomenclature describing an infection with one of several species of *Candida* organisms. However, many publications use the term

candidiasis to describe the same disease, even though the suffix “-iasis” is characteristically used to describe parasitic infections such as schistosomiasis or amebiasis.

One or more species of *Candida* can be found as a component of the normal oral flora in about 60% of healthy adults. The organism can exist in one of three states: the yeast form consisting of blastospores measuring 1.5 μm to 5 μm in diameter, elongated pseudohyphae, and chlamydoconidia measuring 7 μm to 17 μm in diameter. In its commensal state, the organism usually exists only as spores or pseudohyphae.

Candidosis is usually an opportunistic infection caused by a localized or systemic suppression of the immune system. Commonly recognized causes of candidosis include the use of broad-spectrum antibiotics, xerostomia, chronic diseases of the immune system, and therapy for malignant disease including chemotherapy or radiation.

Oral infections involving *Candida* species may appear as one of three clinical forms: acute, chronic, and mucocutaneous. Candidosis characteristically shows erythematous mucosa with or without overlying white plaques, which may be rubbed away with light abrasive pressure (Figure 36-1). The dorsum of the tongue

usually shows diffuse patches of papillary atrophy (Figure 36-2). Occasional small or confluent ulcerations may be noted. Angular cheilitis is a prominent clinical feature of oral candidosis. Patients characteristically complain of an oral “burning” sensation. *Denture-sore mouth* (denture stomatitis) is a clinical term used to describe patients with mucosal erythema or inflammatory papillary hyperplasia, usually related to a localized candidosis under a removable prosthodontic appliance.

Clinical features of oral candidosis usually include foci of mucosal erythema, which is the result of inflammation and mucosal atrophy, areas of ulceration, and sometimes white pseudomembranous plaques, which are seen to consist of candidal pseudohyphae and spores if examined microscopically (Figure 36-3). These pseudomembranous plaques, although usually present in acute-onset cases of candidosis, are frequently absent in cases of chronic candidosis such as those related to prosthetic appliances. The lack of white pseudomembranes should not therefore preclude consideration of candidosis in cases of chronic mucositis. Candidosis has also been noted in lesions characterized by focal increases in keratinization such as lichen planus, focal keratosis with or

FIGURE 36-1 A to C, Oral candidosis. White pseudomembranous plaques that can be removed with light abrasion involving buccal, lateral-glossal, and soft palatal mucosa.

without dysplasia (leukoplakia), hairy tongue, hairy leukoplakia, and even squamous cell carcinoma. A recent study showed the presence of candidal hyphae and spores in 31% of biopsy specimens showing oral lichen planus. However, a possible cause-and-effect relationship between candidosis and increased keratinization of the epithelium is difficult to show.

Cytologic Preparations Clinical diagnoses of oral candidosis are easily and quickly confirmed using exfoliative cytology studies. Cytologic specimens are prepared using a wooden tongue blade to scrape the oral mucosa of the involved areas; the exfoliated material is smeared onto a glass slide. The slide is air dried for 5 minutes and then fixed in ethanol (hair sprays with a high alcohol content can be used as fixatives in a clinical setting). The slides are stained with potassium hydroxide, periodic acid–Schiff modified for fungi, or any one of several other stains that delineate the fungal hyphae and

spores. The infection can be further delineated as a species using cultures on Sabouraud dextrose or blood agar.

Oral candidosis is the most common diagnosis made in patients whose chief complaint involves a chronic nonspecific mucositis or burning sensation. Other diseases included in the clinical differential diagnosis include lichen planus, pemphigus, pemphigoid, and medication-related toxic mucositis. As stated above, candidosis may be a secondary component of other chronic oral diseases or localized epithelial thickening lesions.

Management The initial management of oral candidosis following confirmation of the clinical impression with exfoliative cytology studies is the use of one or more antimycotic agents. Of greatest therapeutic value in most patients is ketoconazole, administered in one 200 mg tablet daily for 10 to 14 days. If systemic factors contraindicate the use of ketoconazole, clotrimazole troches, administered in one 10 mg

tablet dissolved in the oral cavity up to five times daily, or chlorhexidine in a 0.12% mouthrinse in a 5 to 10 mL dose twice daily NPO for 1 hour, are usually effective. Nystatin powder or cream may be used to line dentures in patients with denture sore mouth. Of vital importance is a review of the patient's past medical history and current medical status in an attempt to identify the causative factors for this opportunistic infection. In patients who have no identifiable predisposing factors or if the predisposing factors are not correctable, multiple recurrences may be anticipated.

Median Rhomboid Glossitis

Although the early reports of median rhomboid glossitis suggested an origin from the tuberculum impar, many investigators now favor classification of this lesion as a localized candidosis (Figure 36-4).¹ Although the exact cause-and-effect relationship is unclear, *Candida* spp are found in association with many of these lesions, and recent studies have shown the prevalence of median rhomboid glossitis to be higher in adults than in children, a finding contrary to the developmental theory of origin. The lesion appears clinically as an

FIGURE 36-2 Oral candidosis. Atrophy of the filiform papillae on the dorsal tongue.

FIGURE 36-3 Oral candidosis. Cytologic preparation showing hyphae and spore form characteristic of *Candida sp* ($\times 160$ original magnification; stained with periodic acid-Schiff stain modified for fungal organisms).

erythematous patch, which may be roughly ovoid or rhomboid in shape, is asymptomatic, and is located on the dorsal midline of the tongue just anterior to the circumvallate papillae. The area is usually smooth and devoid of filiform papillae.

Unless the lesion is symptomatic, no treatment is indicated. For symptomatic cases, management with antifungal regimens is usually beneficial. The lesions are generally regarded as having no malignant potential.

Bacterial Infections of Oral Mucosa

Acute Necrotizing Ulcerative Gingivitis

Acute necrotizing ulcerative gingivitis is a rare and clinically painful ulcerative disease that presents with progressive necrosis of the interdental papillae, usually beginning in the mandibular incisor region. The interdental papillae necrosis may spread or remain localized. The necrotic papillae are usually covered with a pseudomembrane of necrotic epithelial cells, plaque, and microbial organisms. The patient may have systemic signs and symptoms including fever and regional lymphadenopathy. Patients have a characteristic rancid halitosis caused in part by the presence of necrotic material in the oral cavity.^{2,3}

The probable cause of this disease involves a symbiotic infection by two bacteria, a fusiform bacillus and a spirochete. However, inoculation of these bacteria into healthy tissues does not produce disease, and because moderate numbers of these organisms can be found in otherwise clinically healthy mouths, other factors such as stress and smoking, both of which can affect the host's immune system, have been implicated as causative factors.

Local débridement by scaling and curettage, sometimes under local anesthesia, usually brings about a marked relief of symptoms. A therapeutic dose of an antibiotic such as tetracycline may be indicated for patients with extensive disease or evidence of regional lymph node enlargement. The use of topical antiseptics such as chlorhexidine or diluted hydrogen peroxide is of value for initial management of the lesions. The lesions usually heal within 2 to 3 weeks, and the interdental papillae often regenerate, seldom requiring gingival surgery. Improved oral hygiene through use of a soft-bristled toothbrush and floss is the best long-term therapy and is aimed at recurrence prevention.

Syphilis

Syphilis is a venereal infection that has been documented extensively, beginning in about the fourteenth or fifteenth century. Before the introduction of penicillin in the early 1940s, over 500,000 new cases were documented in the United States each year. The Centers for Disease Control and Prevention reported 6,657 cases of primary and secondary syphilis in the United States in 1999.⁴

The disease is caused by the spirochete *Treponema pallidum* and is acquired by contact with an active lesion. The spirochete can also be transmitted by transfused blood, and it crosses the placental barrier from maternal to fetal circulation.

In cases involving transmission from an active lesion, the site of infection forms

a chancre or ulceration, which is usually accompanied by regional lymphadenopathy. The ulcer and lymphadenopathy usually persist for 3 to 10 weeks and then resolve spontaneously. This initial disease manifestation constitutes primary syphilis. Assuming no treatment is rendered, secondary syphilis develops following a latency period of several weeks. In this stage the now widely disseminated disease causes fever, malaise, a maculopapular rash, and multiple ulcerations or mucous patches on mucosal surfaces. Broad-based, proliferative slightly raised ulcerations known as condyloma latum may occur during secondary syphilis. These lesions also persist for 5 to 10 weeks and then resolve without treatment. If the patient is still untreated, several recurrences of the manifestations of secondary syphilis may occur or the disease may enter a prolonged latency period lasting months or years.⁵⁻⁷

Fortunately tertiary syphilis develops in only a few patients. There are many manifestations of tertiary syphilis, owing to the extensive involvement of organ systems. Central nervous system involvement can present as a generalized paralysis or tabes dorsalis. Inflammation of the circulatory system can result in aneurysms, especially in the aorta. Intraoral manifestations include granulomatous proliferations known as gummas, as well as a poorly understood generalized glossitis.

FIGURE 36-4 Median rhomboid glossitis. A localized form of atrophic candidosis.

The diagnosis of syphilis is usually made following serologic studies, including Venereal Disease Research Laboratory and fluorescent treponemal antibody absorption tests. The treatment of choice for syphilis remains 2.4 million U of benzathine penicillin. For patients allergic to penicillin, erythromycin or tetracycline may be substituted.

Gonorrhoea

Gonorrhoea is currently the most widespread human bacterial infection in the world and is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus.

Transmission is usually venereal, involving genital, oral, or pharyngeal mucosa. The incubation period is about 1 week with the initial features ranging from no evidence of disease to mucosal ulcers and regional lymphadenopathy. These features, although reported in the oral cavity, are rare compared with the much more common pharyngeal infection. Therefore, in patients who present with chronic aphthous-like ulcerations and erythema predominantly involving the pharyngeal mucosa rather than the oral mucosa, a gonorrhoeal infection should be part of the clinical differential diagnosis. The microscopic features are nonspecific, and the clinical features of the disease seldom indicate a biopsy. The diagnosis is based on demonstration of the organism in culture media or through the use of immunofluorescent antibody techniques.^{8,9}

The treatment of choice for gonorrhoea continues to be penicillin. Occasional penicillin-resistant strains are noted during sensitivity cultures and require management with alternative antibiotics.

Pigmented Lesions of Oral Mucosa and Skin

Pigmented lesions of oral mucosa and skin can be divided into generalized lesions, which are diffuse and multifocal, and localized lesions involving one or several locations.

Generalized Pigmentations

Some of the common causes of generalized pigmentations are listed in Table 36-1.

The most common type of generalized pigmentation is hereditary or racial. The pigmentation is diffuse, symmetric, and most commonly located on the gingiva and labial mucosa. Pregnancy and ingestion of oral contraceptives may produce melanin pigmentation called chloasma or melasma. Pigmented macules occur on the labial mucosa, forehead, malar prominences, and around the eyes and lips.¹⁰⁻¹³

Smokers sometimes have melanin pigmentation of the attached gingiva. Numerous medications may cause pigmentation of skin and/or oral mucosa. Antimalarials such as quinine, chloroquine, and amodiaquine may cause pigmentation in approximately 25% of patients taking them for > 3 to 4 months. Cancer chemotherapeutic drugs such as busulfan, cyclophosphamide, and bleomycin have been reported to cause pigmentation, primarily of skin. Hydantoin may produce facial pigmentation resembling chloasma. Minocycline may cause pigmentation of skin, bones, teeth, oral mucosa, and the thyroid. Pigmentation secondary to heavy metals is due to deposition of metals in the skin and oral mucosa. This type of pigmentation is not commonly seen today because of their decreased value as therapeutic agents.

Peutz-Jeghers syndrome is characterized by multiple pigmented macules of the hands and feet; areas surrounding the mouth, eyes, and nose; and intraorally on the buccal mucosa, labial mucosa, gingiva, and palate. Multiple hamartomatous polyps are present in the gastrointestinal tract. Patients with this syndrome have an increased incidence of cancer both within and outside the gastrointestinal tract.

Patients with Addison's disease have increased pigmentation of the skin, lips, gingiva, buccal mucosa, and tongue. Systemic manifestations are prominent and include malaise, weakness, nausea, vomiting, diarrhea, weight loss, and hypotension.

Table 36-1 Generalized Pigmentations of Skin and Oral Mucosa

Hereditary (racial)
Pregnancy (chloasma, melasma)

Mercury
Syndromes and systemic diseases
Peutz-Jeghers syndrome
Addison's disease
Neurofibromatosis
Albright's syndrome

Neurofibromatosis is a relatively common autosomal dominant inherited syndrome. Virtually all patients have six or more brown cutaneous macules > 1.5 cm in diameter known as café au lait spots. Numerous freckles 2 or 3 mm in diameter are often present in the axilla and other intertriginous regions. Other features of neurofibromatosis include multiple neurofibromas, central nervous system tumors, seizures, intellectual handicap, and speech impediments.

Albright's syndrome consists of polyostotic fibrous dysplasia plus multiple café au lait spots. Endocrine abnormalities, most commonly precocious puberty in young females, are also present.

Localized Pigmented Lesions

Localized pigmented lesions can be divided into four classes based on their cause and clinical features: (1) melanocytic,

(2) vascular, (3) extravasated blood, and (4) tattoos.

Melanocytic Lesions Melanocytic lesions are due to increased amounts of melanin pigment in the tissue and/or a proliferation of melanocytes or nevus cells. Melanocytic lesions are gray, brown, black, or blue and do not blanch on pressure.

Ephelides The ephelis or freckle is a small circumscribed brown or black macule that occurs on sun-exposed areas of skin. It appears in childhood and darkens in the summer and fades during the winter. Microscopically, the ephelis shows increased melanin in the basal cell layer of the epidermis but no increase in the number of melanocytes. Ephelides are not premalignant and require no treatment once the diagnosis is established.

Oral Melanotic Macules The oral melanotic macule is an oral mucosal pigmentation with similar microscopic features to ephelis. The lesions are well-circumscribed flat macules that are gray, brown, blue, or black. Most are 1 to 3 mm in diameter. The most common locations are the vermilion border of the lip, gingiva, and buccal mucosa. They are often confused clinically with tattoos and nevi.^{14,15}

Microscopically, oral melanotic macules show increased melanin in the basal cell layer, lamina propria, or both. The cause of oral melanotic macules is unknown, although they may be an atypical manifestation of physiologic pigmentation because the microscopic appearance is identical to racial pigmentation. These macules do not recur or undergo transformation into melanoma, but they may be difficult to distinguish it from nevi or melanoma in situ. They should be excised for microscopic diagnosis or checked frequently.

Lentigo Simplex Lentigo simplex is a macular brown-to-black lesion that is not associated with sun exposure and may occur on

any skin surface. It is not premalignant and requires excision only for microscopic diagnosis. Microscopically, lentigo simplex demonstrates an increased number of melanocytes in the basal cell layer, an increased amount of melanin in the melanocytes and the basal keratinocytes, and elongation of the rete ridges. Macrophages containing melanin (melanophages) are present in the upper dermis.¹⁶

Nevi A nevus is a proliferation of nevus cells or melanocytes. Nevi are extremely common lesions on skin but are relatively uncommon on oral mucosa. Most nevi of skin are absent at birth and appear in childhood. They progress through a series of stages, and then decline in number with increasing age. Nevi begin as junctional nevi, with nests of nevus cells at the dermal-epidermal junction. Compound nevi demonstrate nevus cell nests in the epidermis and upper dermis. Intradermal nevi have nevus cell nests only in the dermis.

Clinically, junctional nevi are flat pigmented macules. The compound nevus is slightly elevated and sometimes has a papillomatous surface. Intradermal nevi are dome shaped and pedunculated. Compound and intradermal nevi may not be pigmented. Normal nevi are round to oval, have a smooth border, and are sharply demarcated from the surrounding skin. They are most commonly found on sun-exposed skin above the waist.^{17,18}

Dysplastic nevi are precursors to melanoma. They may occur sporadically or in an autosomal dominant inherited syndrome in which they are quite numerous. Dysplastic nevi have irregular borders that are indistinct and fade into the surrounding skin. They may demonstrate a mixture of colors, including tan, dark brown, and pink. Dysplastic nevi are typically larger than normal nevi.

It is not necessary to remove normal cutaneous nevi unless they are irritated by clothing. Since dysplastic nevi have an increased potential for developing into

melanoma, they should be removed. In patients with numerous dysplastic nevi, the lesions should be closely monitored and excised if they change.

Nevi of the oral mucosa are usually between 1 and 6 mm in diameter and are most commonly located on the hard palate and buccal mucosa. They are occasionally nonpigmented. The majority of oral nevi are raised and thickened, but a significant number may be flat.

Microscopically, the majority of oral nevi have been reported as intramucosal, but blue, compound, and junctional nevi also occur.¹⁷

Because of the small number of reported cases of oral nevi, their potential for evolving into melanoma is not known. Because of this, lesions in which nevus is part of the clinical differential diagnosis should be completely excised.

Melanomas Melanoma is a malignant neoplasm of nevus cells or melanocytes. Microscopically, melanomas begin at the dermal-epidermal junction and then may demonstrate two different patterns of growth. In radial growth, or melanoma in situ, melanoma cells grow laterally along the dermal-epidermal junction but do not invade the underlying dermis. A melanoma may remain in the radial growth phase for years, and during this time it does not metastasize. During vertical growth the melanoma cells grow into the dermis and are capable of invading vascular channels and nerves and metastasizing.¹⁹⁻²²

Microscopically, melanoma cells are described as epithelioid or spindle shaped. Epithelioid cells are round to cuboidal and form nests. The spindle cells are elongated and do not form nests. The tumor cells demonstrate nuclear pleomorphism, anaplasia, and mitotic figures. The amount of melanin within tumor cells is variable. The Fontana-Masson stain demonstrates melanin in some of the amelanotic-appearing tumor cells. The dopa reaction is more reliable for

demonstrating melanin, but it requires fresh tissue.

There are four types of cutaneous melanoma: lentigo maligna melanoma, superficial spreading melanoma, acral-lentiginous melanoma, and nodular melanoma.

Lentigo maligna (melanotic freckle of Hutchinson) represents lentigo maligna melanoma in situ. It presents as a brown macule with black flecks and irregular margins located on sun-exposed surfaces of elderly persons. It may remain in the radial growth phase for 10 to 15 years before progressing to invasive lentigo maligna melanoma, indicated by the development of nodularity.

Superficial spreading melanoma constitutes about 70% of cutaneous melanomas. It occurs on both exposed and unexposed surfaces, most commonly on the upper back in men and lower legs in women. This melanoma has irregular borders and great variation in color within one lesion, including tan, brown, black, pink, blue, and white areas (Figure 36-5). It often demonstrates nodularity and ulceration. Superficial spreading melanoma remains in the radial growth phase for a shorter time than does lentigo maligna melanoma and thus has a poorer prognosis.

FIGURE 36-5 Melanoma. Alteration in color of a nevocellular nevus with apparent expansion into the surrounding normal skin.

Acral-lentiginous melanoma is the most common melanoma in black persons. It occurs primarily on the palms, soles, and in association with nails. It can metastasize early.

Nodular melanoma presents as a rapidly growing darkly pigmented nodule that is often ulcerated. It is not associated with sun exposure. Since it grows vertically from the beginning, it is often deeply invasive by the time it is diagnosed.

Treatment of cutaneous melanoma usually consists of wide surgical excision. Chemotherapy is sometimes used, but radiation therapy has not proven effective. Incisional biopsy is not thought to cause metastasis of melanomas.

The most important prognostic factor for cutaneous melanoma is the thickness of the lesion. One study reported a 10-year survival rate of 99.5% for patients with melanomas < 0.76 mm thick, as opposed to 48% survival for those with melanomas 3 mm and greater in thickness.²³

Melanoma of oral mucosa is a rare neoplasm most commonly located on the hard palate and maxillary gingiva of patients > 50 years of age. About one-third of patients have preexisting melanosis, or macular hyperpigmentation, which probably represents radial growth of the lesion. This may be present for years before vertical growth occurs. At the time of diagnosis, many oral melanomas are large, ulcerated, and have caused bony erosion. A significant number of tumors are amelanotic.

Treatment of oral melanoma is wide local excision with or without lymph node dissection. The prognosis is quite poor. The 5-year survival in one series was only 13%.²³ This may be due to the advanced stage of oral melanomas at the time of diagnosis.

Vascular Lesions Vascular lesions are due to increased numbers of blood vessels, or blood vessels of increased diameter. These lesions are compressible, blanch on pressure, and are red, blue, or purple.

Hemangioma Hemangioma is a proliferation of blood vessels that is usually congenital and may regress spontaneously. It is commonly found on the skin and in the oral cavity.

Hemangioma of skin may present as a soft tissue enlargement or a flat surface lesion. Nevus flammeus, or port-wine stain, is a red-to-blue macule present at birth. Sturge-Weber syndrome (encephalotrigeminal angiomas) includes congenital port-wine stain in the distribution of the trigeminal nerve, hemangiomas of the leptomeninges, and ipsilateral hemangiomas of the face, skull, jaws, and oral cavity. The hemangiomas often contain calcifications and may result in seizure disorders and other neurologic problems.

Hemangiomas of the oral cavity are compressible red or blue soft tissue enlargements that blanch on pressure. They present most commonly in the lips, tongue, and buccal mucosa.

Microscopically, hemangiomas are classified as cavernous or capillary. Cavernous hemangiomas consist of large vessels lined with a single layer of endothelial cells, whereas capillary hemangiomas contain numerous smaller vessels. During their period of growth, capillary hemangiomas demonstrate marked endothelial proliferation and only a few capillary lumina.

Hemangiomas are unencapsulated lesions and can be difficult to remove surgically. Other treatment modalities include sclerosing agents, cryotherapy, and laser surgery. Treatment is not recommended unless lesions are a functional or cosmetic problem.

Varix A varix is a dilated vein. It occurs most commonly on the lip, buccal mucosa, and ventral surface of the tongue. It increases in frequency with increasing age.

The typical varix is blue, compressible, and blanches on pressure. A thrombosed varix is firm to palpation, does not blanch, and resembles a nevus.

No treatment is necessary for a varix unless nevus or melanoma is included in the clinical differential diagnosis.

Kaposi's Sarcoma Kaposi's sarcoma is a malignancy of endothelial cell origin that occurs in three settings. It was first described as a disease involving the skin of the distal portion of the lower extremities in elderly males of Mediterranean or Jewish origin. It is also endemic in black African children and adults. The African form involves viscera and lymph nodes as well as skin. Recently it has become a common lesion in patients with immunosuppression secondary to organ transplantation or human immunodeficiency virus (HIV) infection.

Kaposi's sarcoma frequently involves the oral cavity, especially in patients with HIV infection. Oral lesions are most common on the hard palate and gingiva. The lesions may be single or multiple, flat or exophytic, and red, blue, or brown. The exophytic lesions blanch on pressure.

The microscopic appearance of early lesions of Kaposi's sarcoma resembles granulation tissue. Increased numbers of dilated capillaries and a chronic inflammatory infiltrate are present. Advanced lesions have vascular and spindle cell components. The vascular channels are lined with prominent endothelial cells. Strands of pleomorphic spindle cells line narrow slits containing erythrocytes. Extravasated erythrocytes and hemosiderin in the stroma help distinguish Kaposi's sarcoma from fibrosarcoma.

Treatment of Kaposi's sarcoma includes radiation therapy, surgery, and/or chemotherapy. African patients and patients with Kaposi's sarcoma secondary to immunosuppression have a poor prognosis. The disease causes death in 10 to 20% of elderly males with the disease.

Lesions Owing to Extravasated Blood Because these lesions are due to the presence of blood outside of blood vessels, they do not blanch on pressure.

Hematoma A hematoma is a blood blister or a circumscribed pool of blood outside of a vessel. It is typically caused by trauma and is most commonly found on the buccal mucosa along the occlusal plane. It appears blue to purple and is compressible to palpation. A hematoma requires no treatment and resolves spontaneously in several weeks.

Ecchymosis and Petechiae An ecchymosis, or bruise, is caused by diffuse bleeding into the tissue secondary to trauma. It is not palpable. It is initially blue but evolves through many color changes before resolving.

Petechiae are multiple discrete round hemorrhagic spots < 2 mm in diameter. They are more reddish than are ecchymoses or hematomas. Petechiae are a result of capillary bleeding. They may be associated with a viral disease or a blood dyscrasia.

Tattoos Tattoos are the most common oral pigmentation. They are the result of intentional or accidental implantation of foreign material, such as amalgam, graphite, ink, or metal, into the skin or oral mucosa. A tattoo on the hard palate is often a result of a child falling on a pencil held in his or her mouth and pushing graphite into the tissue. Amalgam tattoo is usually seen on the gingiva, alveolar mucosa, buccal mucosa, and floor of the mouth.

The most common presentation of a tattoo is an asymptomatic flat nonthickened blue-to-black pigmentation. Occasionally, however, a tattoo may be thickened owing to fibrosis or may enlarge because of phagocytosis of the foreign material by macrophages or incorporation of the material into collagen fibers. Rarely, the foreign material may incite a foreign body granuloma with multinucleated giant cells and macrophages. Radiographs may be helpful in detecting foreign material in the tissue, but not all foreign material can be visualized radiographically.

Excision of a tattoo is necessary only when a nevus or melanoma is included in the clinical diagnosis.

Vesicular, Ulcerated, and Erythematous Lesions

Numerous diseases cause vesicles and/or ulcers of the oral cavity. Some diseases such as herpes simplex and aphthous ulcers are important because they are frequently encountered in practice. Other diseases such as epidermolysis bullosa and pemphigus are serious life-threatening diseases.

Because vesicles are so transient in the oral cavity, it is usually impossible to determine if an ulcer was preceded by a vesicle. If a vesicle was present, then aphthous ulcers, ulcers of infectious mononucleosis, traumatic ulcers, and ulcers owing to bacteria can be excluded from the clinical diagnosis.

A thorough history should be obtained from patients with vesicular/ulcerative diseases and should include the following questions:

1. How long have the lesions been present?
2. Are the lesions recurrent?
3. If yes, how often do they recur?
4. Do they recur in the same locations?
5. Have you noticed vesicles?
6. Have you noticed lesions on the skin, eyes, or genitals?
7. Have you been aware of fever, malaise, and lymphadenopathy in association with the lesions?
8. What medications do you take?

Since there are a large number of diseases that can cause vesicles or ulcers, one of the convenient ways to classify the diseases is by their cause. The discussion of vesicular, ulcerated, and erythematous lesions below is arranged by the cause of lesions, for example, hereditary, viral, or autoimmune.

Hereditary Diseases

Epidermolysis Bullosa The most important hereditary vesicular/ulcerative disease

is epidermolysis bullosa (EB). There are at least 18 types of EB including some that are not inherited.

The current classification of EB is based on where the split that forms the blisters occurs, inheritance, and clinical findings. Intraepidermal forms are non-scarring and have autosomal dominant or X-linked inheritance. The split occurs within the epithelium and is associated with defective tonofilaments of the basal squamous epithelial cells. Junctional forms of EB have autosomal recessive inheritance and demonstrate skin atrophy. The split occurs within the basement membrane and is due to decreased numbers of hemidesmosomes and tonofilaments. Dermal forms have autosomal dominant or recessive inheritance with atrophy and scarring of skin and mucosa. The split occurs in the upper dermis or lamina propria owing to defects in anchoring fibrils associated with the basal lamina. Typing of patients requires the use of electron microscopy, immunofluorescence, and immunohistochemistry.²⁴⁻²⁶

EB simplex Koebner type is an intraepidermal form. Blisters mainly involve the feet, hands, and neck. They begin in infants and are exacerbated by heat. Abnormal nails are sometimes present. Oral blisters are occasionally seen, but the teeth are normal. The disease improves at puberty and is compatible with a normal life span.

EB atrophicans generalisata gravis Herlitz type is a junctional form with autosomal recessive inheritance. Blisters begin within a few days after birth and involve the hands and feet, followed by the trunk, face, and scalp. The nails are lost or dystrophic. Death within the first few months of life is common. Oral blisters and ulcers are found in almost all patients. Enamel is hypoplastic, pitted, and extensively involved with caries.

EB dystrophica Cockayne-Touraine type is a dermal form with autosomal dominant inheritance characterized by

blisters of the ankles, knees, hands, elbows, and feet that produce scars. Milia (epidermal cysts) are common. Nails are thick and dystrophic. Onset is birth to 5 years of age, and the condition improves with age. Some patients have oral bullae.

Another dermal type is EB dystrophica Hallopeau-Siemens. It has autosomal recessive inheritance. Blisters are present shortly after birth and may involve any skin surface. Scars form and cause contraction. Formation of a clawhand and/or mitten-like hand are common. Nails are dystrophic or absent. The larynx, pharynx, and esophagus may be involved. Oral bullae and scarring may result in diminished oral opening, ankyloglossia, tongue atrophy, loss of buccal and vestibular sulci, and perioral stricture. Teeth have hypoplastic enamel, delayed eruption, and retention.

EB bullosa acquisita is a noninherited type that begins in adulthood. Blisters form in areas of trauma. Oral lesions have been reported but are rare.²⁷

EB is a disease that cannot be cured. The treatment is supportive and symptomatic and includes corticosteroids and antibiotics to fight secondary infections.⁵

Viral Infections

The majority of viral infections are subclinical and asymptomatic. We know of their existence because of the development of antibodies in the patients. Symptomatic viral vesicular and ulcerative diseases often have systemic manifestations of malaise, fever, tender lymphadenopathy, and lymphocytosis. They generally have an acute onset and a vesicular stage, with the exception of infectious mononucleosis. Multiple lesions are present.

The herpesvirus family consists of herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus, Epstein-Barr virus (EBV), and cytomegalovirus. Herpesviruses can assume a latent state in the patient. Cytomegalovirus is important in neonates and immunocompromised patients; it is not discussed further in this chapter.

HSV The primary infection with HSV may occur in seronegative patients of any age and results in acute herpetic gingivostomatitis. The patient experiences the abrupt onset of malaise, fever, and tender cervical lymphadenopathy. Multiple vesicles and ulcers can involve any oral mucosal surface and are accompanied by gingival swelling and erythema. The fluid-filled vesicles contain numerous virions and are infectious. The mouth can become extremely painful, resulting in difficulty eating and drinking (Figure 36-6).

After primary infection of the oral mucosa, HSVs travel centripetally along peripheral nerves to nerve cell bodies of the trigeminal ganglion. The viruses remain latent in the ganglion. Reactivation of the latent virus causes transport of viral

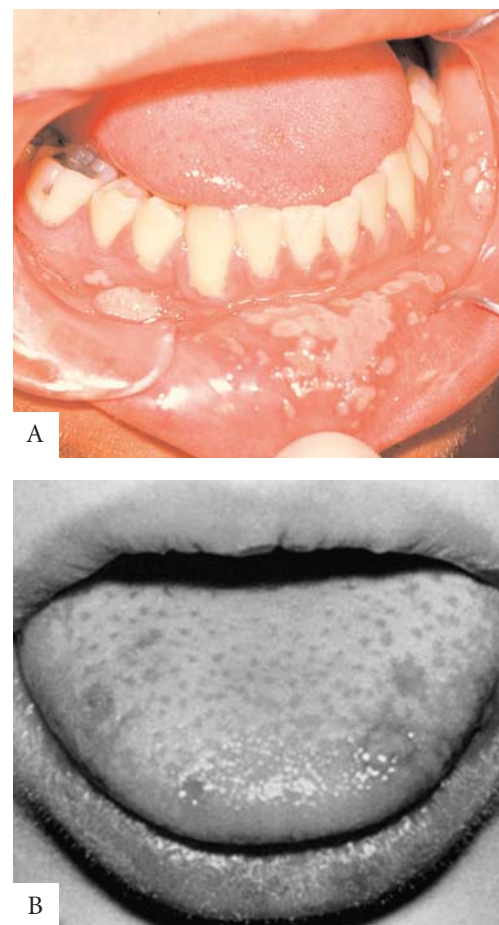

FIGURE 36-6 A and B, Primary herpetic gingivostomatitis. Acute-onset vesicles rupture almost immediately leaving 1 to 2 mm ulcers of keratinized and nonkeratinized oral mucosa.

genomes to the epithelial surface, where replication occurs. Recurrent lesions may result. The most important factors associated with recurrent lesions are ultraviolet radiation, immunosuppression, and local trauma. With regard to immunosuppression, patients with defects in cell-mediated immunity have herpes infections that are more frequent and severe.²⁸⁻³¹

The vesicles and ulcers of recurrent (secondary) herpes occur in small clusters on the lip, gingiva, and hard palate, and they tend to recur in the same location. The lesions are often preceded by a prodrome of tingling, pain, or numbness in the area. Systemic manifestations are not present.

Recurrent herpetic lesions are often confused with aphthous ulcers. They occur on the lip and keratinized oral mucosa, whereas aphthae occur on nonkeratinized mucosa. Recurrent herpetic lesions consist of multiple small ulcers in a group; aphthae consist of one to several larger widely distributed ulcers.

Herpes simplex infection of the finger is called herpetic whitlow (Figure 36-7). The primary infection presents abruptly with edema, erythema, vesicles, and pain in the infected finger, often accompanied by fever and axillary and epitrochlear lymphadenopathy. The lesions may recur.

FIGURE 36-7 Herpetic whitlow. Epidermal vesicles of the index finger.

Either HSV-1 or -2 can infect the oral mucosa and skin. HSV-1 has a predilection for oral mucosa and skin outside of the genital area, whereas HSV-2 prefers the genital region. Genital HSV-1 infections and oral HSV-2 infections have a greatly decreased incidence of recurrence.

The diagnosis of mucocutaneous herpes is usually apparent on the basis of clinical features, so biopsy is rarely done. Microscopic examination of a fluid-filled herpetic lesion demonstrates an intraepithelial vesicle with marked acantholysis. The epithelial cells have swollen homogeneous eosinophilic cytoplasm, known as ballooning degeneration, and one or multiple nuclei. Inclusion bodies may be seen in the nuclei of balloon cells as eosinophilic structures surrounded by a clear halo. Cytologic preparation of a fluid-filled vesicle can also demonstrate multinucleated epithelial cells, and the diagnosis can be augmented by using immunoperoxidase techniques to show antibodies to HSV (Figure 36-8). The diagnosis can also be confirmed by isolating the virus in tissue culture.

Lesions of primary and recurrent herpes resolve spontaneously in 10 to 14 days, and treatment is often unnecessary. When treatment is required, acyclovir is the current drug of choice. Acyclovir inhibits viral replication but has no effect on normal host cell function. However, it does not prevent or eliminate the latent viral state.

Acyclovir is very useful in the treatment of herpes simplex infections in immunocompromised patients. It has been reported to decrease the duration of viral shedding from lesions, the duration of pain, the time to scabbing, and the time to healing of lesions. It can reduce the number of recurrences, but infection can recur after the medication is discontinued.

Acyclovir can decrease viral shedding, time to healing, new lesion formation, and duration of symptoms in primary genital HSV infections. Primary oral herpes would be expected to respond in a similar

FIGURE 36-8 Herpes cytology. Cytologic preparation showing epithelial cells with enlarged nuclei resulting from viral replication ($\times 160$ original magnification; stained with Papanicolaou's stain).

manner, but the medication must be administered during the first 3 days.

The use of topical acyclovir in healthy patients with recurrent herpes labialis has given conflicting results. To have any effect, the medication must be used during the prodrome, or within the first few hours after onset of lesions. Topical sun-blocking agents are useful in reducing the frequency of recurrences of herpes labialis.

In summary, acyclovir is most helpful in the treatment of herpes simplex infections in immunocompromised patients and in patients with frequent or severe recurrences. It appears to have little value in healthy patients with infrequent minor recurrences of herpes labialis.

Varicella-Zoster Virus The primary infection with varicella-zoster virus causes varicella, or chickenpox. Varicella typically has mild systemic manifestations accompanied by papules, vesicles, and ulcers on the skin and mucosa. Successive crops of lesions begin on the trunk and move to the face and extremities. Lesions in various stages are present at the same time and are quite pruritic. Vesicles and ulcers resembling primary herpes sometimes occur on oral mucosa.

Therapeutic management for varicella is symptomatic and is aimed at reducing the pruritus. Antihistamines and topical lotions are helpful in this respect. Varicella typically has a mild clinical course, and complications are rare, except in neonates,

the elderly, and immunocompromised patients. Complications include bacterial infections of skin, encephalitis, Reye's syndrome, and pneumonia.

Infection with the varicella-zoster virus results in a latent state, as in herpes simplex. The recurrent disease is called herpes zoster, or shingles. Reactivation of varicella-zoster virus is not as common as with HSV, except in elderly or immunocompromised patients.

Zoster has a prodrome of pain, burning, or paresthesia, followed by grouped vesicles on an erythematous base. The lesions are unilateral and follow the distribution of a peripheral sensory nerve. They are most common on the trunk and in the distribution of the trigeminal nerve (Figure 36-9). Oral lesions can have a painful prodrome that mimics a toothache in some cases. The lesions in zoster resolve in several weeks, but severe pain in the nerve distribution (postherpetic neuralgia) can persist for weeks to months after the lesions have resolved. The prevalence and duration of pain increases with age. Involvement of the facial nerve can cause Bell's palsy.

The microscopic features of tissues infected with varicella-zoster are identical to those infected with herpes simplex.

Valacyclovir has been shown to be of some value in the treatment of zoster when the drug is started within the first few days of onset of infection.

FIGURE 36-9 *Herpes zoster. Acute-onset ulceration localized to left maxillary soft tissues.*

EBV The EBV causes infectious mononucleosis and is also associated with hairy leukoplakia, Burkitt's lymphoma, nasopharyngeal carcinoma, and lymphoblastic leukemia. EBV infects B lymphocytes and salivary glands and persists within these tissues for the lifetime of the host. The ability of EBV to reactivate depends on the competency of the cellular immune system.

Infants and children infected with EBV usually have an asymptomatic course, but about one-half of infected adolescents and adults develop acute infectious mononucleosis. The clinical features include malaise, fever, pharyngitis, and lymphadenopathy of cervical, axillary, and inguinal chains. Splenomegaly, hepatomegaly, and hepatitis with abnormal liver function tests may be present. Occasionally an erythematous skin rash is seen.

Ulcers may involve the oral mucosa, but a vesicular stage does not occur. The ulcers are secondary to decreased host resistance and appear after the systemic manifestations. Petechiae occur on the palate in about one-third of patients. The oropharynx is inflamed and may be ulcerated.

Laboratory features of acute infection include an increase in relative and absolute numbers of lymphocytes and monocytes exceeding 50%, with > 10% atypical lymphocytes in the peripheral blood. The atypical lymphocytes are called Downey cells, and they have indented or horseshoe-shaped nuclei and abundant basophilic foamy cytoplasm. The total leukocyte count is between 10,000 and 20,000 by the second or third week of the illness. Serologic findings include high titers of heterophil antibodies, which clump red blood cells of sheep. The antibodies may not appear until several weeks after the onset of signs and symptoms, and they decline during the ensuing 3 to 6 months.

Involved lymph nodes microscopically show reactive lymphadenitis. Lymphoid nodules in the inner cortex are hyperplastic. The germinal centers are markedly enlarged and contain macrophages with

nuclear debris and numerous mitoses. Sometimes very large cells with multilobed nuclei and prominent nucleoli resemble Reed-Sternberg cells of Hodgkin's disease.³²

There have been reports of a chronic fatigue syndrome associated with EBV. Patients describe this as a flulike illness with muscle aches, pharyngitis, tender lymphadenopathy, low-grade fever, and persistent severe fatigue. Elevated titers of immunoglobulin G (IgG) antibodies to viral capsid or early antigens of EBV are present.

Treatment of infectious mononucleosis is supportive. The acute disease usually resolves within 2 to 4 weeks. Splenic rupture is one of the few fatal complications of the disease, but it is extremely rare.

Group A Coxsackievirus The two most important group A coxsackievirus infections involving the oral cavity are herpangina and hand, foot, and mouth disease. Herpangina begins with fever, pharyngitis, and anorexia. Vesicles and ulcers occur primarily on the soft palate, uvula, and anterior tonsillar pillar. The disease resolves in several days and requires only symptomatic treatment.

Hand, foot, and mouth disease has a prodrome of fever, malaise, and headache, followed by macules and vesicles on the palms and soles. Vesicles and ulcers can be located anywhere in the oral cavity. Treatment is symptomatic, and the disease resolves within several weeks.

Measles Although a vaccine for measles exists, outbreaks of the disease still occur, primarily on college campuses. Measles begins with high fever, conjunctivitis, photophobia, cough, and nasal discharge. Leukopenia is common during this prodromal phase. Red vesicles with white centers (Koplik's spots) appear on the buccal mucosa, followed in several days by an erythematous maculopapular skin rash. The rash first appears on the face and then spreads to the trunk and extremities.³¹

Microscopic examination of the oral mucosal vesicles reveals epithelial necrosis, intercellular edema, cytoplasmic and nuclear inclusions, and multinucleated epithelial giant cells. Lymph nodes and tonsils show lymphoid hyperplasia and giant cells (Warthin-Finkeldey cells).

Therapeutic management for measles is symptomatic. It is usually a self-limited disease but may have a number of serious complications, including croup, bacterial pneumonia, otitis media, and encephalitis.

Rubella Rubella (German measles) is a mild infectious disease, but it can cause serious fetal malformations when it occurs in pregnant women. The prodrome consists of malaise, fever, mild conjunctivitis, and lymphadenopathy. Oral vesicles and ulcers may be present, but they are not distinctive. A maculopapular skin rash begins on the face and spreads downward to the trunk and extremities. It usually lasts for about 3 days. Arthralgia may involve wrists, fingers, and knees. Rubella may be completely asymptomatic or consist of lymphadenopathy without the rash.^{33,34}

Congenital rubella syndrome usually results from maternal infection during the first trimester of pregnancy. The classic parts of the syndrome include cardiac malformations of patent ductus arteriosus, interventricular septal defect, or pulmonary stenosis; eye lesions of cataracts, chorioretinitis, and microphthalmia; mental retardation; and deafness.

Rubella is usually a benign disease requiring only symptomatic treatment. A live attenuated vaccine is effective, but it should not be given to pregnant women or to those who may become pregnant within 2 months of vaccination.

HIV HIV infects and destroys helper T lymphocytes, resulting in profound immunosuppression that predisposes to opportunistic infections and malignant tumors.

HIV is transmitted by sexual intercourse, through contact with blood or blood products, and perinatally. It is found in saliva, but transmission by saliva is unlikely.

The clinical spectrum of HIV infection includes an acute viral syndrome with malaise, fever, and lymphadenopathy; an asymptomatic carrier state in which there are circulating antibodies to HIV, and a wasting syndrome. Neurologic disorders are common and range from subtle memory loss to dementia. Numerous opportunistic infections, both fatal and nonfatal, and malignant neoplasms are a characteristic part of acquired immunodeficiency syndrome (AIDS). Many of these can be present in the oral cavity.³⁵

Oral Manifestations OPPORTUNISTIC INFECTIONS A common oral disease in HIV-infected patients is candidosis. Four clinical types of candidosis can be present in HIV patients. Pseudomembranous candidosis appears as white plaques that rub off, leaving an erythematous and/or bleeding base. Hyperplastic candidosis presents as white rough plaques that do not rub off. Erythematous candidosis is characterized by diffuse or localized patches of red mucosa. Angular cheilitis presents as cracks or fissures of the commissures, sometimes associated with white plaques. Candidosis in HIV infection responds to antimycotic medications, but it is chronic and recurrent.³⁶

Hairy leukoplakia consists of unilateral or bilateral white rough plaques that do not rub off, most commonly found on the lateral surface of the tongue. It is seen mainly in homosexual males but is also found in other HIV-risk groups. Deoxyribonucleic acid (DNA) hybridization demonstrates EBV in epithelial cells of the lesion. Hairy leukoplakia is pathognomonic of HIV infection and is highly predictive that the patient will develop AIDS.^{36,37}

Microscopically, hairy leukoplakia is a lesion of squamous epithelium demon-

strating hyper-keratosis, acanthosis, and swollen ballooning epithelial cells.

Hairy leukoplakia is usually an asymptomatic infection requiring no treatment. For those patients requiring treatment, acyclovir 200 mg tablets 12 times per day for 3 weeks has been used with some temporary success. In addition, cytology smears for candidosis should be performed and antifungal medication prescribed for patients with candidal organisms.

Herpes simplex and herpes zoster are more frequent and severe in HIV patients as are nonspecific aphthous-like ulcers. Prolonged postzoster neuralgia can be extremely painful. High-dose acyclovir can be useful in the treatment of either disease.^{38,39}

PERIODONTAL DISEASE A unique form of periodontal disease is present in many HIV patients. Clinical features include chronic gingival erythema, severe pain, soft tissue necrosis, and rapid destruction of alveolar bone and the periodontal attachment. Pocket formation is minimal or absent. The cause of HIV periodontitis may be an overgrowth of virulent organisms possessing tissue-damaging capabilities. This is probably a result of compromised immunity owing to HIV infection.

HIV periodontitis does not respond to conventional therapy alone. However, it does reportedly respond to twice-daily rinsing with chlorhexidine combined with conventional methods.⁴⁰

MALIGNANT NEOPLASMS The most common malignant neoplasms involving the oral cavity in HIV patients are Kaposi's sarcoma, non-Hodgkin's lymphoma, and squamous cell carcinoma. Most HIV patients with Kaposi's sarcoma have oral lesions, and these may be the first sign of the disease. The lesions are red, blue, or purple and may be flat or elevated. They are most common on the hard palate and gingiva. Treatment includes radiation therapy, laser surgery, and/or chemotherapy.⁴¹⁻⁴³

Non-Hodgkin's lymphoma of the oral cavity in HIV patients is characterized by

rapid growth, tendency to occur on the palate or alveolar ridge, and poor prognosis. Most of these lymphomas are of B-cell origin, and in situ hybridization techniques often reveal Epstein-Barr virus DNA in the tumor cells.

Other oral manifestations of HIV infection include salivary gland enlargement, xerostomia, and ulcerations similar to aphthous ulcers.³⁶

Autoimmune Diseases

Autoimmune diseases typically have a gradual onset and a chronic progressive course with exacerbations and remissions. Lymphadenopathy is rare.

It is important to perform an incisional biopsy to establish a definitive diagnosis. A gingival biopsy should be avoided, if possible, because nonspecific gingival inflammation makes microscopic diagnosis difficult. Topical or systemic corticosteroids usually control but do not cure autoimmune diseases.

Pemphigus Two types of pemphigus, vulgaris and vegetans, have oral manifestations. Pemphigus vulgaris is the most common and is characterized by flaccid bullae that quickly rupture forming painful ulcers. Large areas of skin and mucosa can be involved, causing serious problems with infection.

Oral mucosal lesions are almost always present, and they are the initial lesions in the majority of cases. Extensive areas of mucosa may be involved, making eating extremely painful and difficult. Rubbing or blowing air on clinically uninvolved mucosa creates a blister, a phenomenon called Nikolsky's sign. A Nikolsky's sign is most commonly associated with pemphigus vulgaris and benign mucous membrane pemphigoid, but it may also be present in bullous pemphigoid and lichen planus. In pemphigus vegetans the blisters have a rough warty surface.^{44, 45}

Pemphigus is caused by circulating autoantibodies directed against desmo-

somes of squamous epithelium. This results in loss of epithelial cell cohesion and formation of an intraepithelial blister in the lower spinous cell layer. The basal epithelial cells remain attached to the underlying connective tissue. Acantholytic epithelial cells floating in the vesicle are termed Tzanck cells. They have rounded cytoplasm and large hyperchromatic nuclei. Cytologic preparation made from an early blister and stained with Papanicolaou's stain can demonstrate Tzanck cells. A cytologic smear gives only a preliminary diagnosis and does not replace a biopsy.

Direct immunofluorescent studies, using the patient's own skin or mucosa, reveal in vivo bound IgG antibody in the intercellular spaces of the epithelium in almost all cases (Figure 36-10). IgA, IgM, and C3 are present less often. Indirect immunofluorescence tests for autoantibodies in the patient's serum. In pemphigus, circulating IgG antibodies can be demonstrated in the serum in most patients at some time during the course of the disease. Indirect immunofluorescence is not as sensitive as the direct technique. However, the titer of antibodies in the serum is often proportional to the severity of the disease.

Early diagnosis of pemphigus is important because it is a serious disease requiring aggressive treatment with corticosteroids. It is often fatal if not treated. Even with treatment, 10 to 15% of patients die owing to the effects of corticosteroids.

Cicatricial Pemphigoid In cicatricial pemphigoid (benign mucous membrane pemphigoid [BMMP]), autoantibodies are formed against components in the epithelial basement membrane. This results in painful vesicles and ulcers that may heal with scarring. BMMP has a marked predilection for females and adults past middle age.⁴⁶

BMMP initially involves oral mucosa in almost all cases. The lesions consist of erythema, vesicles, and ulcers, most commonly involving the gingiva. Because the

FIGURE 36-10 Pemphigus antibodies. Immunoglobulin G antibodies revealed via immunofluorescence in stratum spinosum ($\times 160$ original magnification).

epithelium becomes detached from the connective tissue, BMMP is sometimes called chronic desquamative gingivitis, a nonspecific clinical description that can be applied, less commonly, to pemphigus and lichen planus (Figure 36-11). BMMP can also involve conjunctiva; nasal, pharyngeal, esophageal, and vaginal mucosa; and skin. Scarring and adhesion between the bulbar and palpebral conjunctivae (symblepharon) causes visual impairment.

The microscopic features of BMMP include subepithelial vesicle formation and nonspecific inflammatory infiltrate in the connective tissue (Figure 36-12). Direct immunofluorescence reveals linear

FIGURE 36-11 Cicatricial pemphigoid. A Nikolsky's sign caused by an air syringe directed at marginal gingiva.

continuous deposits of IgG and C3 along the basement membrane zone. Circulating IgG antibodies against the basement membrane zone are present in low titer and in only a minority of cases.

Topical and/or systemic corticosteroids usually control the disease. The most serious aspect of BMMP is conjunctival scarring, which can lead to blindness.⁴⁷⁻⁵²

Bullous Pemphigoid Bullous pemphigoid (BP) and BMMP have similar causes and microscopic features but a different distribution of lesions. The skin in all patients with BP demonstrates large thick-walled bullae, but oral mucosal lesions are less common.

Direct immunofluorescent findings are identical in BMMP and BP. Indirect immunofluorescence reveals circulating IgG antibodies against the basement membrane in the vast majority of BP patients but only rarely in patients with BMMP. There appears to be no correlation between antibody titer and disease severity in BP.^{47,52}

Lupus Erythematosus Lupus erythematosus is an autoimmune disease in which autoantibodies form to a wide variety of tissues including skin and oral mucosa. The autoantibodies can be directed against the cell's nuclear material (antinuclear antibodies [ANA]) or cytoplasmic antigens.^{53,54}

FIGURE 36-12 *Cicatricial pemphigoid. Uniform separation of epithelium from underlying connective tissue at the level of the basement membrane (×60 original magnification; stained with hematoxylin and eosin).*

Discoid lupus erythematosus (DLE) is a skin disease that most commonly involves the face, scalp, and ears. The skin lesions appear as erythematous patches, often scaly and hyperpigmented. Older lesions may have atrophic scarring centrally and hyperkeratosis at the periphery.

Oral lesions of DLE are uncommon in the absence of skin lesions. They characteristically show central erythema with white spots and a border zone of white striae surrounded by telangiectases. Less typical oral lesions can resemble lichen planus or hyperkeratosis.

Systemic lupus erythematosus (SLE) is a chronic multisystem disease most common in young women between the ages of 15 and 40 years. Arthritis is typically present, often at the onset. Central nervous system manifestations include seizures and psychoses. The leading cause of death is renal disease, leading to destruction of glomeruli and hypertension. Other manifestations include vasculitis, Raynaud's phenomenon, pleurisy, and pericarditis.

Numerous laboratory abnormalities may be present in SLE. The most important include elevated titers of antibody to native DNA, positive LE cell preparation, persistent false-positive serologic test for syphilis, anemia, leukopenia, thrombocytopenia, proteinuria > 0.5 g/d, and cellular casts in the urine.

The classic skin lesion of SLE is an erythematous rash located on sun-exposed surfaces such as the malar eminences. The oral lesions are similar to those of DLE. Oral ulceration is a well-known manifestation of SLE. Oral candidiasis secondary to corticosteroid therapy is common in SLE.

Certain medications have been reported to cause lupus-like reactions. The most common of these include procainamide, hydralazine, phenytoin, penicillamine, methyl dopa, trimethadione, primidone, thiouracil, and carbamazepine. Systemic involvement is less common with the drug-induced syndrome, and the signs

and symptoms usually resolve when the drug is withdrawn.

The microscopic appearance of lupus is variable. The epithelium is hyperkeratotic and shows alternating areas of atrophy and hyperplasia. The lamina propria is edematous and has dense perivascular and deep inflammatory infiltrates. Periodic acid-Schiff stain demonstrates deposits subjacent to the epithelium and thickening of blood vessel walls.

Direct immunofluorescence on oral lesions reveals deposits of Ig and C3 in the basement membrane zone of the epithelium in the majority of cases of DLE and SLE.

Therapeutic management of oral lesions of lupus includes topical and/or systemic corticosteroids and antimycotic medications as necessary for candidiasis. DLE has a good prognosis. The prognosis for SLE depends upon the extent of systemic involvement of the disease.

Idiopathic Vesiculoulcerative Diseases

Idiopathic diseases have causes that are unknown or poorly understood. They do not have clinical characteristics common to the entire class, and they must be considered individually when formulating a clinical differential diagnosis.

Aphthous Ulcers Aphthous ulcers are common painful lesions that have periodic recurrences. Most patients have only a single ulcer during a given episode, although occasionally two or three ulcers may be present (Figure 36-13). Vesicles do not occur. Unlike recurrent herpes, aphthous ulcers are found on nonkeratinized oral mucosal surfaces. They have an acute onset, and each ulcer heals spontaneously without scarring in 10 to 14 days. There are no systemic manifestations and usually no lymphadenopathy.⁵⁵⁻⁶¹

Major aphthae, also known as peradenitis mucosa necrotica recurrens, or Sutton's disease, is characterized by multiple large mucosal ulcers. A patient has at

FIGURE 36-13 *Aphthous stomatitis. Well-circumscribed nonindurated ulcer of the ventral glossal mucosa.*

least one ulcer present all the time. The ulcers may take up to 6 weeks to heal, and healing is accompanied by scarring.

Behçet's syndrome is a systemic disease that can affect most organ systems. The most common lesions are recurrent oral aphthous ulcers, genital ulcers, skin lesions, and eye lesions. The skin lesions consist of erythema nodosum-like eruptions and thrombophlebitis. The eye may be affected by recurrent iritis, uveitis, and retinitis, which can lead to blindness. Other less common problems include arthritis, ileal and colonic ulcers, aneurysms, arterial and venous occlusion, and a variety of central nervous system diseases.

Aphthous ulcers have been associated with a number of factors, but the cause is unclear. Aphthae do not appear to be caused by deficiencies in serum vitamin B₁₂, red blood cell folate, iron, or total iron-binding capacity, or malabsorption enteropathies. An allergic response to certain foods such as walnuts, strawberries, and tomatoes does not appear to be important.

Genetic factors are significant as the frequency of human leukocyte DR7 antigen is significantly increased in aphthae patients, and aphthae are more common in related persons. Women commonly state that the ulcers appear with the onset of menstruation, supporting the role of endocrine factors.

The microscopic features of aphthous ulcers are those of any nonspecific ulcer

and are not diagnostic. The history and clinical findings determine the diagnosis.

The goal of therapeutic management is to decrease the inflammatory response; topical corticosteroids accomplish this for most patients. Patients with major aphthae usually require systemic corticosteroids.

Lichen Planus Lichen planus is a chronic disease of skin and mucosa. Skin lesions are often extremely pruritic and appear as violet-colored flat-topped papules and plaques with a shiny surface. The lesions are most commonly located on the volar surface of the wrists, anterior surface of the legs, and penis.

Oral lesions of lichen planus are most common in adults > 40 years. The lesions have several forms. The reticular form presents as a network of lacy white lines called Wickham's striae (Figure 36-14). The plaque form appears as white homogenous plaques. The white lesions in both forms are nonpainful, rough to palpation, and do not rub off. The atrophic form consists of erythematous mucosa plus a reticular keratotic pattern along the periphery. The erosive form combines ulcerations with atrophic features (Figures 36-15 and 36-16). The atrophic and erosive forms are typically symptomatic. Occasionally, vesicles are seen, which quickly rupture to form painful ulcers. Ulcers and erosions can involve the attached gingiva producing a

FIGURE 36-14 *Lichen planus. Hyperkeratotic striations of the buccal mucosa.*

FIGURE 36-15 *A and B, Lichen planus. Hyperkeratotic striations, erythema, and ulceration of lateroventral glossal mucosa.*

desquamative gingivitis pattern in 25% of patients. Candidosis is another common finding in patients with lichen planus. Oral lesions of lichen planus are multifocal and can involve any mucosal surface. The most common locations are the buccal mucosa, followed by gingiva and the tongue. One-fifth of patients with oral lesions have skin lesions.⁶²⁻⁶⁸

Drugs can cause lichenoid reactions of skin and mucosa that are clinically similar

FIGURE 36-16 *Lichen planus. Dorsal tongue lichen planus often characterized by hyperkeratotic plaques rather than striations.*

to lichen planus. The reactions resolve when the drug is discontinued. The most commonly implicated drugs include methyl dopa, amiphenazole, chloroquine, hydroxychloroquine, quinacrine, chlorpropamide, tolbutamide, tetracycline, chlorothiazide, practolol, dapsone, furosemide, phenothiazines, quinidine, triprolidine, para-aminosalicylic acid, arsenicals, bismuth, gold salts, and mercury. Lichenoid reactions also occur during the chronic phase of graft-versus-host disease following bone marrow transplantations.

Lichen planus is considered a disease of the cellular immune system involving T lymphocytes, Langerhans' cells, and macrophages. The Langerhans' cells and macrophages process antigens and present the antigenic material to T lymphocytes. The lymphocytes proliferate and become cytotoxic for basal cells of the squamous epithelium. A similar immune mechanism has been reported in graft-versus-host disease and erythema multiforme.

The microscopic features of lichen planus are variable, and clinical features are important in establishing the diagnosis. The primary microscopic features include hyperkeratosis and a band-like inflammatory infiltrate, consisting primarily of lymphocytes, subjacent to the epithelium (Figure 36-17). The epithelium-connective tissue interface is obscured owing to liquefaction degeneration of the epithelial basal cell layer and/or infiltration with lymphocytes. An eosinophilic band may be seen between the inflammatory infiltrate and the epithelium. The spinous cell layer is often hyperplastic. Colloid or Civatte bodies, representing necrotic epithelial cells, are occasionally seen as eosinophilic bodies in the lower layers of the epithelium.

Direct immunofluorescence reveals fibrinogen deposition in the basement membrane zone in almost all cases, and less commonly in colloid bodies and walls of blood vessels.

Lichen planus is a chronic or recurrent disease that only rarely undergoes spontaneous remission. The goal of treatment is control of symptoms. Asymptomatic lesions require no treatment, whereas symptomatic cases are usually controlled with topical and/or systemic corticosteroids. In one study of 570 patients with oral lichen planus, 63% experienced improvement and 29% experienced complete remission while maintained on corticosteroids.⁶⁹ Antifungal medication is necessary if candidosis is present.

It appears that oral carcinoma occurs in lichen planus patients at a slightly higher rate than in the general population. However, the frequency of malignant transformation is unknown, and the classification of lichen planus as a premalignant lesion does not appear justified. Periodic recall examinations are necessary.

Erythema Multiforme Erythema multiforme (EM) can involve skin and oral mucosa independently or simultaneously. It has traditionally been described as acute and self-limited, requiring an average of 3 weeks for resolution. Some patients have a variable pattern of recurrence. In other patients EM has a chronic course.

The cause of EM is unknown, although it appears to be some type of immune dysfunction. It may be related to immune complexes deposited in walls of blood vessels in the dermis or submucosa. In about half the cases EM appears to be triggered by infections or drugs. The most common infections reported include herpes simplex viruses, tuberculosis, and histoplasmosis. The most frequently implicated drugs are sulfonamides, barbiturates, phenylbutazone, oxy-phenbutazone, phenazone, penicillins, chlorpropamide, phenytoin, and carbamazepine.

The skin lesions of EM include macules, papules, vesicles, and bullae. The most characteristic lesion, known as the iris or target lesion, appears as a central vesicle surrounded by erythematous and

skin-colored rings. The lesions are symmetrically distributed, most commonly on the extremities and face.

One-fourth to one-half of patients with skin lesions have oral lesions (Figure 36-18). Ulcers are present, most commonly on the lips, buccal mucosa, and tongue, as well as erythematous mucosa. The oral lesions vary from mild to so severe that patients cannot speak or eat. The lesions may be accompanied by headache, fever, and malaise.^{70,71}

Stevens-Johnson syndrome is a severe form of EM with more serious systemic manifestations. Extensive skin lesions, conjunctivitis, and oral and genital mucosal lesions are present. The oral lesions often begin as vesicles, which rupture forming painful ulcers. Lesions on the labial mucosa may have a bloody crust.

Toxic epidermal necrolysis is an even more serious form of EM characterized by large flaccid bullae and sloughing of the epidermis in large sheets. Oral lesions may be prominent, especially on the buccal

FIGURE 36-17 Lichen planus. Focal hyperkeratosis, basal cell liquefaction degeneration, and a superficial infiltration of lymphocytes ($\times 60$ original magnification; stained with hematoxylin and eosin).

FIGURE 36-18 *Erythema multiforme*. Acute-onset ulcerative mucositis involving palatal, buccal, gingival, and labial mucosa.

mucosa. Toxic epidermal necrolysis is usually caused by drugs. The patient is acutely ill, and the disease is often fatal.

The microscopic features of EM are not diagnostic. The epithelium demonstrates edema and necrosis of keratinocytes. The connective tissue contains perivascular infiltrates of lymphocytes, plasma cells, and macrophages. Immunofluorescence reveals deposits of IgM and C3 in the vascular walls, suggesting immune complex deposition is important in the pathogenesis.

Treatment may not be necessary for mild forms of EM, which have a good prognosis, although they may be recurrent. More serious types respond well to corticosteroids; however, Stevens-Johnson syndrome is occasionally fatal.

Head and Neck Skin Cancer

Michael F. Zide, DMD

Yan Trokel, MD, DDS

Skin cancer is the most common cancer afflicting mankind. In the United States alone, an estimated 1 million new lesions are diagnosed each year.¹ Skin cancer may be grouped into two subsets: nonmelanoma skin cancer (NMSC) and melanoma. NMSC comprises 95% of all skin cancers. Melanoma, of which 1 to 8% occurs in the head and neck, fills the remaining 5%.²⁻⁴

Even with this low incidence, melanoma is responsible for about 75% of skin cancer-related deaths. The overall mortality for NMSC is relatively low, with an estimated 5-year survival rate of 95%.^{5,6} Regardless, NMSC may be locally aggressive, leading to significant morbidity, disfigurement, loss of function, and high health care costs.⁷ This chapter focuses on the epidemiology, etiology, clinical characteristics, and management (medical and surgical) of these cutaneous malignancies.

Nonmelanoma Skin Cancer

Epidemiology

The NMSCs include basal cell carcinoma (BCC; 75% of NMSCs), squamous cell carcinoma (SCC; 20% of NMSCs), and a few rarer malignancies, such as Merkel cell tumor, dermatofibrosarcoma protuberans, and adnexal tumors.⁵ Incidence data for the United States should be interpreted skeptically as most NMSCs are treated in outpatient clinics or private offices and are not routinely reported to cancer reg-

istries.³ Reported yearly skin cancer rates are approximately 2 in 1,000 in the continental United States, 1 in 100 on the island of Kauai, and > 2 in 100 in Australia.⁸

Epidemiologic studies demonstrate a positive correlation between ultraviolet (UV) radiation exposure and the incidence of NMSC. NMSC is predominantly a Caucasian disease ($\geq 98\%$) but does occur in Blacks and Hispanics.³ The risk of developing NMSC increases the closer one lives to the equator, and the more one's outdoor activities increase the concentration of sun exposure through reflection.^{8,9} Examples of the latter include work around snow, water, cement, and roofing.

For all races 75% of NMSCs appear on body areas most chronically exposed to sunlight, such as the head, face, neck, and dorsum of the hands.⁵ The incidence of BCC and SCC at early ages is comparable for men and women, but men > 45 years have a three times greater incidence of NMSC, specifically SCC.^{10,11} In men common sites are the ears and nose, whereas in women the nose and lower extremities are most common.

The incidence of NMSC had been increasing for decades. The mortality rate, however, has recently leveled off and is now beginning to decrease, perhaps owing to public information programs.¹² Overall, NMSC has an excellent prognosis, but approximately 2,000 deaths occur annually, three-fourths of which are from metastatic SCC.^{13,14}

Etiology

The etiology of NMSC is multifactorial but can be broadly categorized into host-related and environmental causes. Host factors include an individual's phenotype, genetic syndromes, precursor lesions, and immunologic issues. Environmental variables include exposure to UV radiation, ionizing radiation, and chemicals.²

Host Factors Tanning is the body's defense mechanism against NMSC. One's ability to tan is directly related to the amount of melanin in the skin, which is genetically determined and cannot be influenced. Skin melanin determines a person's photosensitivity. The more melanin an individual has, the less damage UV radiation inflicts. Deleterious effects of UV radiation are attenuated by the stratum corneum via refraction, reflection, and direct absorption by melanin.

Fitzpatrick classified skin into six different groupings or types (Table 37-1).¹⁵ Each group was categorized based on the results of 30 minutes of direct sunlight to the skin in the northern hemisphere. The groups are based on the amount of melanin an individual possesses, inherent pigmentation, and sensitivity to UV light. For example, a person in type 1 is the classic freckle-faced light-eyed redhead who burns and never tans, a Celtic type. People in type 1 are highly susceptible to skin cancer but remarkably also heal from

Table 37-1 Fitzpatrick Skin Types*

Type	Characterization
1	Always burns easily, shows no immediate pigment darkening, and never tans
2	Always burns easily, shows trace immediate pigment darkening, tans minimally and with difficulty
3	Burns minimally, + immediate pigment darkening, tans gradually and uniformly (light brown)
4	Burns minimally, ++ immediate pigment darkening, tans well (moderate brown)
5	Rarely burns, +++ immediate pigment darkening, tans very well (dark brown)
6	Rarely burns, +++ immediate pigment darkening, tans profusely (black)

*Fitzpatrick skin phenotypes portray the outcomes of 30 min of sun exposure at midday in the northern hemisphere. + indicates a relative level of pigment darkening, with +++ being the highest. From Fitzpatrick TB.¹⁵

reconstruction wounds with the least perceptible scar. Type 2 is typified by the blond-haired blue-eyed person, a Scandinavian type. A type 3 person has olive skin and often dark eyes and occasionally burns but tans readily, a Mediterranean type. The descent of people in type 4 is Hispanic, type 5 is Arabic/Indian, and type 6 is African. Remarkably, as resistance to skin cancer increases, scarification becomes more obvious, often pigmentation or forming keloids.

Host factors contribute to a patient's ongoing risk of developing new cancers. A patient with a prior history of NMSC has a 36 to 52% 5-year risk of another cancer arising.^{16,17}

Syndromes Genetics plays a starring role in determining who gets skin cancer. Newer drugs to treat skin cancers, for example, 5% imiquimod cream applied topically three times per week, show great promise in treating skin cancers through inherent immune responses.¹⁸ There are several syndromes that predispose a person to skin cancer:

- Basal cell nevus syndrome (Gorlin's syndrome) is an autosomal dominant disorder characterized by multiple BCCs, odontogenic keratocysts, bifid ribs, scoliosis, brachymetacarpalism, palmar and plantar pits, calcification

of the falx cerebri, prominent supra-orbital ridges, and hypertelorism. The BCCs that are produced look like small nevi (Figure 37-1) but act just like common nodular BCC. Control with a CO₂ laser or curettage and electrodesiccation (C and E) is critical before enlargement destroys anatomic structures.^{19–21}

- Xeroderma pigmentosa is an autosomal recessive disorder resulting in defects in repair of deoxyribonucleic acid (DNA). UV radiation results in skin DNA damage; therefore, xeroderma pigmentosa is characterized by hypersensitivity to sun exposure and the development of multiple skin cancers. Children with this disorder must modify their lifestyles to function as night people. There are summer camps for them, at which activities begin at their wake-up time—sundown
- Albinism is an autosomal recessive disorder resulting in the absence of melanin with a subsequent increase in development of skin cancer, especially SCC
- Epidermodysplasia verruciformis is an autosomal recessive disorder. It results in the development of BCC from flat warts in sun-exposed areas in homozygous individuals infected with human papillomavirus type 3 or 5

Predisposing Lesions Several congenital and acquired lesions predispose to skin cancer:

- Nevus sebaceus of Jadassohn is a well-circumscribed slightly raised hairless lesion on the scalp or face present at birth that becomes verrucous and nodular during puberty. Approximately 10% of such lesions undergo malignant transformation to BCC (Figure 37-2)
- Actinic keratosis (AK), also known as solar or senile keratosis, is the most common precancerous lesion of the epidermis. AK is characterized by red, yellow, brown, or colorless macules or papules with scaly irregular surfaces, ranging in size from a few millimeters to several centimeters. Left untreated, there is a 10 to 13% risk of malignant transformation of AK to SCC (Figure 37-3); therefore, the American Academy of Dermatology recommends treatment.^{22–25} All suspicious lesions should undergo biopsy. Treatment options include chemical peel, laser, cryotherapy, C and E, tangential excision, or 5-fluorouracil (5-FU)
- Cutaneous horns are hard keratotic growths that protrude from the skin. Histologically they are advanced AK. Approximately 10% of these lesions have an underlying SCC²⁶

Immunologic Factors Immunosuppression predisposes a person to several types of cancers including skin cancer. Immunosuppression alters the immune surveillance mechanism that typically destroys potentially malignant cells.³ Human immunodeficiency virus infection, lymphoproliferative disease, occult malignancy, organ transplantation, and a variety of other medical conditions result in immunosuppression. Renal transplantation patients on long-term immunosuppressive therapy not only have a higher incidence of SCC and metastasis, their

FIGURE 37-1 This 30-year-old woman was first seen 10 years prior for treatment of multiple odontogenic keratocysts. A, The small pigmented dots are all incipient or growing basal cell skin cancers, which are slow growing and less aggressive than most cancers resulting from sun exposure. B, Intraoperatively. Excision is indicated for the larger lesions; curettage and electrodesiccation or CO₂ laser is used for incipient lesions. C, Improvement is noted after 1 month.

tumors appear years earlier than in any control population.^{27–30} However, most studies suggest that some other risk factor such as ionizing radiation or viral infection, along with a decreased immune system, is necessary for the development of these tumors in this subset of patients.^{3,31}

Environmental Factors Ionizing radiation, certain chemicals, and skin damage from the environment can also cause skin

FIGURE 37-2 Nevus sebaceus.

cancer. UV radiation has been fingered as the primary environmental culprit. There are three types of UV radiation: UVA (320–400 nm), UVB (290–320 nm), and UVC (200–280nm). UVB rays are the most carcinogenic, triggering skin cancer via photochemical damage to DNA, injury to DNA repair mechanisms, and partial suppression of cell-mediated immunity.^{5,32} UVA, originally thought to be harmless, is now known to enhance the effects of UVB as a cocarcinogen.³ Most UVC is filtered out by the ozone layer. As the ozone layer thins, as it has over Antarctica and parts of Australia, UVC enhances the development of skin cancer. The most common historic reports for NMSC as well as melanoma are two to three childhood blistering sunburns or ≥ 3 years of intense sun exposure.

A comment must be made about the two methods of tanning used in tanning parlors. The method using UVA light, in our estimation, enhances new skin cancers.³² We have seen skin cancers even in teenagers who have used tanning parlors. The “California” spray tan, a skin dye that lasts for 3 to 5 weeks, is harmless.

Chemicals such as arsenic, polycyclic aromatic hydrocarbons, and psoralens used in combination with UVA (a treat-

ment for psoriasis) have all been implicated as originators for NMSC.³³ Patients suffering from chronic inflammatory skin conditions, such as chronic radiation keratosis, burn scars, and ulcers, have an increased risk of developing skin cancers.

Prevention

Although a doctor may be capable of treating skin cancer effectively, the informed patient is the greatest resource against the development of new cancers. Preventive measures can be classified into three types: sunscreens, clothing, and education. Sun protection is rated by sun protection factor

FIGURE 37-3 Scaly actinic keratoses on the scalp, some of which have progressed to squamous cell carcinoma (*in situ*).

(SPF). The SPF is a ratio of the smallest amount of radiation needed to produce erythema on protected skin compared with the same degree of redness produced on unprotected skin. Sunscreens function either chemically or physically. Chemical sunscreens, such as para-aminobenzoic acid, benzophenones, and cinnamates, reduce UV skin penetration by absorbing solar rays. Physical sunscreens including titanium dioxide, zinc oxide, and kaolin, act as physical barriers.

It is now known that regular application of SPF 30 sunblock may reduce the evolution of new actinic keratoses by 50% after 3 years. Additionally, patients should be told that the application of SPF 30 does not abrogate the need for behavioral modification. For example, a farmer who applies SPF 30 at the start of the day will have the protection wear off shortly after a few hours of sweating.

Clothing may provide some protection, but a wet T-shirt has an SPF of 0 to 1.³³ High SPF clothing is available, but it is expensive and not very comfortable.

Basal Cell Carcinoma

Basal cell tumors originate from pluripotential cells in the epidermis and hair follicles. They are often slow growing and may take years to enlarge significantly.³³

Typically, patients with BCC are categorized as Fitzpatrick types 1 to 3 with a history of sun exposure. Eighty to 93% of the cancers occur on sun-exposed areas of the head and neck, and 26 to 30% occur on the nose.³⁴ BCCs can be divided into several subtypes: superficial, nodulo-ulcerative (or nodular), pigmented, infiltrative, micronodular, morphea-like, and basosquamous.

Superficial BCC represents approximately 10% of all BCCs (Figure 37-4).³⁵ They present as slightly elevated plaques or discrete macules that may be scaly. They can resemble eczema or fungal infections.

Nodulo-ulcerative BCC is the most common type, accounting for approxi-

mately 75% of all BCCs (see Figure 37-4).³⁵ Clinically, they present as well-defined translucent pearly nodules that are either round or oval with rolled borders and occasional ulcerations. Telangiectasias are commonly seen coursing through the lesion.

Pigmented BCCs range from brown to blue-black and can be mistaken for melanoma. Morphea-like BCCs present as firm plaques that are yellow or white with an ill-defined border. They can be quite large and do not show more than 1 to 2 mm elevation. This tumor is likely to have positive margins after excision.

Basosquamous carcinomas have both basal and squamous cell differentiations. They have a higher growth rate as well as a higher metastatic potential than do other BCCs.

Micronodular, infiltrative, and morphea-like BCCs are the more aggressive variants of BCC and together account for 10% of BCCs.⁷

Death from BCC is rare, with a rate of metastasis of 0.0028 to 0.1%.³⁶ Size, depth of invasion, and histologic type are important predictors for metastasis.¹⁰ Favored sites of metastasis include regional lymph nodes, liver, lung, bone, and skin. This rare metastasis is twice as common in males as in females.³⁶

Squamous Cell Carcinoma

SCC is the second most common skin cancer and accounts for 20% of all NMSC cases. SCC is a malignant proliferation of epidermal keratinocytes. Histologically SCC is composed of nests and cords of atypical squamous cells from the epidermis infiltrating into the dermis; it often contains keratin pearls. The lifetime risk of developing SCC is 4 to 14%, and the incidence has increased by 20% in the past decade alone.^{11,37,38}

Men with a fair complexion who are > 50 years and have had heavy sun exposure in the past several years typically get multiple actinic keratoses and SCC. SCC presents as a painless poorly defined ery-

thematous nodule with raised borders (Figure 37-5). Cutaneous horns or a hyperkeratotic crust with ulcerations may be present. The surrounding skin may reveal signs of chronic sun damage.

Unlike BCC, SCC may grow rapidly and metastasize. Metastasis is most common in lesions > 4 mm deep. The cumulative rate of metastasis is between 2 and 6%, and the 5-year survival rate for metastatic SCC is only 34%.^{11,38} Metastasis can occur either through the lymphatics or by hematogenous spread, with common sites being the regional lymph nodes, the lungs, and the liver. The location of the primary lesion influences the rate of recurrence and metastasis. SCCs occurring on the lip, ear, melolabial crease, and periorbital and preauricular areas have higher rates of recurrence and metastasis (10–14%).^{38,39}

The most common precursor for SCC is AK. The rate of transformation of AK to SCC is 1 in 1,000 per year.³⁹ Approximately 40% of people > 40 years have had at least one AK. Keratoacanthoma is a commonly confused with SCC, both clinically and histologically. Keratoacanthoma is a self-healing raised growth lesion with a central keratin-filled plug. It grows quickly but often spontaneously involutes after 2 to 6 months, leaving only a depressed white scar.

Bowen's disease is an in situ SCC presenting as a slow-growing erythematous scaling plaque with an irregular but sharp outline. These lesions rarely transform into invasive SCC.

SCC may evolve from chronically unhealed or unstable wounds, burn scars, or ulcers. These lesions, sometimes called Marjolin's ulcers, have a 20% higher rate of lymph node metastasis than does UV-induced SCC.^{40,41}

Histologic features, such as the degree of differentiation, depth of invasion, and perineural involvement, as well as tumor size are prognostic indicators that may dictate selection of width of the excisional margin. More differentiated lesions have a lower invasive tendency and, hence,

FIGURE 37-4 A, Superficial and nodulo-ulcerative basal cell carcinomas (confirmed with biopsy) are excised under local anesthesia in the office. The specimens are sent for permanent histopathology. B, Five days later, in the operating room, the defects are ready for reconstructive closure. C, Finger pressure (inherent elasticity) reveals that the largest defect is tight but amenable to advancement flap closure. D, The upper defect is presutured with 3-0 nylon (mechanical creep). E, Margins are excised (0.5–1 mm sharp squaring of the rounded edges with scraping of debris) and complex closures of the lower defects are accomplished. F, The nylon sutures are released and the tension-free upper defect is repaired with an advancement flap and M-plasty. G, Results at suture removal 1 week later.

a better prognosis. Larger tumors and those that invade deeply along tissue planes have a greater risk of recurrence and metastasis. Tumors > 2 cm have a twofold increase in recurrence rate and are three times more likely to metastasize. Tumors arising in scars or wounds are usually more aggressive and have a metastasis rate between 18 and 38%.⁷ With SCC the first shot at cure is crucial as recurrent SCCs have a metastatic rate of 24 to 45%; if they metastasize the 5-year survival rate is around 50%.⁷

Melanoma

Melanoma is a potentially deadly and aggressive neoplasm resulting from the malignant transformation of melanocytes. The incidence of melanoma is increasing faster than any other cancer. It is estimated that the frequency of melanoma will double every 10 to 15 years, and that > 40,000 new cases of melanoma will be diagnosed this year in the United States alone.^{7,41,42} Melanoma occurrence increases the closer one's residence is to the equator, with resi-

dents of Queensland, Australia, having the highest rate of melanoma, approaching 1 in 14.⁴³ An estimated 1 in 75 people develop melanoma in their lifetime, up from 1 in 150 persons in 1985.⁴⁴ Melanoma accounts for over three times more deaths than the combined fatalities from all other skin malignancies.⁴⁵

Risk Factors

People in Fitzpatrick groups 1 and 2 are the most susceptible to melanoma. The role of UV is not precisely known for

FIGURE 37-5 A, This 60-year-old has confirmed squamous cell cancer on his nasal tip (and basal cell cancers elsewhere). B, Five days after excision of the cancers, with permanent histology assuring margin clearance, the patient undergoes Doppler ultrasonography in preparation to identify the location of the axial vessel for a paramedian forehead flap. C, The flap is designed on the right supratrochlear vessels. D, The lower recipient site has been trimmed sharply, and the pink vascular flap is ready for inset. E, The flap in place. F, The sutured flap revascularizes for 3 weeks. At this time, it may be thinned again or divided and inset according to topographic principles. G, Two months postoperatively, the results of surgery are inconspicuous.

melanoma, but lots of freckles and a history of three or more blistering sunburns, the use of a tanning bed, and having undergone psoralen plus UVA therapy have been implicated.^{43,46}

Several additional risk factors for melanoma have been identified. About 10% of patients with melanoma have a first-degree relative with the disease.⁴⁷ “Common moles,” also known as acquired melanocytic nevi, can be a risk factor. Individuals with > 100 of these moles

have a tenfold risk of developing melanoma.^{4,48} When combined with a family history of melanoma, dysplastic nevi (atypical moles), which are present in approximately 10% of the population, represent a significantly increased risk of developing melanoma. Congenital (black hairy) nevi have a 4% lifetime risk of developing into melanomas.⁴³ Lentigo maligna, or melanotic freckle of Hutchinson, is a precursor in situ lesion that becomes malignant in approximately 5%

of cases (Figure 37-6). Thirty percent of melanomas arise from preexisting lesions, whereas 70% arise de novo.

Clinical and Histologic Description

The mnemonic ABCD is useful in categorizing the characteristics of melanomas: *asymmetry*, *border irregularity*, *color changes or variation*, *diameter of lesion* (< or > 6 mm). The practitioner should not place the patient under

FIGURE 37-6 A, This 65-year-old man has a lentigo maligna on his cheek and a basal cell cancer on his nose. B and C, After margin clearance by permanent histology (7 d later), the cheek defect and the nasal defect are each repaired with a rotational flap and back cut. D, An excellent esthetic result is evident.

casual observation (ie, not perform a biopsy) just because these common indicators might be absent. Approximately 40% of board-certified dermatologists and 50%+ of other clinicians do not identify melanoma correctly by clinical intuition alone. Other suspicious factors include the color pink in a dark lesion and persistent itching.

Melanoma in situ is an intraepithelial lesion that can progress to an invasive lesion. When it is still in the epithelium, it is described as being in a horizontal growth phase, but when it invades dermis and approximates blood vessels, it is in a vertical growth phase and thickens. Hence, deeper melanomas are more deadly. Histopathologically, malignant melanoma presents as a proliferation of atypical melanocytes. The tumor originates at the epidermal-dermal junction. The cells then invade upward into the epidermis or extend downward into the dermis.

Melanomas are categorized into four main clinical and histologic subtypes: superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral-lentiginous melanoma. Superficial spreading melanoma accounts for 70% of all melanomas. Clinically superficial spreading melanoma is a flat or slightly elevated dark lesion with asymmetric

borders; it can be present for up to 5 years prior to invasion of the dermis.

Nodular melanoma is the second most common variant, accounting for 15 to 30% of melanomas. It appears as a raised black, brown, blue, or red nodule, perhaps with ulcerations, bleeding, or crusting. It may look just like a BCC, but contrary to BCC, the lesion grows rapidly over a few months. Around 5% of nodular melanomas lack pigmentation and are pinkish “amelanotic” melanomas. Nodular melanomas are thicker and metastasize rapidly.

Lentigo maligna melanoma comprises 4 to 10% of melanomas. It arises in sun-exposed areas and occurs in the elderly.

Acral-lentiginous melanoma accounts for 2 to 8% of all melanomas in Caucasians but is the most common type in African Americans, Asians, and Hispanics. Clinically, they present as pigmented lesions with irregular borders. Papules and nodules are frequently seen within the lesion.

Biopsy is the only fail-safe method to prove or disprove melanoma. If melanoma is suspected, incisional and excisional biopsies are much more diagnostic and prognostic than is a shave biopsy. Regardless, if a shave biopsy is performed and melanoma returns as the diagnosis, the

next step is to obtain a full-thickness specimen (via punch or incisional biopsy) to ascertain the diagnosis and confirm true depth. Neither incisional nor excisional biopsy disseminates tumor.

Incisional biopsy should be reserved for lesions > 2 cm or those located at anatomically restricted areas (eg, eyelids, ears). The biopsy should be at the most raised site or the darkest area of the lesion (Figure 37-7). Full-thickness excisional biopsy with a 2 mm margin is the preferred method for lesions < 2 cm.

Once the diagnosis has been established, melanoma is staged either by measuring the tumor depth from the granular cell layer of the epidermis to the farthest depth of tumor invasion (Breslow classification) or by determining the anatomic level of invasion (Clark classification). Melanomas measuring < 0.76 mm have a 5-year survival rate of > 93%, whereas lesions > 4 mm thick have a 5-year survival rate of < 50%.^{49,50} Melanomas with ulceration or histologically high mitosis rates predictably worsen prognoses. Discovery of locoregional or distant metastasis lowers 5-year survival to 40% or 5%, respectively.⁵¹ The most frequent sites of melanoma metastasis include the skin, lymph nodes, lung, liver, brain, bone, and gastrointestinal tract. On the other hand, the presence of a

FIGURE 37-7 Large multicolored pigmented lesions should undergo biopsy with a full-thickness incision at the darkest area.

great number of tumor-infiltrating lymphocytes and a lack of vascular invasion improve survival prognosis.⁷

Controversy exists regarding the value of elective lymph node dissection (ELND), although it is well accepted that there is no benefit to ELND performed concurrently with primary tumor resection. Our current management protocol is not to suggest ELND or sentinel node biopsy for lesions measuring < 1 mm or > 4 mm. Intermediate depth tumors (1–4 mm) are referred for sentinel node biopsy based on studies suggesting that it increases the 5-year survival rate by 10% (ie, from 35 to 45%) (Tables 37-2 and 37-3).⁵²

Management of NMSC Lesions

Regardless of the obvious appearance of some cancers, a biopsy should be performed for histologic confirmation and

Table 37-3 Melanoma: Biopsy Strategies		
Tumor Thickness	Margin Excision	Lymph Node Dissection?
Lentigo maligna, in situ	5 mm–1.0 cm	No
Melanoma < 1.00 mm	1 cm	No
Melanoma 1.01–4.00 mm	2 cm	Possible sentinel lymph node dissection 1.0–4.0 mm
Melanoma > 4.01 mm	2–3 cm	For diagnostic purposes

typing. The histologic characteristics influence clinical behavior, recurrence, and metastatic potential. Determination of margin size for tumor clearance should be based on a compilation of all available information.

Biopsy techniques are personal. Any technique that delivers adequate histologic material for diagnosis is acceptable. Shave biopsy with a scalpel or curved razor blade is simple. Shave biopsy leaves a 5 to 6 mm saucer-shaped defect, removing epidermis and some dermis. The only drawback to shave biopsy is that histologic and prognostic features may be deeper than the shave. Thus, a shave biopsy might potentially be so superficial as to limit pathologic differentiation between an in situ versus an invasive lesion. Shave biopsy is contraindicated in potential melanomas. A “pseudoshave” biopsy might be performed with a curetted specimen prior to electrodesiccation.

Punch biopsy garners a full-thickness specimen. The punch has a circular cutting edge, which is pushed and turned into a suspicious lesion just like a hole saw. The punched out defect may be sutured or may heal secondarily. Punch biopsies, although

worthwhile for melanoma in which depth discernment is critical, may be too aggressive for a superficial lesion as the punch may force the tumor deeper into tissue.

Incisional and excisional biopsies are well known to surgeons. Deciding whether to use one revolves around whether the diagnosis is obvious (eg, a dysplastic nevus in a patient with a history of them), the tumor size, and whether a small biopsy will influence the excision clearance margin. When indicated, excisional biopsies should be oriented with sutures or dye for tumor margin clearance.

Fine-needle aspiration (FNA) may also be used to obtain specimens for histologic examination of deep material. FNA is worthwhile to differentiate a dermal cyst from a parotid tumor in the periauricular region. With FNA the pathologist aspirates tissue with a 23- or 25-gauge needle and stains and fixes the material on a glass slide.

Once the pathologic diagnosis of skin cancer is confirmed, the surgeon plans for tumor destruction by correlating tumor characteristics with patient’s age, skin history, medical history, social history, and cosmetic expectations. Treatment options

Table 37-2 Melanoma: Survival Rates			
Breslow Classification	Clark Classification	Tumor Thickness (mm)	5-Year Survival (%)
No evidence of primary tumor	I. Tumor in epidermis (noninvasive)	< 0.76	99
Thickness > 0.76 mm	II. Melanoma cells in papillary dermis	0.76–1.5	94
Thickness 0.76–1.5 mm	III. Melanoma cells fill papillary dermis	1.51–2.25	83
Thickness 1.51–3.0 mm	IV. Melanoma cells in reticular dermis	2.26–3.0	72
Thickness > 3.0 mm	V. Melanoma cells in subcutaneous fat	> 3.0	< 50

might include liquid nitrogen cryotherapy, standard excision, Mohs' micrographic surgery (MMS), radiation, C and E, topical chemotherapy, laser ablation, photodynamic therapy, interferon, and retinoids. We review most of these options below.

Standard Excision

Commonly, skin cancers are excised and assessed for margin clearance. Exceptions include some AKs and some superficial SCCs or BCCs, which may be treated by other modalities.⁵² Excision may be done under local anesthesia or in the outpatient surgery setting. Tables 37-4 and 37-5 outline acceptable margins for clearing most lesions.

The lesion and indicated margin for clearance is outlined with a marking pen. Local anesthesia with epinephrine does not affect pathologic margin assessment but may reduce the surgeon's ability to monitor vascularity to an adjacent random flap. Clearer delineation of tumor margins may be enhanced with adjunctive procedures for melanoma, BCC, and AK. In the case of melanoma, subcutaneous extension should be viewed with a Wood's light. In the cases of BCC and AK, pre-excision curettage delineates tumor margins more accurately. Some BCCs, morphea-like and infiltrative, may not be as curable as soft tumors, but the BCCs that are curable have a 25% higher chance of being cleared with the first excision than if excised without curettage (Figure 37-8).⁵²

Ideally, specimens should be examined histologically on the entire lateral and deep margin. Circumstances may reduce the likelihood of this beneficial extensive eval-

Table 37-5 Margin Control for Basal Cell Cancers

<i>Tumor Description</i>	<i>Margin Control</i>
5 mm or less	2 mm
5 mm–1 cm	3–4 mm
1–2 cm	5–7 mm
> 2 cm, morphea-like, or unusual pathologic behavior	7–10 mm margin or Mohs' micrographic surgery or delayed reconstruction following permanent histology
Unusual pathologic behavior, recurrent tumors, tumors on lips, ear, nose, medial canthus, eyelids	Mohs' micrographic surgery or delayed reconstruction following permanent histology

uation. For example, frozen histologic evaluations (while the patient is anesthetized in the operating room) are often three to four representative "loaf-of-bread" slices. You can imagine how much time would be consumed should the pathologist section and examine a large tumor in toto.² To abrogate the inherent limitations of frozen sections, many surgeons routinely delay reconstruction until after all margins are cleared by permanent histology, or send the patient to a specialist in MMS.

Permanent histology after office excision and subsequent delayed reconstruction provides benefits to surgeon and patient alike. Office excision allows the patient to visualize the extent of the defect and to add input into personal reconstructive desires and expectations. The surgeon has the option to research effective methods of reconstruction away from the operating room and to subsequently go to the operating room with a plan; the patient will know prior to the surgery exactly where the scars will be located. Delayed reconstruction has been proven beneficial for patients receiving skin grafts as the

delay eliminates the potential for hematoma and may allow buildup of a higher granulation base.

MMS offers the same "delayed" opportunity. The patient's entire tumor is resected prior to reconstruction, which may be performed on an elective basis often up to a week later. The only surgical difference between immediate (within 24 h) and delayed reconstruction (≥ 48 h) is that defects reconstructed later are circumferentially excised for 0.5 to 1 mm to expose a new distinct margin. Debris may also need to be curetted from the base. Regardless, this step-by-step delayed technique is almost painless and does not foster infection (Figure 37-9).^{51,53} Antibiotics are not necessary.

Mohs' Micrographic Surgery

MMS is based on two principles: (1) most tumors spread by contiguous growth and (2) all tumor cells must be excised for cure. Dermatologist Frederic E. Mohs, MD, originated his method in the 1930s and published results in 1941. Mohs' technique evaluates the entire circumference and deep margins after frozen sections. Unlike the representative breadloaf method, in which the pathologist might suggest further removal of an entire positive superior margin of the tumor, Mohs' technique pinpoints the actual location of tumor extension. Identified tumor extensions are re-excised

Table 37-4 Margin Control for Squamous Cell Cancers

<i>Tumor Description</i>	<i>Margin Control</i>

Lesion on upper lips, eyelids, nose, ears, etc.	Consider Mohs' micrographic surgery

FIGURE 37-8 A, This 50-year-old man has what appears to be an imposing basal cell cancer. B, Curettage of the soft tumor allows easy visualization and control of peripheral and deep margins. C, Seven days after resection and margin clearance by permanent histology, a cervicofacial-type flap above the superficial musculoaponeurotic system is planned. D, The flap is advanced superiorly. E, Hairlines and sideburns are realigned. F, At 2 weeks the results are very esthetic.

and rescrutinized until the tumor is totally removed. Hence, MMS is more predictable for total cure and tissue sparing as well.^{54–56}

Over the years we have noted certain limitations to Mohs' technique, such as overconservative treatment for some aggressive tumors. This deficiency, not inherent in the Mohs' technique, is proved by the fact that not all microscopic extensions are visible to the human eye; therefore, even tumors excised with Mohs' techniques may recur. As a result, we believe

that a large SCC of the scalp is better served with an aggressive non-Mohs' excision. Controversy exists as to whether Mohs' technique is justified for melanoma and dermatofibrosarcoma protuberans, for example.

For a 1 cm nodulo-ulcerative BCC, Mohs' technique proceeds as follows: the lesion is debulked with a curette and then excised with a 2 to 3 mm margin angled at 45° toward the center of the tumor. The specimen is anatomically oriented, subdivided into numbered color-coded sec-

tions, and mapped. Mapped segments are pressed flat on their freshly cut border, frozen, and sectioned so that the entire fresh border is visualized.

The cure rates for primary BCCs < 2 cm treated with MMS approach 99% (vs 90–95% by routine pathologic examination).^{56,57} Standard vertical breadloaf sections evaluate < 1% of the surgical margins. Recurrent BCC cure rates range from 94 to 96% with MMS versus 85% with other modalities.^{56,57} For primary SCC, MMS boasts a cure

FIGURE 37-9 A, In the office the surgeon, donning nonsterile gloves, curettes (with a dermatologic curette, pictured) this biopsy-proven nasal basal cell cancer. The patient is under local anesthesia. B, Curettage reveals that the tumor is small and superficial. C, After tagging the tumor for margin identification (always short 12:00 superior and long left or lateral), the wound is dressed very specifically. (If there is any potential bleeding, a piece of surgicel may be placed at the base). D, Bacitracin is swabbed only within the defect. E, Mastisol or tincture of benzoin is wiped peripherally. F, A nonadherent dressing covers the wound base; the overdressing has an absorbent piece of gauze within a conforming mesh bandage, which is placed over the wound. One or 2 days later, in the office the surgeon, donning nonsterile gloves, removes the dressing. This procedure is performed without the use of anesthesia. The area is cleaned with 50:50 peroxide and water, and the patient is instructed how to redress the wound daily after a shower (which includes washing out the defect with mild soap and water). G, The patient dresses the wound with bacitracin, a nonadhesive dressing, and tape only. No scabs should form. In this case the histology analysis returned declaring that the superior tumor margin was within one high-power field. H, On the day of surgery, a small amount of tissue is planned for excision superiorly (and peripherally to square the margins), and a bilobed flap is planned as the defect is < 1.5 cm in diameter. I, The excisions have been made. J, During the closure the entire nasal dorsum is undermined submuscularly and supraperichondrally. K, The second lobe of the flap is oriented perpendicular to the alar rim to avoid lifting the rim. L, After 2 months the result is excellent.

rate from 94 to 99% as opposed to 90% for non-Mohs' techniques.^{39,54,58} Recurrent SCC cure rates with MMS approach 90% as opposed to 76% for other treatment modalities.⁵⁴

Under these circumstances MMS is indicated for the treatment of recurrent BCC, histologically difficult BCC (ie, micronodular, infiltrative, and morphealike), and BCCs in which conservation of tissue is critical (eg, on the nose, lip, ear). For SCC, MMS might be indicated for lower lip cancer, some poorly differentiated SCCs, and areas where maximum tissue preservation is essential.⁷

Radiation Therapy

Radiation therapy (RT) has been mentioned for treatment of skin malignancies for almost a century, but currently it plays a role as an adjunctive or salvage measure, rarely a curative role. The curative advantage of radiation is preservation of normal tissue next to the irradiation site. RT might therefore be considered for the eyelid, lip, nose, and ear. Unfortunately, RT conveys some unwanted potential side effects: cutaneous erythema, necrosis, hypopigmentation, telangiectasia, atrophy, fibrosis, hair loss, delayed healing, and risk of the development of future NMSCs when administered to younger patients.⁵⁹

RT of tumors < 2 mm has a cure rate of 90% and 85 to 95% for BCC and SCC, respectively.^{60,61} However, larger lesions have a much lower success rate. For melanoma, local recurrence rates of up to 50% have been reported.⁶² Thus, RT for melanoma is only a viable option for medically compromised patients who cannot withstand surgery or for patients who refuse surgery.

Cryosurgery

Cryosurgery destroys skin cancers and some adjacent tissue by freezing. Cryosurgery cure rates for AK, BCC, SCC, and lentigo maligna range from 94 to

99%.^{63,64} Liquid nitrogen may be sprayed on the lesion directly or through a cryoprobe. Rapid freezing of the treated skin occurs as heat is transferred from the skin to the probe. Intracellular ice crystals form, and cell membranes disrupt as the temperature is lowered to -50°C to -60°C . When thawing occurs electrolytes recrystallize, resulting in vascular stasis and local alterations in the microcirculation, thus producing further tissue damage.^{2,65}

Most doctors freeze lesions plus a 4 to 6 mm margin to account for tumor extension. Freeze-thaw cycles may be repeated for maximal effect. Healing occurs by secondary intention, with a flat hypopigmented scar.

The side effects of cryosurgery include pain, erythema, edema, blistering, exudation, and scarring. This technique is inexpensive, and there are no costs for pathology. Hence, a lesion chosen for cryotherapy should be relatively small and well demarcated.

Curettage and Electrodesiccation

C and E is a cost-effective but technique-dependent therapy of NMSC. The lesion area is cleaned with alcohol, outlined with a provisional margin by a skin marker, and anesthetized. The lesion is curetted aggressively with the skin tensed, after which electrodesiccation (hyfrecation) for hemostasis and adjacent tissue kill occurs. This cycle may be repeated three to five times.

The major advantage to C and E is expedience, fostering treatment of multiple lesions within a single visit. Disadvantages include prolonged healing, often weeks depending on size and care, hypopigmentation, and possibly hypertrophic scar. Material from curettage may be sent for initial pathology, but margin control after C and E is not possible (unless curettage is used as a precursor to excisional pathology).

The clinician's experience and the tumor's anatomic site and size are prognostic factors limiting success following

C and E. BCCs < 5 mm have an 8.5% recurrence rate after C and E by an experienced clinician.⁶⁶ Lesions of the nose, ear, and perioral and periocular areas may recur at a rate of 16%.⁶⁶ This rate soars to 26% for lesions > 20 mm.⁶⁶ Therapeutic C and E is therefore contraindicated for larger lesions, poorly differentiated SCC, or melanoma.

Topical Chemotherapy

Topical 5-FU or 5% imiquimod medically eliminates surface lesions. Retinoids are occasionally used concurrently. 5-FU is a thymine analog that interferes with DNA synthesis causing cell death by acting as an inhibitor of thymidylate synthase. Imiquimod induces production of interferon- α and messenger ribonucleic acid cytokines. Application of 5-FU is recommended twice daily for 2 to 3 weeks for superficial AK and for 3 to 6 weeks for more diffuse worrisome lesions. Imiquimod is applied only three times per week but currently is much more expensive than 5-FU. Cure rates with 5-FU and imiquimod range from 92% for SCC in situ to 95% for superficial BCC and AK.^{2,67}

Patients need to be warned that there is an ugly inflammatory scabby reaction during topical therapy, but the cosmetic outcome is usually very good as long as compliance is nurtured.

Lasers

The CO₂ laser focuses a beam of light with a wavelength of 10,600 nm. Laser light is absorbed by water and nonselectively vaporizes the skin. The CO₂ laser can be used as a cutting instrument (in the focused mode) to excise or ablate lesions (in a defocused mode) such as multiple AKs, superficial BCC, and SCC. We have found its greatest benefit in ablation of superficial AK and superficial SCC, both on the skin and lower lips. Presurgical skin preparation with retinoids may foster more rapid healing. We have not prescribed preoperative antibiotics or antivirals for small

localized areas but continue to do so when large areas of the face are treated.

Photodynamic Therapy

Photodynamic therapy is not widely accepted for skin cancer therapy but has been applied to lung, breast, colon, and bladder cancers. Aminolevulinic acid is wiped on a lesion; it is metabolized in cancer cells to produce porphyrins, which act as photosensitizers. Four to 6 hours later, the area is irradiated with visible light from a laser or noncoherent light source. Reactive O₂ species are generated within the cells producing cell death.⁶⁸

Cure rates for photodynamic therapy for AKs, superficial SCC, and BCC are reported to be > 90% in some studies, but tumors thicker than 2 mm are photoresistant.⁶⁹

Interferons

Interferons are cytokines that may effect cell growth and differentiation and accent immune responses and antiviral activity. Intralesional injection of interferon- α can attain cure rates of > 80% for superficial and nodulo-ulcerative BCC.^{70,71}

Retinoids

Retinoids are vitamin A derivatives that are crucial for control of cell growth, differentiation, and apoptosis. Topical retinoids are somewhat effective against AKs but much less so against even superficial BCCs and SCCs. Application of retinoids as a skin cancer preventative is a long-term proposition as the effects of the drug plateau at around 6 months and reverse shortly after discontinuation.

Retinoids do appear to act synergistically with 5-FU and may be applied in an exfoliation regimen. Noted complaints include dryness and flaking, minor side effects compared with the clinical effects of 5-FU.

Applied Skin Anatomy

The skin is composed of two layers: the superficial epidermis and, beneath it, the

dermis. The epidermis is composed of four distinct layers. From deep to superficial, they are as follows: basal cell (stratum basale), prickle cell (stratum spinosum), granular cell (stratum granulosum), and keratin (stratum corneum). Cells from the stratum basale divide and migrate upward toward the stratum corneum. The dynamic epidermis turns over and exfoliates every 30 days. This is why buried epithelium from a cyst might continue to produce sebaceous keratin.

The epidermis contains four cell types: keratinocytes, Langerhans' cells, melanocytes, and Merkel cells. Keratinocytes constitute 80% of the epidermal cell makeup.

Langerhans' cells are antigen-presenting cells, which capture and process antigens and present them to skin-specific lymphocytes. Aging and significant sun exposure both lessen the total number of Langerhans' cells. This is one partial explanation for the increase of skin neoplasms in the elderly.⁷²

Melanocytes are of neural crest origin and are found in the basal layer. Melanocytes produce melanin, which, in turn, protects the nucleus of the keratinocyte from UV radiation. Although numbers of melanocytes are constant for all individuals, the activity of the melanocytes differs from one race to the next. For example, melanocyte activity in darkly pigmented skin is higher than in light-colored skin. As with Langerhans' cells, numbers of melanocytes decrease with age, another explanation for more skin cancers developing as we get older.^{73,74} Merkel cells, found in the epidermis and dermis, have an unclear function.

The dermis, situated between the epidermis and subcutaneous fat, adheres to the epidermis at the basement membrane. The basement membrane mechanically supports the epidermis and acts as a mechanical barrier. The two dermal layers are the superficial papillary dermis and a deeper thicker reticular layer. The dermis is com-

posed of collagen, elastic tissue, and ground substance. Collagen decreases by 1% a year throughout adulthood.⁷⁵ Topical tretinoin inhibits dermal collagenase, thus slowing the degradation rate of collagen.^{76,77}

Elastic fibers in the dermis provide skin with recoil. With aging, elastic fibers decrease causing skin laxity, bags, and jowls. Chronic sun exposure thickens elastic fibers, and clumps form in the papillary layer. Chemical peels, dermabrasion, and laser resurfacing can remove some of these clumps.⁷⁸

The dermal ground substance is made up of glycosaminoglycans, hyaluronic acid, chondroitin 4-sulfate, fibronectin, and dermatan sulfate. These constituents hydrate the skin and maintain tensile elasticity.⁷⁸ The principle cell of the dermis is the fibroblast, whose functions include production of collagen, elastin, and ground substance. Fibroblasts enhance wound healing through contraction and production of scar.

Aging affects skin quality. Fine wrinkling, dermal atrophy, and a decrease in subdermal adipose tissue are aging phenomena. Epidermal regeneration may slow down by up to 50%, retarding secondary wound healing.⁷⁹ (Note: Isotretinoin retards epithelial regeneration chemically; hence, elective surgery should be limited on patients having used isotretinoin until the medication has been discontinued for 6–8 mo.) Natural collagen decreases in quality and quantity. Skin becomes more compact as the collagen rearranges itself into thick coarse bundles or loosely woven straight fibers. The dermal blood vessels may be collapsed, disorganized, or absent in the elderly, potentiating a greater risk for flap necrosis.^{21,80}

Skin has a rich nerve supply. In the epidermis the Merkel cell may provide touch perception. Meissner's corpuscles, located in the papillary dermis, provide fine touch sensation. Pacinian corpuscles, located in the deeper subcutaneous tissue, mediate deep pressure and vibratory

sensation. Autonomic efferent nerves innervate blood vessels and appendageal structures. Hair-bearing skin is commonly referred to as nonglabrous and smooth non-hair-bearing skin as glabrous. Skin conditions vary between individuals and from region to region with respect to mobility, color, scars, Fitzpatrick type, texture, thickness, and adnexal structures.⁸¹

The blood supply to the skin serves two functions: nutrition and thermal regulation. Two major routes of blood supply exist—musculocutaneous and septocutaneous arteries.⁸² The musculocutaneous system traverses the muscle and enters the subcutaneous tissue in a random pattern (the basis for random skin flaps). Random-pattern blood flow to the tip of the flap is via the interconnecting subdermal plexus. The superficial vascular plexus located in the reticular dermis provides the capillary loops in the dermal papillae. The deeper vascular plexus, or subdermal plexus, lies between the dermis and subcutaneous fat. A septocutaneous vessel travels through the septal fascia and courses parallel to the skin surface with an accompanying vein. Named septocutaneous vessels (eg, supratrochlear) provide an axially based flap with a rich blood supply. A large interconnecting vascular arcade exists between the systems.⁸³ Understanding the facial vascular network is crucial to creating flaps that survive.

Flaps and Grafts and Secondary Intention Healing

Definitions and Concepts The removal of any tumor leaves a defect. The hole created after tumor excision may be called the primary defect. The secondary defect is the wound created after tissue is transposed to close the primary defect. Every flap creates a potential secondary defect. Ideally, secondary defects should be easy to close, within relaxed skin tension lines (RSTLs), in areas of loose adjacent tissue, and within anatomic boundaries.⁸⁴

Options for defect repair include (1) primary closure, (2) local or distant flap, (3) graft, and (4) healing by secondary intention. Elasticity and movability are two inherent skin characteristics that enable relocation and, perhaps, primary closure. Elasticity is the ability of the skin to stretch. Skin in the cheek and neck is very elastic. Movability is not related to elasticity. Temple skin is less movable than cheek skin, and the scalp is relatively immobile.

Flaps move tissue, skin and subcutaneous from one area to another with an accompanying vascular supply. Flaps are cosmetic, use well-matched skin, and functionally protect underlying structures such as bone or cartilage, which may not have adequate blood supply to support a graft. Three types of “impure” flap movements are classically defined—advancement, rotation, and transposition—although some suggest there are only two types of movement—sliding and lifting.^{84–86} *Sliding* refers to stretching or mobilizing tissue from one site to another (advancement and rotation). *Lifting* tissue across a bridge of normal tissue to close a defect is similar to transposition.⁸⁴ All flaps (except free flaps) have some pivotal restraint, whether it be adjacent skin, subcutaneous tissue, or blood vessels.

Delay increases viability to a flap by enlarging and realigning the subdermal vasculature plexus. It is now known that skin flap reliability is based on “angiosome” units; therefore, wide and thin random flaps run out of blood supply in roughly the same location. Delay may augment survivability. Methods include raising and suturing tissue without disturbing the pedicle, and tissue expansion. Subsequently (9–12 d later), the flap is mobilized.^{84,87} The mechanisms that increase the blood flow with delay include the depletion of vasoconstricting substances, formation of vascular collaterals and reorientation of vascular channels, stimu-

lation of an inflammatory response, and release of vasodilating substances.

Esthetic flaps are not mere hole fillers. They are designed to complement natural esthetic units and facial borders. Defects that trespass multiple esthetic units are designed to reproduce these independent units. For example, a cheek tumor defect that encroaches on the nose might be reconstructed with different flaps and/or grafts for the cheek and nose.

Grafts are easy to position into recipient defects and are ideal for monitoring tumors. Grafts must be placed on a well-vascularized bed. Sometimes exposed bone should be allowed to build a granulation base before grafting. Grafts may be of full thickness or split thickness. Harvesting methods include punching, shaving with a dermatome, and excision. Graft donor sites are selected based on esthetic and tumor considerations. Ideally, grafts to the nose are well matched with preauricular skin, but any supraclavicular facial graft (from the blush area) matches the facial color better than does any torso or thigh graft.

Healing by secondary intention is a painless but time-consuming process. It is indicated for patients who do not want more surgery, who can accept or obtain the daily care, and who can accept a scarred result. Secondary healing can be used for small defects (< 1 cm) or for larger defects in areas where the resulting scar would be inconspicuous or tumor observation is critical.

Healing by secondary intention is similar to open-wound therapy. Following tumor excision and hemostasis, the wound is dressed with antibiotic ointment (eg, bacitracin and/or polymyxin B sulfate). The outer edges of the wound are coated with an adhesive (eg, adhesive bandage or tincture of benzoin). A nonadherent dressing is applied over the wound and a small rim of peripheral tissue. This is topped with a dry piece of gauze to absorb any blood, which is then covered with a

contour mesh tape. When the defect is atop bone, the raw bone may be covered with two layers of moisture-retaining wet gauze, but any method that abrogates desiccation is acceptable (Figure 37-10).

Three days later the dressing is removed and the wound inspected. Any oozing and crusting should be removed with a 50:50 peroxide and water solution. The wound is redressed in three layers—antibiotic ointment within the wound followed by a nonadherent dressing, which is then covered with mesh tape. The patient redresses the wound in this fashion on a daily basis to keep the area moist and free

of scabs. Areas amenable to secondary epithelialization include the scalp, the retroauricular area, and some concavities away from mobile apertures. Secondary epithelialization would be a poor choice around the mouth, for example, where retraction might distort the lips.

Three caveats regarding secondary healing are useful to keep in mind. First, scabs should not form. Scabs hinder epithelialization and harbor bacteria. Second, continuous application of antibiotic ointment can lead to allergic reactions and yeast infections. This is more common with ointments that contain neomycin

sulfate than with bacitracin. Alternatively, petrolatum can be substituted for the antibiotic ointment. Finally, some patients can be so incapacitated by their medical illnesses that they cannot dress their wounds. Home health care nursing can be enlisted to aid in their daily wound care.

Skin Biomechanics Skin is a heterogeneous material with unique mechanical properties. As skin is stretched, the randomly oriented collagen and elastic fibers are stretched in the direction of the applied force. This continues until all of the available collagen and elastic fibers are

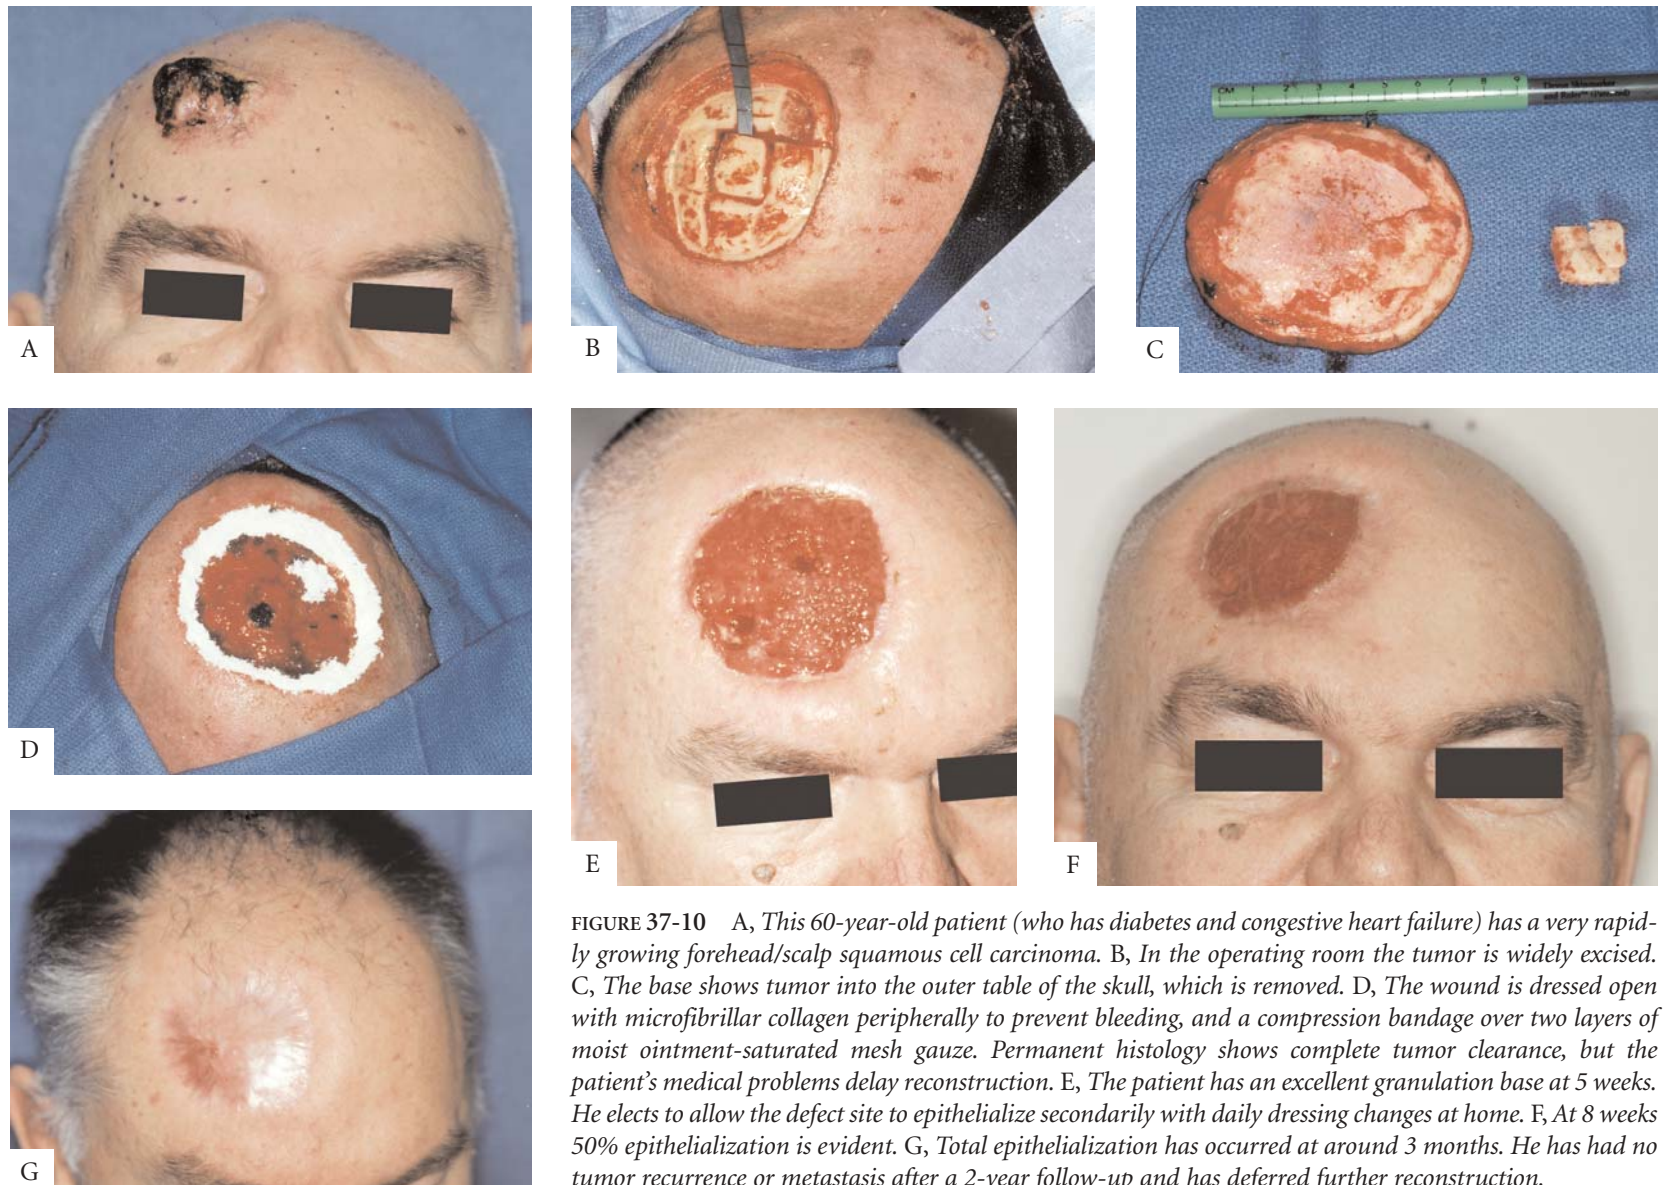

FIGURE 37-10 A, This 60-year-old patient (who has diabetes and congestive heart failure) has a very rapidly growing forehead/scalp squamous cell carcinoma. B, In the operating room the tumor is widely excised. C, The base shows tumor into the outer table of the skull, which is removed. D, The wound is dressed open with microfibrillar collagen peripherally to prevent bleeding, and a compression bandage over two layers of moist ointment-saturated mesh gauze. Permanent histology shows complete tumor clearance, but the patient's medical problems delay reconstruction. E, The patient has an excellent granulation base at 5 weeks. He elects to allow the defect site to epithelialize secondarily with daily dressing changes at home. F, At 8 weeks 50% epithelialization is evident. G, Total epithelialization has occurred at around 3 months. He has had no tumor recurrence or metastasis after a 2-year follow-up and has deferred further reconstruction.

recruited and no further lengthening occurs. After the maximum amount of stretch is reached, the skin may rupture. Permanent striae may scar the skin surface, as is often noted in pregnancy. Overstretching the skin collagen effaces the blood vessels under tension; thus, necrosis secondary to decreased perfusion to a distal flap may occur (Figure 37-11).⁸⁸

Skin tension exists in all directions on the face but is greatest along the RSTLs. Ideally, elective incisions should be placed parallel to the RSTLs. Incisions made perpendicular to RSTLs (or in the lines of maximum extensibility [LME]) gape and heal with more obtrusive scars.⁸⁹ The rhombic flap, once considered by many as the “workhorse” facial flap, has been used less over time because some of the final legs lie within the LME. Today flaps are more commonly designed with topographic units and RSTLs as primary considerations, rather than just to fill a hole.

Skin is elastic and stretches easily at low stress levels. This is related to the inherent extensibility of the skin. At higher forces skin may become viscoelastic,

that is, it can extend out a little more in spite of its thick state. This phenomenon is explicable through the two time-dependent characteristics: creep and stress relaxation.⁸⁸

Mechanical creep refers to the change in length that is seen when skin is held under a constant stress or force. The force that is exerted to stretch skin decreases with time.⁸⁸ The surgeon routinely notes this mechanism at work after he *tightly* sutures an avulsive forehead wound. Two days later the forehead is relaxed again. High stress loads therefore produce a degree of creep. The skin may not be totally relaxed for several months. Serial excision is a technique that harnesses the relaxation of skin over time. Wide defects may be closed sequentially over time.

Stress relaxation is the decrease in stress that occurs over time when skin is held under tension at a constant strain or is cyclically loaded.⁸⁸ It may be effected intraoperatively with the placement of a balloon under the skin or by scoring the scalp galea and pulling the skin. Additionally, there are skin stretchers that are made for this purpose (Figure 37-12).

Finally, *biologic creep* is a slow methodic stretching of skin, yielding brand new skin.⁸⁸ Skin expanders do just that (Figure 37-13).

Flap Undermining Safe flap closure of a defect is dependent on harnessing the inbred stretchable bendable nature of skin without exceeding the limits of stretch or blood supply. Some tissues can be stretched for centimeters without undermining occurring, whereas others must be separated from tethering subcutaneous tissues. On the other hand, a subcutaneous island flap, totally separated from the tether of skin, depends on the mobile vascular subcutaneous pedicle.

Undermining releases the vertical attachments between the dermis and subcutaneous planes, thereby reducing shearing forces and allowing the skin to slide and redrape in another position.⁷⁸ The mobilization benefits from undermining facial skin usually occur within the first 2 cm. Animal studies reveal that undermining beyond 4 cm produces little skin edge advance and possibly a more difficult stretch of tissue.^{90,91}

A correct undermining level provides the critical balance between mobility and blood supply. For example, simple random flaps, undermined in the superficial fat, are easy to raise on the cheek. Submuscular flaps maintain a robust blood supply to small relatively immobile nasal flaps.

Flap Designs *Advancement Flaps* An advancement flap is advanced linearly over a defect. It consists of a classic elliptic closure with adjacent undermining; there are no rotational or pivotal movements. Tissue elasticity provides adequate horizontal motion with a flat closure effected as Burow's triangles are removed from the ends. The length of the ellipse is three to four times the width of the defect.

Advancement flaps can be constructed with multiple modifications: simple,

FIGURE 37-11 This large basal cell cancer was excised (A) and closed with two flaps (B). The patient, a smoker, had excess tension placed on the lower flap, leading ultimately to almost 1 cm of tip necrosis.

FIGURE 37-12 A, This 95-year-old woman has a relatively small scalp defect. B, Finger pressure shows that significant tension is necessary to close it elliptically. C, After limited subgaleal undermining, two pins are placed subcutaneously. D, A skin stretcher (courtesy of Life Sciences Medical) is hooked onto the pins. Slow loading is applied for 30 minutes. E, After the end triangles are excised, the wound is stapled closed. F, The site after 2 months.

square, bilateral, Burow's triangle repositioning, and A- or O- to T-shaped designs.⁹² The experienced surgeon realizes that the tethering forces of advancing skin also constrict the size of the leading edge. Modifications are useful in specific instances. All flaps, including simple advancement flaps, presuppose that the surgeon can disguise, adjust, transpose, or eliminate “dog-ears” or excess tissue that gathers as tissue is transposed.

There are seven ways to deal with dog-ears^{93–96}:

1. Do nothing; this approach works well on the scalp as bunched up tissue lies down with time
2. Close opposite lines of uneven lengths by spreading out the problem—halving (Figure 37-14A)
3. Remove the excess to a hidden area—an end or middle triangle (Figure 37-14B)
4. Lengthen the incision. This eliminates bunching (Figure 37-14C)
5. Perform an M-plasty (sometimes called a T-plasty), which shortens the problem (Figure 37-14D)
6. Reverse the S loop and hide the excess elsewhere (Figure 37-14E)
7. Advance the dog-ear as a flap (subcutaneous “island”) or use it as a free graft (Figure 37-14 F; also see Figure 37-6)

Rotational Flaps Curvilinear rotation flaps rotate from a tethered pivot point. These flaps fill triangular defects. The length of the arc is dependent on many variables, such as existing laxity, the size of the defect, the location, and blood supply to the flap.^{85,97–101} Rotation flaps rarely fit

FIGURE 37-13 A, This 45-year-old heavy smoker had a squamous cell cancer removed from his midforehead and a basal cell cancer from the left temple. Direct advancement closure was impossible. B, After allowing some granulation tissue to form at the base, a split graft was placed on the midforehead. An 8×6 cm skin expander was placed laterally and expanded twice weekly for just over 2 months. C, The expanded rotation flap was mobilized to cover the midforehead defect. D, The result 1 month after closure. Note the well-healed direct closure of the right cheek defect and the depression of the left temple full-thickness skin graft.

perfected geometric schemes of success. Rather, the surgeon often finds himself adjusting to the specific variables of a given situation (Figure 37-15). There are two exceptions to this complexity that have been worked out fairly precisely:

1. The nasal bilobed flap of Zitelli has excellent results when applied toward lower or middle nasal defects of 1.5 cm or less.¹⁰² This occurs as long as the second lobe of the flap is perpendicular to the alar rim and the first lobe does not cross deep concavities such as the alar groove

2. The scalp rotation method of Ahuja fills defects of up to 3 cm with minimal adjustments¹⁰³

Advantages to rotational flaps include broad-based reliable vascularity, flexibility in design, and easy placement of scars into esthetic/cosmetic zones or RSTLs. A major advantage is that the flap can be rotated again should additional tissue need to be removed secondary to tumor concerns or should laxity be lacking.^{98,104}

Disadvantages to rotational flaps include the problems associated with any pivotal flap such as standing cutaneous

deformities and the need for larger flaps. Regardless, rotational flaps may be ideally designed to reconstruct medium to large defects of the cheek, neck, scalp, and forehead.

Transposition Flaps Transposition flaps transfer defined tissue along an arc of rotation, often over normal tissue, to repair a primary defect. Actual tissue movement may be rotational, linear, or both (Figure 37-16). Transposition flaps tend to be more confined than are rotation flaps, and design is critical for success. The design/location of the pivot point is the most important factor. After tissue is transposed, flap tensions should be diffused to prevent strangulation of tissue and distortion of adjacent structures. The regional differences in tissue mobility impact the geometry of the flap design, with the classic transposition being a rhombus.

The rhombic flap is an equilateral parallelogram with oblique angles. The (Limberg) rhombic flap, first described in 1963, was an equilateral rhombus with 60° and 120° internal angles.¹⁰⁵

According to the classic (Borges) design, eight potential rhombic flaps may close a defect. These flaps are constructed as umbrellas, drawn off the obtuse side of two potential parallelograms. These parallelograms each have two sides parallel to the LME. These LME are always perpendicular to RSTLs and run in the direction that tissue stretches most efficaciously.

The rhombic flap, whose short diagonal line parallels the LME and whose mobilization does not interfere with adjacent structures, is usually chosen for the rhombic transposition. The resulting tension vector in rhombic flaps lies 20° from the short diagonal in a loose tissue plane.

Dufourtmental, Webster, and others modified the classic rhombic design.¹⁰⁶ The Dufourtmental flap was designed to close rhombic defects with acute angles approximating 90° or a square defect. As

FIGURE 37-14 Six of the seven ways to deal with dog-ears (the seventh being to do nothing). A, Halving. Close opposite lines of uneven lengths by spreading out the problem. B, End or middle triangle. Remove the excess in a hidden area. C, Lengthen the incision. This eliminates bunching. D, M-plasty (sometimes called a T-plasty). This procedure shortens the problem. E, Reverse the S. Hide the excess elsewhere. F, Advance the dog-ear as a flap (subcutaneous island) or use it as a free graft (see also Figure 37-6). RSTL = relaxed skin tension lines.

FIGURE 37-15 A, This 70-year-old has an indiscreet temple basal cell cancer, which is removed by Mohs' micrographic surgery. B, Closure includes a large rotational scalp flap designed with the center of the arc of rotation at the 18-gauge needle position, and a temple advancement flap. C and D, The flaps are mobilized and stapled into position prior to final closure. E, The result is excellent at 1 month.

with the Limberg design, the peripheral lines were equal in length, but unlike the rhombic flap, the short diagonal differed in angle size. Dufourtmental designed two isosceles triangles situated base to base. Once the sides of the triangles were drawn, the short diagonal was extended, as was one of the adjacent sides. A third line bisecting these two lines creates the first flap. The cutback line was drawn paralleling the long diagonal completing the second flap. The Webster 30° flap allowed for easier closure by bisecting the 60° angle into two 30° angles via an M-plasty.

Here, the short diagonal had to be at least 110° to prevent puckering and to maintain flap viability.

Rhombic, banner, note flaps, and others have been modified to close circular defects over all areas of the face.

Axial Pattern Flaps Axial pattern flaps are based on named vessels in the head and neck. Classic designs include the Abbe (Figure 37-17) and Estlander flaps and the paramedian forehead flap.⁹⁷ A full description of these flaps is discussed in Chapter 38, "Local and Regional Flaps."

Skin Grafts Skin grafting involves the removal of donor skin (epidermis and varying levels of dermis, fat, or muscle) from one area to revascularize at another. The success of skin grafts is based on factors that affect angiogenesis and capillary ingrowth into the graft.

Recipient bed vascularity and intimate graft-host contact as well as overall host health or condition affect graft success. Wounds with a poor vascular supply may not support a graft or may need to be prepared before grafting. Cartilage base; irradiated tissue; fibrosis; and foreign, crushed, or nonviable tissue can compromise success. Additional procedures, such as bringing in vascular tissue from elsewhere, may be required to optimize the recipient bed prior to skin grafting.⁹⁸

Bed vascularity may be compromised by bleeding or cautery to arrest bleeding. Thus, there is an inherent benefit to delaying grafting or placing a pressure bolster bandage on top of the graft to prevent bleeding. We do not touch full-thickness graft bolsters for 6 or 7 days.

Mechanical shear forces may disrupt contact between the graft and recipient bed, promoting graft failure. Although this may be minimized with appropriate suturing techniques as well as the placement of dressings, the force of a hard shower can dislodge a graft and should be avoided.

Wound infections rarely jeopardize skin grafts in the head and neck. It is common for surgeons to confuse the dark eschar of a failing graft in a smoker with infection. Regardless, some local measures that decrease wound bacteria include saline dressings, sulfadiazine silver, mafenide acetate cream, acetic acid solutions, sodium hypochlorite solutions, and vinegar and water.

A patient's overall medical health can influence the success of skin grafting. Autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, hematologic disorders, diabetes mellitus,

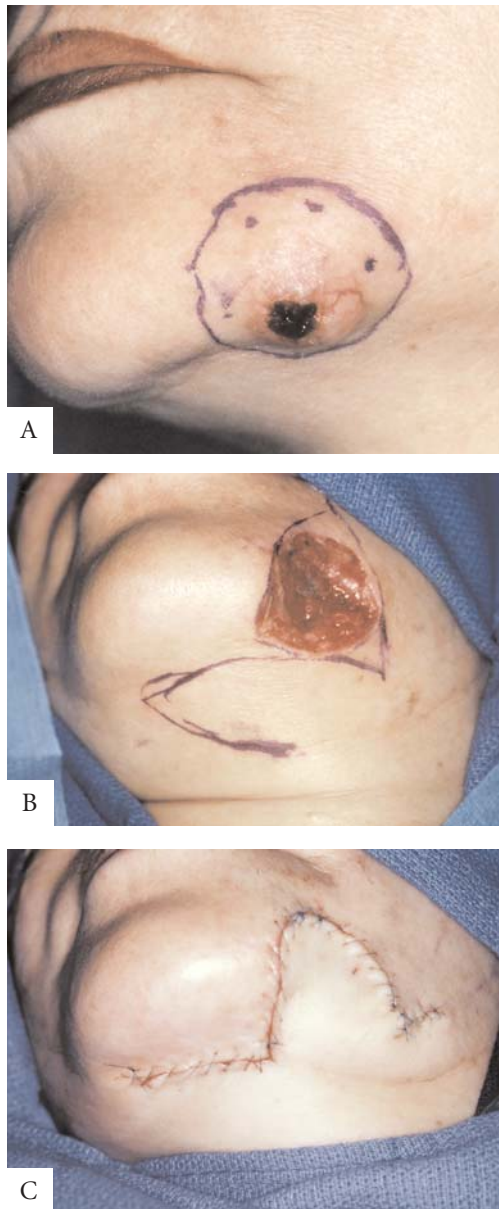

FIGURE 37-16 A, This 45-year-old woman has had a basal cell carcinoma for the past 3 years. B, It is repaired with a simple submental transposition flap. C, Perhaps the lateral submandibular bulkiness will need to be removed in the future, but the submental fat removal was highly esthetic.

poor nutrition, and smoking as well as medications such as corticosteroids and chemotherapeutic agents may compromise graft success.^{99–101}

Full-Thickness Skin Grafts Full-thickness skin grafts (FTSGs) are chosen when local or distant flaps are not feasible or when the FTSG would offer acceptable cosmesis

and function. Examples include the multi-operated face, upper nasal surface defects, nasal lining tissue, and medial canthal area. FTSGs resist contraction and may possess the texture and color of normal skin. In children FTSGs have the potential to grow.⁹⁸

The FTSG is preferred over the split-thickness skin graft (STSG) in areas where a wound contracture may lead to a functional deformity. An example is the lower eyelid, where wound contracture would result in ectropion. An excellent FTSG for this example would include upper eyelid skin and orbicularis oculi muscle, which has been shown to predictably revascularize.

Selection criteria for a head and neck FTSG directs the surgeon to carefully consider particulars of a variety of sites—the upper eyelid, post- or preauricular skin, and the lateral neck or supraclavicular region. For example, postauricular skin is photoprotected and has few adnexal structures, which may not be suitable for nasal defects. Preauricular skin grafts in males can lead to sideburn asymmetry. Supraclavicular and neck skin is thin and may be more photodamaged than the face. In addition, a supraclavicular scar may be a nuisance for women who wear clothing with low necklines.

The harvesting of most FTSGs involves cutting out a simple template of the defect (eg, from suture packaging) (Figure 37-18). Since an FTSG contracts by 10 to 15% after harvest, the donor graft pattern must be enlarged by around 20%.¹⁰² This contracture issue is critical in areas of mobility such as in the lower eyelid. Here, grafts should be enlarged by 150 to 200% vertically to avoid ectropion/contraction occurring.^{98,101}

The FTSG may be defatted with serrated scissors or by scraping with a blade. Defatting is complete when the shiny dermis is homogeneously exposed. FTSG should fit into a wound bed with maximum surface contact without any tenting.

Basting sutures may be used to affix the graft to the underlying bed to squeeze out dead space prior to peripheral suturing.^{98,103} Peripheral sutures are easier to insert when passed from the graft through the host skin with a tapered needle.

Any nonadherent (to the graft) bolster of cotton, gauze petrolatum dressing, or plastic, for example, secured a few millimeters outside the grafted tissue is acceptable. Some surgeons prefer to remove the bolster after 48 hours to inspect the surgical site

FIGURE 37-17 A, This 70-year-old man has a large basal cell cancer removed by Mohs' micrographic surgery. B, Subsequently a midline axially based Abbe flap is inserted. C, Three weeks later, the Abbe flap is divided and inset as an in-office procedure. The esthetic result 2 weeks later shows the flap is not exactly in the midline but simulates the philtral area effectively.

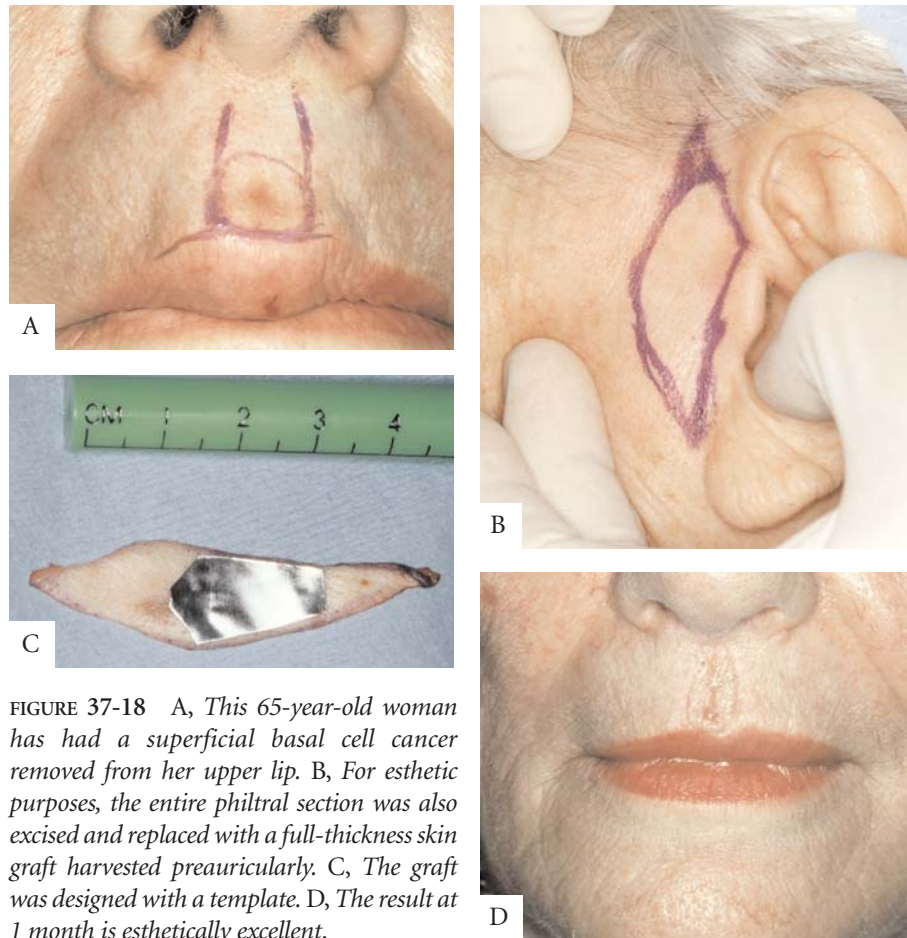

FIGURE 37-18 A, This 65-year-old woman has had a superficial basal cell cancer removed from her upper lip. B, For esthetic purposes, the entire philtral section was also excised and replaced with a full-thickness skin graft harvested preauricularly. C, The graft was designed with a template. D, The result at 1 month is esthetically excellent.

and then replace the bolster with a more conventional dressing.

FTSGs undergo an evolutionary sequence. Initially, a graft is white followed by a period of cyanosis or a bluish/violaceous hue. Subsequently there is a period of hyperemia or a red state, which fades over time until the graft assumes its normal color. If the graft fails, the entire epidermis turns black and sloughs off, followed by reepithelialization.⁹⁸ The necrotic graft acts as a biologic dressing, allowing healing to occur by secondary intention from the wound edges as well as from adnexal structures.

Split-Thickness Skin Grafts An STSG is defined as thin if its thickness measures 0.02 to 0.03 cm, medium from 0.03 to 0.046 cm, and thick from 0.046 to 0.076 cm. Thinner STSGs have improved survival rates compared with thicker ones because there is

greater exposure of the graft to the underlying vasculature, and less tissue is needed for revascularization. STSGs have a higher degree of contraction than do FTSGs and do not grow in children. Thin grafts afford less protection to the underlying tissues and do not withstand repeated trauma well. For example, an STSG may be chosen to cover a bare pericranium/skull after removal of a scalp tumor; subsequently, the patient may report breakdown sites or scabs from sleeping on the grafted sites.

STSGs are generally less pleasing cosmetically than are FTSGs and are employed for functional reconstruction (Figure 37-19).

STSGs are worthwhile for (1) wounds too large to repair with a local flap or an FTSG, (2) wounds requiring monitoring for tumor recurrence, or (3) temporary coverage of a wound prior to definitive

reconstruction. Contraindications include areas that might compromise functional or esthetic expectations.

STSG donor sites for facial reconstructions include the “blush zone” of the lateral neck and supraclavicular area and the scalp, owing to their similarity in color and texture. The hip, thigh, buttock, abdomen, torso, and inner aspect of the arm are also applicable at times.^{98,100,104}

There are varying types of dermatomes ranging from machine to manual. The Brown dermatome allows for precise modification of graft thickness. The graft dimensions should be at least 25% larger than the wound defect.⁹⁸ Other dermatomes include the Padgett, Davol-Simon, Castroviejo, Reese, and Padgett-Hood dermatomes and the Weck knife.

The sterile donor site is lubricated with mineral oil. Traction and countertraction are applied, and the dermatome is engaged and advanced with a slight downward and forward pressure. The donor site bleeds if it is cut in the correct plane. After pressure or thrombin control, a semipermeable occlusive dressing covers the donor site and is left in place for 1 week to 10 days. Semipermeable membrane dressings decrease the pain of the donor site and enhance wound healing by maintaining a moist environment.⁹⁷

Other dressing materials include Allevyn and Nobecutane spray. Allevyn is a hydrophilic polyurethane material that is highly absorbable and nonadherent. Its outer layer is waterproof and bacteria proof. The dressing is soft, absorbent, and comfortable for the patient. Nobecutane spray when applied on the wound forms a transparent plastic film. Nobecutane contains a modified acrylic resin in an organic solvent along with the bactericidal-fungicidal agent tetramethylthiuram disulfide. Brodovsky and colleagues showed that this spray is an effective temporary dressing that promotes rapid painless healing. The film is shed spontaneously with epidermal regeneration.¹⁰⁷

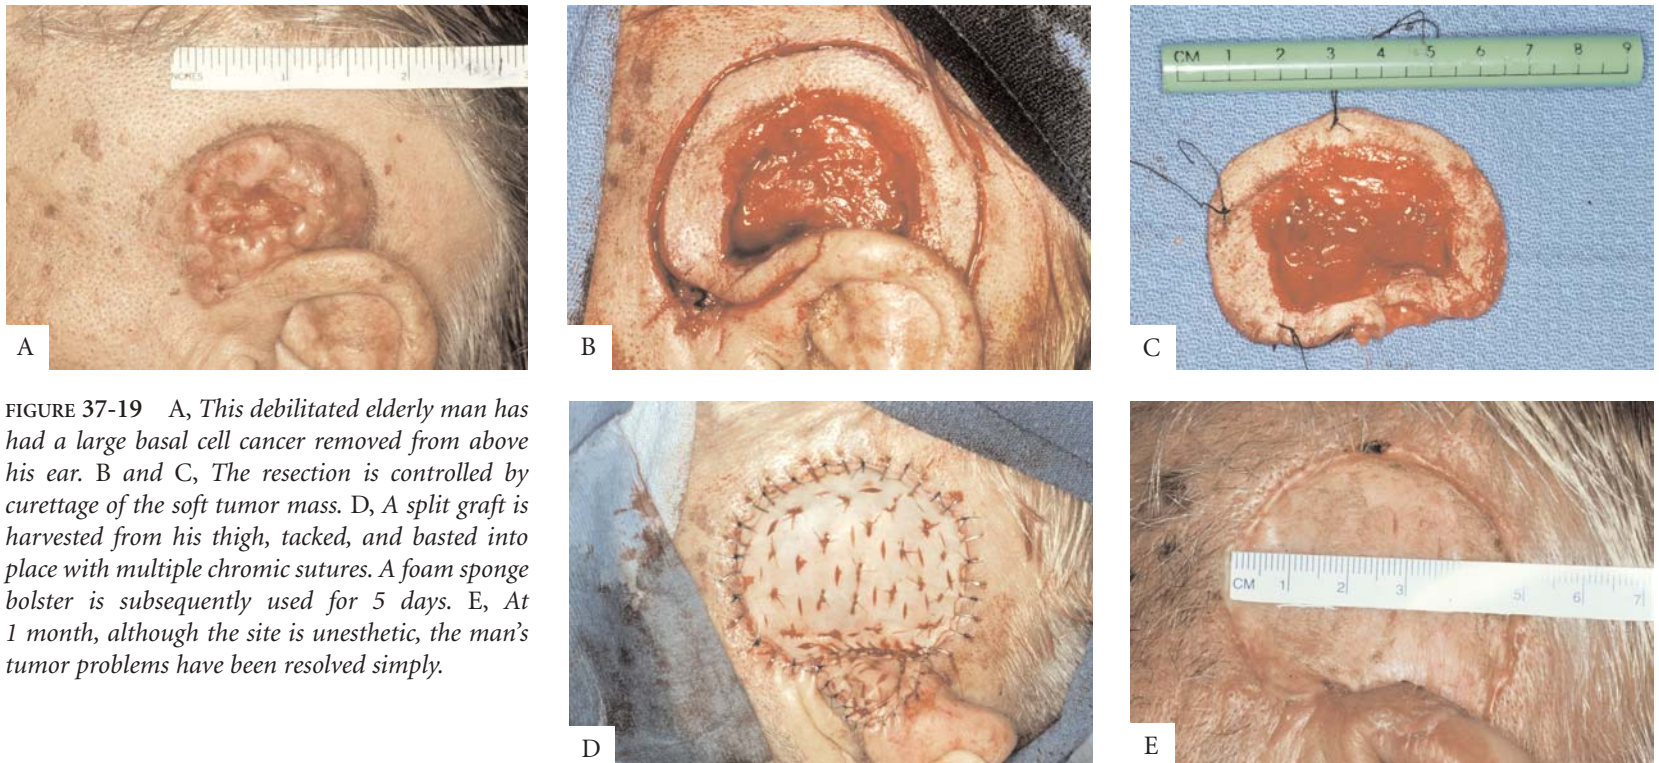

FIGURE 37-19 A, This debilitated elderly man has had a large basal cell cancer removed from above his ear. B and C, The resection is controlled by curettage of the soft tumor mass. D, A split graft is harvested from his thigh, tacked, and basted into place with multiple chromic sutures. A foam sponge bolster is subsequently used for 5 days. E, At 1 month, although the site is unesthetic, the man's tumor problems have been resolved simply.

Unlike for an FTSG, a tie-over dressing may not be necessary for STSG. A good compression dressing and/or basting stitches may suffice to promote adherence between the graft and underlying tissue and to prevent fluid accumulation. A variation to placing interrupted basting sutures is the spiral basting stitch. The suture is started at the edge of the graft with the “tail” left long.¹⁰⁸ The suture is then run along the periphery of the graft, spiraling toward the center, and then tied to the tail. The graft can then be dressed in a similar fashion to that for an FTSG.

Composite Grafts Composite grafts contain two or more tissue layers. Composite grafts are ideal for reconstructing the nasal ala rim, auricular defects, and eyebrows. Composite grafts are able to maintain the thinness and contour of the structure with minimal contracture. The most common donor site for composite grafts is the ear, including the crus of helix, rim, antihelix, tragus, and earlobe.

A major disadvantage to composite grafts is the risk of graft failure, which is higher than for FTSG and STSG and is attributed to the high metabolic demands of the grafts. Harvesting (donor) adjacent dermis attached to the composite graft and inserting the de-epithelialized dermis into adjacent subcutaneous tunnels (recipient) may improve vascularity substantially.¹⁰⁹ Cooling the composite graft with ice for 24 hours also helps.

Regardless, composite grafts are technique sensitive. Generally, composite grafts should be no larger than 1.5 to 2.0 cm. Avelar and colleagues have shown composite grafts greater than 2.0 cm grafted successfully to nasal and auricular defects.¹¹⁰ Similarly, Skouge has effectively grafted larger defects using a “tongue and groove” technique and turndown hinged flaps.¹⁰⁴ The postoperative appearance of composite grafts is distinctive. At placement, the graft is white or blanched. Within 6 hours it becomes pink, and by 24 hours it is cyanotic. By postoperative day 3, it resumes its pink

color. Grafts that fail develop an eschar with subsequent necrosis and sloughing.

Complications There are risks to all procedures. Patients who receive skin cancer procedures should be warned of the potential for recurrence of the tumor as well as revision of any reconstructive procedure. Flap problems include necrosis, infection, hematoma, wound dehiscence, and scarring.

Smoking greatly increases the risk of necrosis. Patients who smoke one pack per day triple the risk of flap or graft necrosis compared with nonsmokers. Smoking affects the blood supply via two mechanisms. First, nicotine is a potent vasoconstrictor that may lower tissue oxygenation by > 50%. Nicotine effects are visible within 10 minutes and can last up to 50 minutes. Second, carbon monoxide is a competitor with oxygen for hemoglobin. It has a higher affinity for hemoglobin than does oxygen, resulting in high levels of carboxyhemoglobin. This leads to tissue hypoxia.

Infection Infections are rare in vascularized head and neck tissues, and necrosis may be mistaken for infection. More common causes of redness include stitch abscesses, which are foreign body reactions, and allergies to antibiotic ointment. Infections, handled by drainage (when indicated), irrigation, and antibiotics, usually resolve readily.

Bleeding Bleeding may be caused by patient factors or surgical issues. Patient factors include medical conditions such as renal failure, liver failure, collagen vascular disease, various cancers (hematopoietic malignancies), and medications. Medications that can cause bleeding include warfarin, heparin, antithrombotics, nonsteroidal anti-inflammatory drugs, acetylsalicylic acid, and cold remedies. Furthermore, commonly used herbal medications such as garlic, feverfew, and vitamin E can inhibit thrombocyte function.

The surgeon must weigh the benefits of discontinuing anticoagulants against the risks of surgery since there have been several documented cases of stroke when anticoagulants were stopped prior to dermatologic surgery. Consultation and coordination with the patient's internist and appropriate preoperative laboratory data are helpful. There is no need to discontinue any anticoagulant prior to performing a biopsy.

Surgical issues may arise intraoperatively or during the postoperative period. Decisions must be made concerning judicious cautery, the use of drains, the effect of vasoconstrictors, and postoperative pressure. Seepage may occur from any facial flap, but hematoma may necrose the flap. A hematoma, in the space created between the flap and underlying tissue is detrimental to flap circulation because it creates tension, and it acts as a physical barrier preventing cohesion to the underlying tissue base. Additionally, stagnating blood may promote wound infection.

An early hematoma may often be pushed out and washed away, but a

reforming hematoma must be explored. Likewise, late collections of jellied blood should be manually extruded.

Poor Cosmetic Results Facial flaps should restore anatomic continuity, maintain functional integrity, and provide an esthetically pleasing result. In spite of well-executed surgical techniques, less than optimal results may occur because of unpredictable scarring and trapdoor deformity.

Part 6

MAXILLOFACIAL RECONSTRUCTION

Local and Regional Flaps

Alan S. Herford, DDS, MD

G. E. Ghali, DDS, MD

Flap Principles

Over the past 50 years the development and application of several different flaps has led to reliable reconstruction of facial defects. Most defects can be reconstructed immediately, leading to better restoration of form and function with early rehabilitation.¹ Reconstructing facial defects can be both challenging and rewarding. Missing tissue most often results from either trauma or oncologic surgery. Commonly there is a wide range of options for repairing a given defect, including healing by secondary intention, primary closure, placement of a skin graft, or mobilization of local or regional tissue. Compared to skin grafts, local flaps often produce superior functional and esthetic results.²⁻⁶ A great advantage of local tissue transfer is that the tissue closely resembles the missing skin in color and texture. These flaps can be rotated, advanced, or transposed into a tissue defect. Regional tissue can also be recruited to repair facial defects.

When deciding which option to use, there should be a progression from simple to complex treatments. Consideration should be given to primary closure or the use of skin grafts first, followed by local, then regional, and finally distant pedicled or microsurgical free tissue transfer. Flaps require additional incisions and tissue movement, which increase the risks of postoperative bleeding, hematoma, pain,

and infection. Confirmation of tumor-free margins should be done prior to flap reconstruction if a malignant lesion has been excised.⁷

Some defects are amenable to closure with a single flap, but others require a combination of flaps for optimal results.⁸ An advantage of using multiple flaps is that they can be harvested from separate esthetic units. This decreases the size of the secondary defect and may allow placement of scars between esthetic units, thus improving scar camouflage leading to better cosmesis. Often, separated repair of individual facial subunits with separate flaps provides a better cosmetic result than if a single flap is used to reconstruct the entire defect.

Flaps differ from grafts in that they maintain their blood supply as they are moved. Abundant dermal and subdermal plexus allow for predictable elevation of random cutaneous flaps. A cutaneous flap may also have its arterial supply based on a dominant artery in the subcutaneous layer. Muscular perforating arteries are important contributors to the cutaneous vascular bed. The most important variable for flap viability is not the length-to-width ratio but, rather, the perfusion pressure and vascularity at the pedicle base.⁹ Because local flaps provide their own blood supply, they are particularly useful in patients with compromised recipient sites such as those that have been irradiated.

As local flaps heal, regaining of blood flow and cutaneous sensibility increases. The rate of blood flow and two-point discrimination on the surface of local flaps is statistically no different when compared with the corresponding area of the unoperated side.¹⁰ The recovery of sensory nerve function in facial flaps is dependent on the intimacy of contact between the flap and the recipient bed and on the viability of the type of restoration.

Relaxed skin tension lines (RSTLs) result from vectors within the skin that reflect the intrinsic tension of the skin at rest. They are due to the microarchitecture of the skin and represent the directional pull on wounds. The RSTLs are generally parallel to the facial rhytids. Lines of minimal tension (rhytids) result from repeated bending of the skin from muscular contraction. A permanent crease results from the adhesions between the dermis and deeper tissues. These natural skin creases run perpendicular to the direction of muscle pull and can guide incision orientation for optimal scar camouflage and cosmesis.

The face is composed of esthetic subunits.^{11,12} The areas where these subunits meet are referred to as anatomic borders. The esthetic subunit principle is based on the fact that our eyes see objects as a series of block images that are spatially organized. Scars that are located at the junction of two adjacent anatomic subunits are

inconspicuous because one expects to see a delineation between these areas.

Flap Nomenclature

There are many methods described for classifying cutaneous flaps: by the arrangement of their blood supply, their configuration, location, tissue content, and method of transferring the flap.

Blood Supply

Cutaneous flaps consist of skin and subcutaneous tissue and can be characterized by their predominant arterial supply. These include random pattern, axial pattern, and pedicle flaps (Figure 38-1). Random flaps are supplied by the dermal and subdermal plexus alone and are the most common type of flap used for reconstructing facial defects. Axial pattern flaps are supplied by more dominant superficial vessels that are oriented longitudinally along the flap axis. Pedicle flaps are supplied by large named arteries that supply the skin paddle through muscular perforating vessels. Free tissue transfer refers to flaps that are harvested from a

remote region and have the vascular connection reestablished at the recipient site.

Location

Another means of classification is by the region from which the tissue is mobilized. This includes local, regional, and distant flaps. Local flaps imply use of tissue adjacent to the defect, whereas regional flaps refer to those flaps recruited from different areas of the same part of the body. Distant flaps are harvested from different parts of the body.

Configuration

Flaps are often referred to by their geometric configuration. Examples of these flaps include bilobed, rhombic, and Z-plasty.

Tissue Content

The layers of tissue contained within the flap can also be used to classify a flap. *Cutaneous flap* refers to those flaps that contain the skin only. When other layers are incorporated into the flap they are classified accordingly. Examples include myocutaneous and fasciocutaneous flaps.

Method of Transfer

The most common method of classifying flaps is based on the method of transfer. Advancement flaps are mobilized along a linear axis toward the defect (Figure 38-2). Rotation flaps pivot around a point at the base of the flap (Figure 38-3). Although most flaps are moved by a combination of rotation and advancement into the defect, the major mechanism of tissue transfer is used to classify a given flap. *Transposition flap* refers to one that is mobilized toward an adjacent defect over an incomplete bridge of skin. Examples of transposition flaps include rhombic flaps and bilobed flaps (Figure 38-4). Interposition flaps differ from transposition flaps in that the incomplete bridge of adjacent skin is also elevated and mobilized. An example of an interposition flap is a Z-plasty. Interpolated flaps are those flaps that are mobilized either over or beneath a complete bridge of intact skin via a pedicle. These flaps often require a secondary surgery for pedicle division. Microvascular free tissue transfer

FIGURE 38-3 A, Rotation flap for closure of a forehead defect. B, Closure of the defect.

from a different part of the body relies on reanastomosis of the vascular pedicle.

Designing the Flap

There are many options for reconstructing facial defects. Often the optimal method is not readily apparent. A stepwise approach can be helpful in selecting and designing a flap. The characteristics of the defect and adjacent tissue must be analyzed. These include color, elasticity, and texture of the missing tissue. The defect size, depth, and location are evaluated as well as the availability and characteristics of adjacent or regional tissue. It is important to determine the mobility of adjacent structures and to identify those anatomic landmarks that must not be distorted. The orientation of the RSTLs and esthetic units should be analyzed closely.

Potential flap designs should be drawn on the skin surface being careful to avoid those designs that obliterate or distort anatomic landmarks. The final location of the resultant scar should be anticipated by previsualizing suture lines and choosing flaps that place the lines in normal creases.

FIGURE 38-4 A, Bilobed flap for closure of a nasal tip defect. B, Closure of the defect. C, Rhombic flap for closure of a cheek defect. Note the 120 and 60° angles. D, Closure of the defect.

The secondary defect that is created as the tissue is transferred into the primary defect must be able to be closed easily. When designing a flap, it is important to avoid secondary deformities that distort important facial landmarks or affect function. Avoid obliterating critical anatomic lines that are essential for normal function and appearance.

Proper surgical technique involves gentle handling of the tissue by grasping the skin margins with skin hooks or fine-toothed tissue forceps. Avoid traumatizing the vascular supply by twisting or kinking the base of the flap. Deep pexing sutures minimize tension on the flap and eliminate dead space. Excessive tension on the flap may decrease blood flow and cause flap necrosis. Meticulous hemostasis should be achieved prior to final suturing so that a hematoma does not develop beneath the flap. It is important to

adequately mobilize and extend the flap, which should be of adequate size to remain in place without tension to minimize the chance of dehiscence, scarring, or ectropion.

Types of Flaps

Local Flaps

Advancement Flaps Advancement flaps have a linear configuration and are advanced into the defect along a single vector. These flaps can be single or double. Advancement flaps are often chosen when the surrounding skin exhibits good tissue laxity and the resulting incision lines can be hidden in natural creases. Advancement flaps limit wound tension to a single vector with minimal perpendicular tension. They are often helpful in reconstructing defects involving the forehead, helical rim, lips, and cheek. In these areas advancement flaps capitalize on the natural forehead furrows without causing vertical distortion of the hairline superiorly or the eyebrow inferiorly (Figure 38-5).

FIGURE 38-5 A, Advancement flap for closure of forehead defect. B, Closure of defect with incision lines placed in natural forehead crease.

Advancement flaps are created by parallel incisions approximately the width of the defect. Standing cutaneous deformities (“dog ears”) are usually created and are managed with excision. A Z-plasty incision or Burow’s triangle may be performed at the base of the flap, reducing the standing cutaneous deformities.

A variation of the advancement flap is the V-Y flap. A triangular island of tissue adjacent to the defect is isolated and attached only to the subcutaneous tissue. It relies on a subcutaneous pedicle for blood supply. As it is advanced into the defect, the secondary defect is closed primarily in a simple V-Y manner. These flaps are especially amenable for cheek defects along the alar facial groove and are generally avoided where there are superficial nerves because of the depth of the incisions.

Intraoral uses of advancement flaps include covering oroantral fistulas and alveolar clefts. A disadvantage of buccal advancement flaps is the decrease in vestibular sulcus depth (Figure 38-6).

Rotation Flaps Rotation flaps have a curvilinear configuration. Defects reconstructed with rotation flaps should be somewhat triangular or modified by removing normal tissue to create a triangular defect. These flaps have a large base and are usually random in their vascularity but may be axial. One or more rotation flaps are often used to reconstruct scalp defects. Because of the relative inelasticity of the scalp tissue, these flaps must be large relative to the size of the defect. Scoring of the galea is helpful in gaining additional rotation and advancement (Figure 38-7).

The axial frontonasal flap is a modified simple rotation flap with a back cut.¹³⁻¹⁶ It is useful for closing nasal defects (Figure 38-8). The flap is based on a vascular pedicle at the level of the medial canthus. This pedicle consists of a branch of the angular artery and the supraorbital artery.

Rotated palatal flaps are helpful for closing large oroantral fistulas.^{8,17} Fistulas < 5 mm in diameter usually close

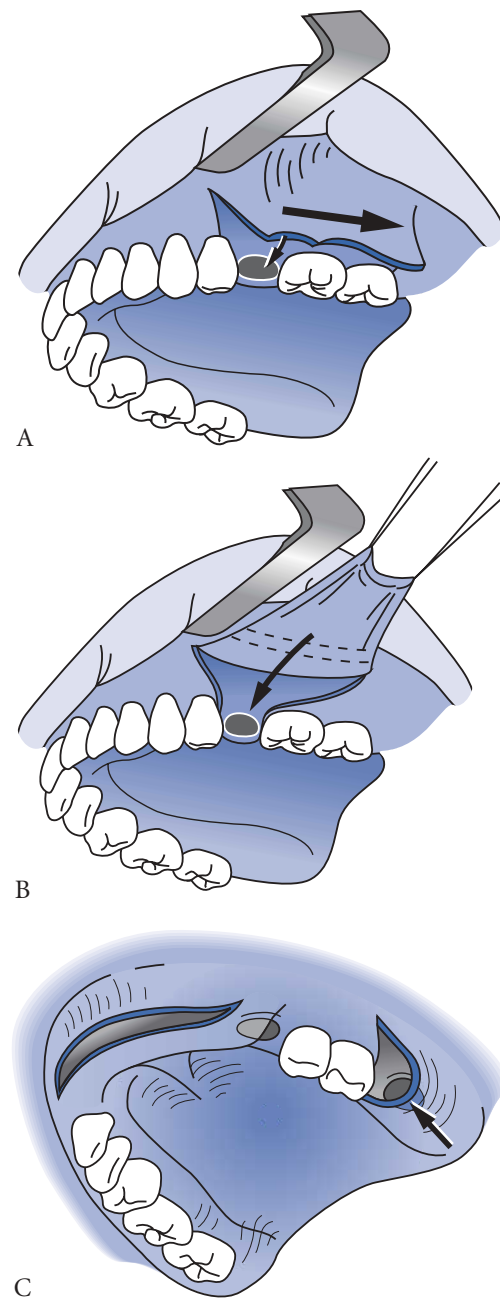

FIGURE 38-6 Buccal advancement flaps can be used to cover an oroantral fistula. A, A Moczaik buccal sliding trapezoidal flap is slid (arrow) to use the papilla of the adjacent tooth to rotate into the defect. B, Rehrman’s buccal advancement flap uses a flap that has vertical extensions. To adequately mobilize this flap to cover the defect without tension, the periosteum must be incised (broken line) along its base and the flap advanced (arrow) over the defect. C, If the fistula is present along an edentulous region, a transverse flap or bipedicle flap can be used.

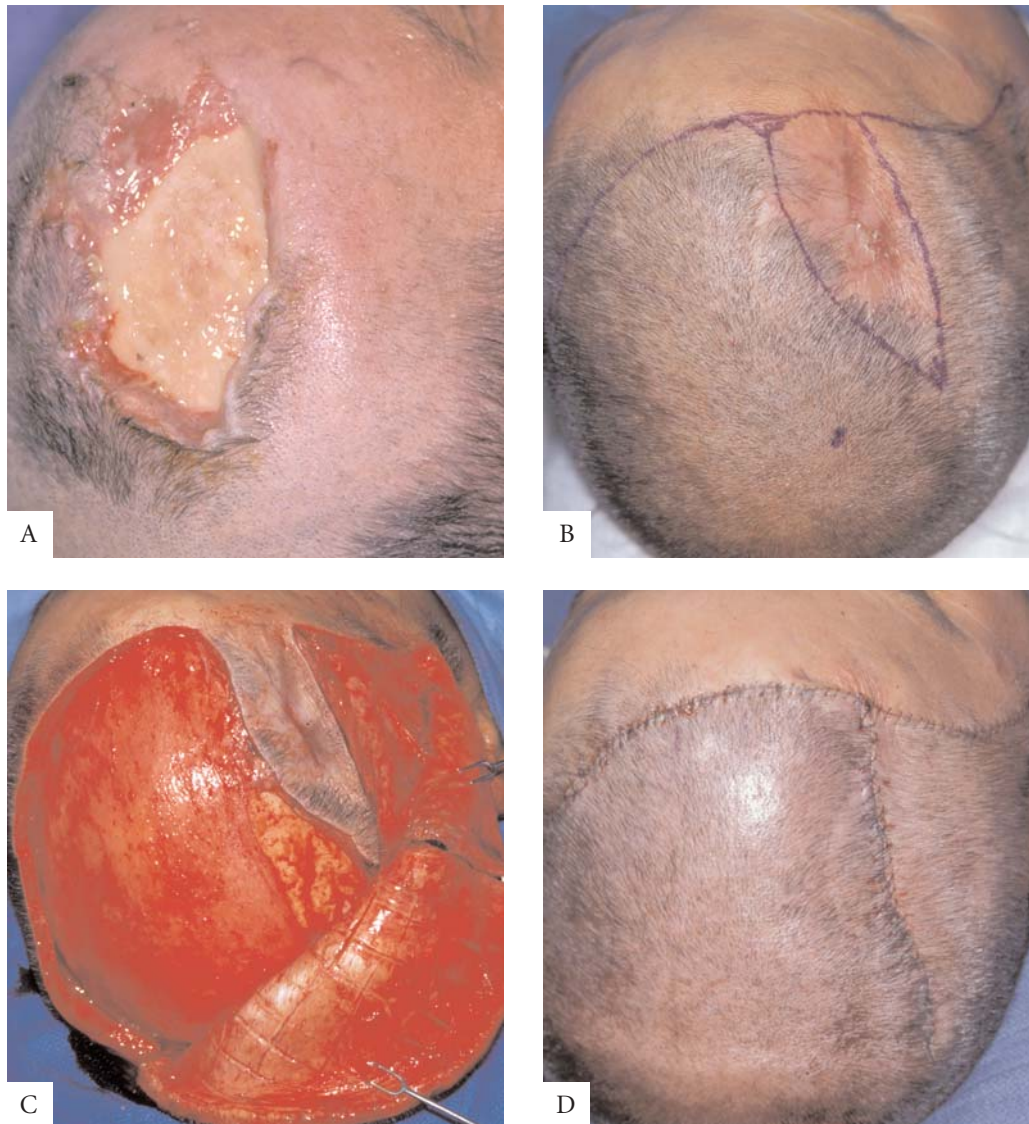

FIGURE 38-7 A, A large scalp defect secondary to trauma. B, Outline of scalp flaps. C, Elevation of flaps with scoring of the galea. D, Closure of the defect.

spontaneously.^{18,19} Local flaps or grafts can be used to close larger fistulas. Two-layer closures are less prone to developing

recurrence of oroantral fistulas. Approximately 75% of the palatal soft tissue can be rotated to cover adjacent defects.

FIGURE 38-8 A, Axial frontonasal flap for repair of a nasal defect. B, Elevation of the flap with thorough undermining. C, Closure of the defect

Transposition Flaps These flaps are rotated and advanced over adjacent skin to close a defect. Examples of transposition flaps include rhombic flaps and bilobed flaps. These flaps are advantageous in areas where it is desired to transfer the tension away from closure of the primary defect and into the repair of the secondary defect. Transposition flaps have a straight linear axis and are usually designed so that one border of the flap is also a border of the defect. An advantage of this type of flap is that it can be developed at variable distances. Areas where these flaps are often used include the nasal tip and ala, the inferior eyelid, and the lips.

The rhombic flap is a precise geometric flap that is useful for many defects of the face.^{20,21} The traditional rhombic (“Limberg”) flap is designed with 60 and 120° angles and equal-length sides. The angle of the leading edge of the rhombic flap is approximately 120° but may vary. The flap is begun by extending an incision along the short axis of the defect that is equal to the length of one side of the rhombic defect. Another incision is then made at 60° to the first and of equal length (Figure 38-9). Disadvantages of the rhombic flap are the significant tension at the closure point as well as the amount of discarded tissue to transform a circular defect into a rhombus.

The bilobed flap is a transposition flap with two circular skin paddles (see Figure 38-4).^{22,23} Esser is credited with the design of the bilobed flap in 1918. It

FIGURE 38-9 A, Outline for a rhombic flap. B, Resection of the lesion. C, The flap is transposed into the defect. D, Postoperative result with the incisions placed in the relaxed skin tension lines.

is useful for skin repairing of lateral nose and nasal tip defects up to 1.5 cm. The bilobed flap has a random pattern blood supply. The flap is primarily rotated around a pivot point and the paddles are transposed over an incomplete bridge of skin. The second lobe allows the transfer of tension further from the primary defect closure. The bilobed design rotates around an arc that is usually 90 to 100°. In the bilobed flap the first lobe closes the defect and the second closes the first lobe defect. The flap is designed with a pivot point approximately a radius of the defect away from the wound margin. The first lobe is usually the same size as the defect, and the second lobe is slightly smaller with a triangular apex to allow for primary closure. The axis of the second flap is roughly 90 to 100° from the primary defect and undermined widely to distribute the tension.

An advantage of the bilobed flap is that one can construct a flap at some distance from the defect with an axis that is independent of the linear axis of the

defect. A disadvantage of this flap is that it leaves a circular scar that does not blend with the existing skin creases. During healing the flap may become elevated (“pin cushioning”) because of the narrow pedicle that is prone to congestion, scar tissue that impedes lymphatic drainage, and curvilinear scars that tend to bunch the flap up as they shorten.

Interpolation Flaps Interpolation flaps contain a pedicle that must pass over or under intact intervening tissue. A disadvantage of these types of flaps is that for those passing over bridging skin, the pedicle must be detached during a second surgical procedure. Occasionally it is possible to perform a single-stage procedure by de-epithelializing the pedicle and passing it under the intervening skin. Advantages of interpolation flaps include their excellent vascularity, and also their skin color and texture match.

The forehead flap (median and paramedian) is a commonly used interpolation flap and remains the workhorse flap for

large nasal defects.²⁴⁻²⁷ It is a robust and dependable flap. The forehead flap is primarily based on the supratrochlear vessel, is relatively narrow, and uses a skin paddle from the forehead region. The flap is supplied by a rich anastomosis between the supratrochlear and angular arteries. Because of the marked vascularity, it is possible to incorporate cartilage or tissue grafts for nasal reconstruction. The forehead flap has abundant tissue available, allowing resurfacing of the entire nasal unit with a single flap and provides a good texture and color match to the native nose.

The technique for elevating the forehead flap is straightforward. The flap can be designed directly in the midline or in a paramidline location. A template of the defect is used to outline the flap. Elevation of the flap proceeds in either a subgaleal or subcutaneous plane. The pedicle is always elevated in such a way as to incorporate the frontalis muscle. The width of the pedicle is usually 1.0 to 1.5 cm, which allows for easy rotation of the pedicle. Prior to inset the skin paddle is selectively thinned to match the native skin thickness. The pedicle is divided approximately 3 weeks later, with the base of the pedicle inset into the glabellar area to reestablish brow symmetry. The incision, and resulting scar, is perpendicular to the RSTLs but tends to heal well (Figure 38-10).

The nasolabial flap (melolabial) is useful for reconstructing defects involving the oral cavity and those involving the lower third of the nose (Figure 38-11).²⁸⁻³¹ It can be used as an interpolation flap with either a single or staged technique. The flap is supplied by the angular artery, intraorbital artery, and infratrochlear artery and can be based either superiorly or inferiorly. The area of recruitment for nasal reconstruction is in closer proximity to the primary defect than is the forehead flap. A disadvantage of the nasolabial flap is that there is a limited amount of tissue available, and asymmetry can occur along the

FIGURE 38-10 A, Nasal defect after excision of squamous cell carcinoma lesion. B, Use of Doppler ultrasonography to locate the supra-trochlear artery. C, The forehead flap has been elevated. D, The flap is turned 180° and sutured into place. E, The pedicle is divided 2 to 3 weeks later. F, Postoperative result

nasolabial flap folds. When the pedicle is divided, the defect can be closed primarily by placing the scar in the nasal facial junction and the nasolabial flap fold.

The lip-switch flap (Abbe) can be taken from either lip, but it is most commonly switched from the lower to the upper lip.³²⁻³⁴ This flap can be used to reconstruct as much as one-third of the

upper lip. The lower lip can supply a flap of one-quarter of its length, and the Abbe flap offers immediate replacement of total lip anatomy (Figure 38-12). The labial artery supplies the flap and should be maintained with a small cuff of subcutaneous tissue and muscle surrounding the vascular pedicle. The pedicle is divided after approximately 2 to 3 weeks.

Tongue flaps are excellent flaps for intraoral reconstruction. They use adjacent tissue, have an excellent blood supply, and are associated with minimal morbidity. The tongue has excellent axial and collateral circulation, with the lingual artery providing the main blood supply. Up to one-half of the tongue can be rotated for tissue coverage without compromising speech,

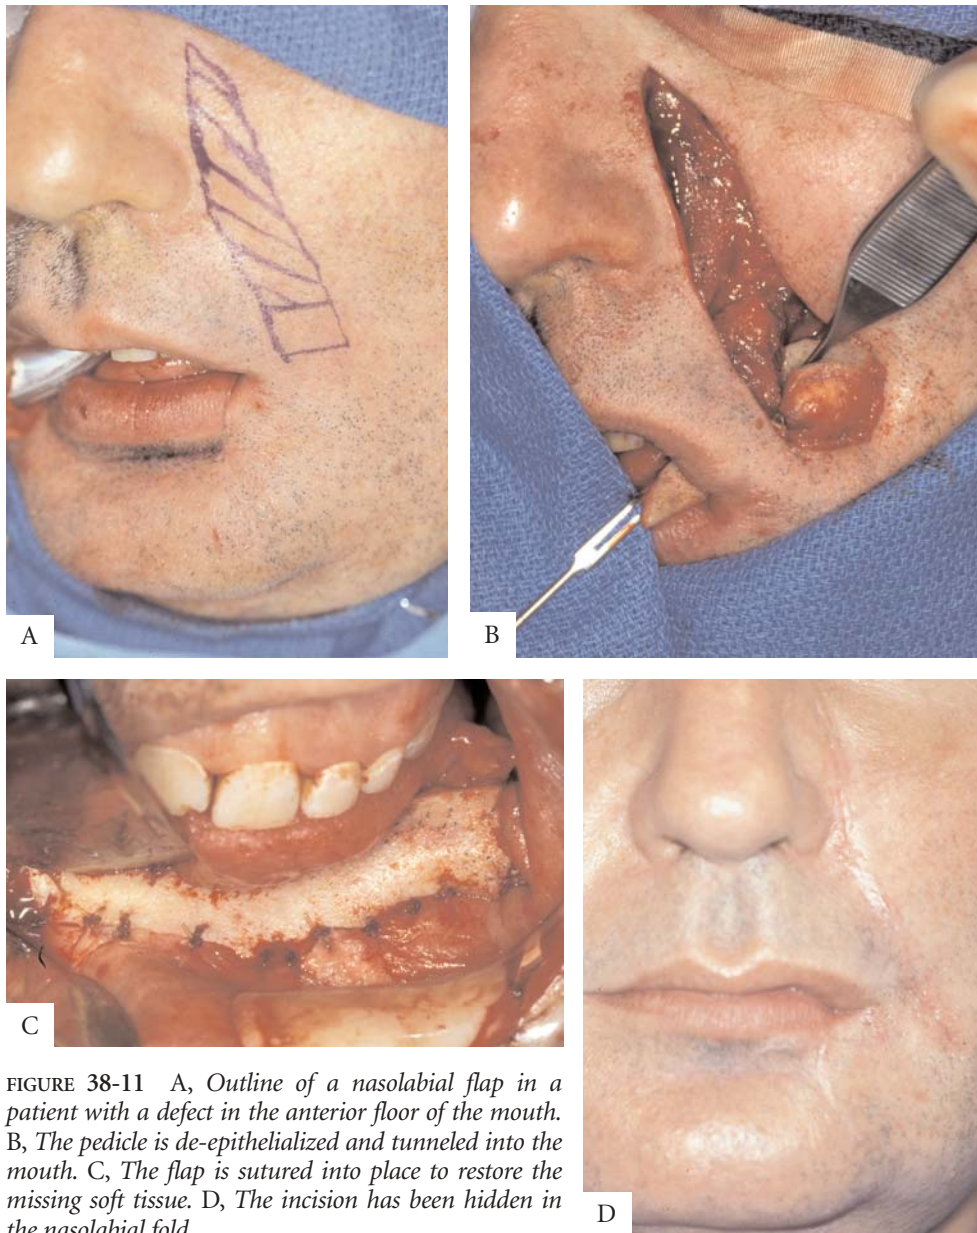

FIGURE 38-11 A, Outline of a nasolabial flap in a patient with a defect in the anterior floor of the mouth. B, The pedicle is de-epithelialized and tunneled into the mouth. C, The flap is sutured into place to restore the missing soft tissue. D, The incision has been hidden in the nasolabial fold.

mastication, or deglutition.³⁵ A variety of flap designs have been described including anterior- and posterior-based tongue flaps (Figure 38-13). Some indications include repair of oral defects and fistula closure. These flaps are helpful for providing closure of large oroantral fistulas.

Regional Flaps

For large facial defects, local flaps may not provide sufficient tissue to adequately restore the missing tissue. In these cases consideration should be given to using a regional flap.^{36,37} Regional flaps are

defined as those that are located near a defect but are not in the immediate proximity. They are frequently harvested from the neck, chest, or axilla and can provide coverage of large surface areas on the face. Selection of a specific regional flap depends on the size and location of the defect and also on the intrinsic properties of the flap. Advantages of regional flaps include the large amount of soft tissue and skin available. Disadvantages of these types of flaps include poor color and texture match, excessive bulkiness of the flap, and donor site morbidity.

FIGURE 38-13 A and B, Use of an anteriorly based tongue flap to cover the soft tissue deficit resulting from an alveolar cleft. C, This type of flap is also useful for closing large oroantral fistulas..

Pectoralis Major Myocutaneous Flap

The pectoralis major myocutaneous flap remains a workhorse of reconstructive surgery.³⁸⁻⁴⁰ The flap was introduced by Ariyan⁴¹ and has provided a reliable method of soft tissue reconstruction of bone and soft tissue defects of the mandible and maxilla. The pectoralis major myocutaneous flap can be rotated around a pivot point 180° and is supplied by two separate blood supplies (Figure 38-14). The thoracoacromial artery arises from the second portion of the axillary artery and forms four branches as it penetrates the fascia. The pectoral branch is the major artery that supplies the pectoralis major myocutaneous flap. The position of the vascular pedicle can be approximated by drawing a line from the shoulder point to the xiphoid. The pectoral branch descends at a right angle from the middle of the clavicle until it meets this line. Branches of the internal mammary artery supply the medial portion of the muscle and skin over the sternum. The flap provides good coverage

FIGURE 38-14 The pectoralis major myocutaneous flap is divided lateral to the internal mammary artery perforating vessels. The muscle can be divided lateral to the skin island to leave the lateral portion of the muscle intact; this preserves the axillary fold.

for the carotid artery when combined with a neck dissection.

Deltopectoral Flap The introduction of the deltopectoral flap by Bakamjian and colleagues represented a significant improvement for reconstructing large ablative resections for head and neck cancer.⁴²⁻⁴⁴ Currently it is used as an alternative to the pectoralis major myocutaneous flap for soft tissue reconstruction of the mandible and maxilla. This flap is composed of fascia, subcutaneous tissue, and skin but does not contain muscle (Figure 38-15). Perforators from the internal mammary artery provide vascular supply to the flap. The secondary defect is covered with a skin graft.

Temporalis Flap The temporalis flap was introduced by Golovine in 1898 and remains useful for covering intraoral defects (Figure 38-16).⁴⁵⁻⁴⁸ The outer portion of the muscle is invested by the deep temporal fascia. This fascia is supplied by the middle temporal vessel, which originates just below the zygomatic arch. The temporalis muscle is supplied by both the anterior and posterior deep temporal arteries, which arise from the second portion of

the internal maxillary artery. This dual blood supply allows for splitting of the muscle into anterior and posterior flaps.

When elevating the muscle, it is important to remain on the deep temporal fascia beneath the superficial temporal fascia to avoid damage to the frontal branch of the facial nerve. Elevation of

the inferior portion of the flap is performed in a subperiosteal plane to avoid damage to the deep temporal arteries, which lie on the undersurface of the muscle. An osteotomy of the zygomatic arch is often helpful to facilitate placement of the muscle into the mouth. The arch can be put back into place and secured with

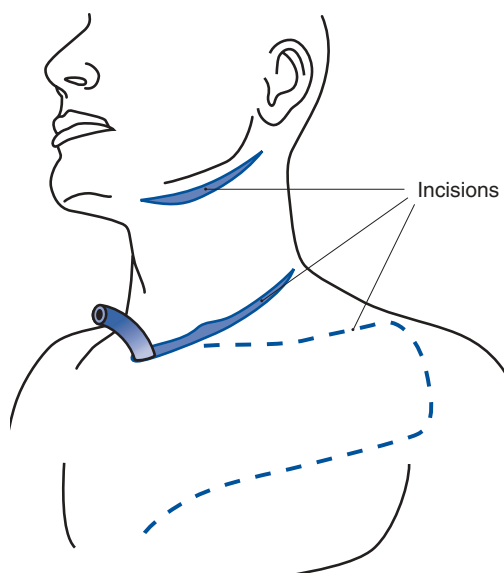

FIGURE 38-15 Incisions for a deltopectoral flap.

FIGURE 38-16 A, Temporalis muscle flap for repair of a midface defect caused from a shotgun wound. B, The temporalis muscle is divided, and the posterior portion is sutured into place. C, Cranial bone is used to restore the missing tissue. D, The anterior portion of the temporalis flap is sutured into place to “sandwich” the bone grafts.

FIGURE 38-17 Blood to the sternocleidomastoid muscle is supplied through three arteries.

plates and screws. A disadvantage of the temporalis flap is the minimal cosmetic deformity of hollowing in the temporal region; this can be corrected with autogenous or alloplastic materials and can be minimized by using either an anterior or a posterior flap.

Sternocleidomastoid Flap First described by Jinau in 1909 for facial reanimation, the sternocleidomastoid flap was repopularized by Owens.^{49–55} The muscle is invested by the deep cervical fascia and is supplied by three arteries. The dominant vessel is the occipital artery, which

enters the muscle below the mastoid tip and supplies the superior portion of the muscle. The superior thyroid artery supplies the middle portion, and the thyrocervical trunk supplies the inferior third of the muscle.

The muscle is elevated over the deep cervical fascia superior to the carotid sheath. It is recommended to maintain two of the three vessels when elevating the flap to enhance the viability of the flap. The spinal accessory nerve enters the deep portion of the muscle approximately at the carotid bifurcation and should be preserved to prevent denervation atrophy of the muscle (Figure 38-17). Advantages of the sternocleidomastoid flap include its close proximity to the defect and minimal donor site defect (Figures 38-18 and 38-19).

Trapezius Myocutaneous Flap The trapezius myocutaneous flap is supplied by three arteries, allowing several flaps to be used. The main vessel supplying the trapezius muscle is the transverse cervical artery, which is a branch of the thyrocervical trunk. The upper portion of the muscle is supplied by the occipital artery. The trapezius myocutaneous flap is a ready source of skin of uniform thickness without excessive

muscle bulk.⁵⁶ The main disadvantage is the limited rotation and the short pedicle.

Latissimus Dorsi Myocutaneous Flap
Quillen and colleagues first described the use of the latissimus dorsi myocutaneous flap for head and neck reconstruction in 1978.^{57,58} The flap is not commonly used for head and neck reconstruction unless other flaps are unavailable or there are

very large defects requiring coverage. The muscle is supplied by the thoracodorsal artery, which is the dominant vessel, and also by four to six perforators from the posterior intercostals and lumbar vessels. The main advantage of the latissimus dorsi flap is the large amount of skin provided. The main disadvantages are the need to reposition the patient during the operation and morbidity from the donor site.

Complications

Postoperative complications can be minimized with careful preoperative planning of flap design and by early recognition of problems.⁵⁹ A medical history can be used to identify patients with risk factors involving small vessels. These risk factors include smoking, diabetes, hypertension, previous radiation, and preexisting scars.^{60,61} Complications may be reversible or irreversible. Early recognition and treatment can minimize complications and prevent them from becoming irreversible. Two main unwanted outcomes are flap failure and unacceptable cosmetic results.

Flap survival depends on early recognition of flap compromise. Ischemia is defined as an inadequacy of perfusion in providing tissue needs. Signs of arterial ischemia include a pale and cool flap that does not blanch with pressure and typically does not bleed with a pinprick. Flaps are somewhat ischemic initially because the original tissue perfusion has been compromised by flap elevation. Most tissue can survive on 10% of its average blood flow.⁵⁹ Whether the flap will undergo necrosis depends on patient-related and surgery-related factors that influence the risk of necrosis in facial flaps. Smoking is associated with an increased risk of flap failure. The deleterious effects of smoking on flap survival include hypoxemia and vasoconstriction. Patients should be advised to quit smoking during the perioperative period.

Common causes of bleeding in facial reconstruction with local flaps include

inadequate hemostasis and drug-induced coagulopathy. Hematoma formation should be identified and decompressed within 24 hours.⁶² Decompression can be accomplished with aspiration using a 22-gauge needle or by taking out one or two sutures and applying gentle compression on the flap. Hematoma formation may diminish tissue perfusion and can lead to ischemia or necrosis by inducing vasospasm, stretching the subdermal plexus, or separating the flap from its recipient bed. Patients should be questioned carefully about the use of medications that affect coagulation such as acetylsalicylic acid, nonsteroidal anti-inflammatory drugs, and vitamin E. If possible, these medications should be avoided for 2 weeks prior to and 1 week after surgery.

Congestion is the most common vascular problem associated with facial flaps. Signs of a congested flap include warmth, edema, and a purple color that blanches with pressure then immediately refills. A pinprick will cause release of dark venous blood. Venous congestion can lead to arterial compromise and flap necrosis. Management of congested flaps may include temporarily releasing sutures to allow decompression at the flap edges or possible impingement involving the flap pedicle. Tight bandages around the flap pedicle should be removed. Medicinal leeches (*Hirudo medicinalis*) may be useful in decompressing congested flaps.^{63,64} Saliva from the leech contains an anticoagulant and a vasodilator that facilitate continued oozing from the site even up to 6 hours after they detach.

Hyperbaric oxygen (HBO) has been shown to be beneficial in improving the vascularity of marginal tissues.⁶⁵ Prophylactic HBO therapy in cutaneous flap surgery in the irradiated tissue bed may be particularly helpful to combat the hypoxia and hypocellularity. HBO is beneficial in treating both venous congestion and arterial ischemia by creating a local

arterial vasoconstriction through the rise in arterial oxygen content, which reduces the amount of inflow. The tissue oxygen levels continue to rise owing to the improved diffusion even though there is vasoconstriction and a reduction in vascular perfusion. The flap can maintain viability while continued neovascularization occurs. Other options include the use of heparin and dipyridamole to help increase the survival of an ischemic flap.⁶⁶

Infection can complicate flap healing.⁶⁷ The postoperative infection rate for clean wounds in facial surgery is as low as 2.8%, with higher rates in facial reconstruction with local flaps.⁶⁸ Tissue oxygenation is an important factor in prevention of wound infection and is closely related to blood supply. Infections involving local flaps may result in flap failure or poor cosmetic outcome secondary to wound dehiscence and scarring.

Conclusion

A variety of facial flaps are available to the reconstructive surgeon for repairing facial defects. The goal of flap surgery is to restore form, function, and esthetics. There are many advantages to using local and regional flaps, which can lead to optimal esthetic results.

Bony Reconstruction of the Jaws

Randall M. Wilk, DDS, PhD, MD

Overview and Goals

Bony reconstruction of the jaws represents one of the most daunting tasks presenting to the oral and maxillofacial surgeon. The demands of reconstruction of the mandible and maxilla represent challenges for the following reasons. The requirements for success follow a strict criterion for occlusion of the dentition and oral rehabilitation. Minor malpositionings result in occlusal problems that are both perceptible to the patient and provide a formidable task to the restorative dentist. Major malpositions may make oral rehabilitation near impossible. The functional loads to be carried on the bone can challenge both hardware and the reconstituted mandible and maxilla. The environment of the oral cavity can be hostile for adequate healing and regeneration. Indigenous flora of the oral cavity is one of the most diverse in the human body, and the bacterial load can be considerable. When pathogenic flora is present, as is not uncommon in the compromised host, healing can be further challenging. The bones themselves represent complex morphologies, curved shapes, and complex relationships with adjacent structures. Reproducing these parameters adds to the complexity of the task. The jaws by virtue of their prominent placement on the exposed face impart considerable esthetic requirements. Unlike other parts of the body, which are hidden by clothing, the face is rarely concealed.

The goals of reconstruction under the aforementioned conditions are to provide morphology and position of the bone in relation to its opposing jaw, provide adequate height and width of bone, restore continuity of the mandible and maxilla, and provide facial contour and support for soft tissue structures. While these concepts may seem straightforward, surgeons have struggled for centuries to achieve them and success is often elusive. Various success rates have been described for bony reconstruction of the jaws, but criteria have usually been incomplete and rates uninspiring.

The factors leading to the lack of adequate bone development or loss of bone in the first place have a role in the types and methods used to begin a reconstruction. Ablative loss of both bone and associated soft tissue from treatment of neoplastic or other pathologic processes represent a far different task from loss of bone from trauma or infection. Other modulating factors include the presence of systemic diseases, exposure to therapeutic doses of ionizing radiation, or failure of development of normal bony structures. Success rates in irradiated jaws are typically lower by significant amounts, and rates of complications have been reported as high as 81.3%.¹ Complete graft loss in 30% of irradiated patients undergoing bone grafting to the jaws and an additional 50% of patients experiencing partial graft loss after reconstructive procedures have been

reported.² Use of hyperbaric oxygen therapy and microvascular reconstruction has improved these rates.^{3,4}

Bony reconstruction begins with assessing the bone to be reconstructed. The location, size, and relationship to the other structures are the prime factors in planning a reconstruction. A large defect of the angle region is managed differently than a small defect in the same region. A defect in the alveolus of the maxilla is managed differently than a similar-size defect in the hard palate. Defects in areas that are opposed by natural dentition are managed differently than those that are in areas that have little functional consequence.

Anatomic Considerations in Reconstruction of the Jaws

Anatomically the mandible can be divided into four broad regions (Figure 39-1) with somewhat indistinct boundaries: condylar portion, ramus, body, and alveolus. Several subsets or overlapping areas have been described. The coronoid region can be considered as part of the ramus, the angle region encompasses both part of the ramus and body, and the symphysis is the anterior part of the body. Each of the areas presents unique characteristics, and the decision to reconstruct or repair certain areas is dependent on the goals to be achieved.

The condylar region is critical to the masticatory functions of the jaws and overall movements of the mandible. In the

FIGURE 39-1 Mandibular regions.

young and growing patient there are implications for growth of the jaw. The relationship of this area with the temporal bone and the interarticular disk is beyond the scope of this chapter. Anatomic features of the condylar region are the muscular attachments and morphologic support of facial height. The lateral pterygoid muscle attaches to the condylar region and provides for translatory movement of the mandible and its excursive movements. When reconstructing large or entire portions of the condyle with grafts, failure of reattachment of the lateral pterygoid muscles will result in impairment or loss of these functions. The condylar region contributes to the posterior vertical height of the mandible. Loss of the condylar region or insufficient reconstruction results in reduced height with resulting malocclusion and esthetic contour deficiencies. Not only does the reconstructed condyle need to have adequate bulk and form, but it also needs to be placed in appropriate relationship to the temporomandibular joint fossa.

The ramus area participates in masticatory function as the site of attachment of the major muscles of mastication. The masseter, medial pterygoid, and temporalis muscles all attach here and provide the major input for developing bite force. These muscles also serve as a potent blood supply for the reconstructed bone and serve as an excellent recipient bed. The ramus region provides bulk, facial contour, and continuity between major segments of the mandible. Damage or loss of bone structure in this area can lead to

decreased posterior mandibular height with resulting malocclusion, facial contour defects, and decreased masticatory function. The major sensory nerve of the mandible enters this area and is prone to injury during reconstructive efforts. The coronoid process is considered part of the ramus, and its loss can be considered to be trivial. There are no good reasons to reconstruct a coronoid process. As in other parts of the mandible, the relationship of the coronoid process to the surrounding bones is critical. Malpositioning of the coronoid process can impede opening of the jaw owing to interferences with the zygoma and zygomatic arch.

The body of the mandible is probably the most complex area of the mandible to reconstruct for several reasons. It has a complex curved shape that makes reconstruction difficult, it is along the lever of the mandible and has the highest loads placed on it, it contains a sensory nerve that is prone to injury, and it is the site of attachment of a complex array of muscles. The mylohyoid, geniohyoid, digastric, mentalis, buccinator, and tongue musculature all have attachment to this part of the bone. Their presence helps to serve as an excellent recipient bed, but the forces they exert on the bone present problems in reconstruction and maintaining the contour of the bone. In the anterior region the muscle attachments serve a vital function in maintaining airway patency through attachment of the tongue musculature and support of the hyoid complex. The body of the mandible supports the alveolus and tooth-

bearing structures, and it has a critical relationship to the opposing jaw.

The alveolus of the mandible is the site of the functional component of the mandible, the dental occlusion. This portion of the mandible is dependent on the position of the mandibular body for its relationship to the maxillary arch. The alveoli need proper height and width to subserve the functions of the dentition. In the maxilla the alveolus is in relationship to the maxillary sinus and nasal cavity, and this relationship alters reconstructive efforts. In the anterior portion of the jaws this alveolar component is essential to maintaining position of the overlying soft tissue, especially the lips. Loss in this area or inadequate reconstruction can lead to both functional and esthetic deficiencies.

The maxilla, or upper jaw (Figure 39-2), is a complex bone comprising the bulk of the midface. It has relationships with the opposing mandible, the orbital complex, paranasal sinuses, zygoma, and nasal cavity. The palate forms the roof of the mouth and serves to partition the oral and nasal cavities. Incomplete reconstruction of the palate leads to hypernasal speech and regurgitation of the oral cavity contents, unless obturated. The paucity and quality of soft tissue surrounding this region makes bony reconstruction especially difficult. At the posterior aspect of the maxilla, a complex array of muscles attaches and subserves the functions of the

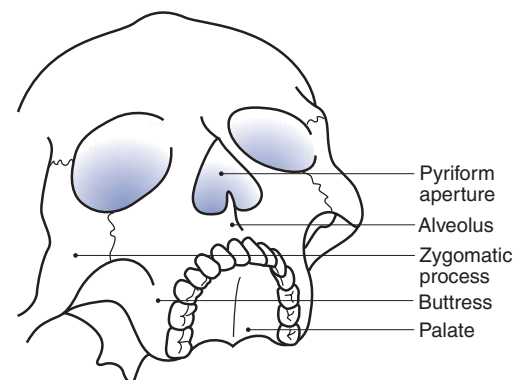

FIGURE 39-2 Maxillary regions.

soft palate. These attachments are involved not only in speech and swallowing but also in eustachian tube function. In the alveolar portion of the maxilla, the relationship to the maxillary sinus is an often-confounding factor in reconstruction. Highly pneumatized sinuses provide little support for grafting procedures. In the anterior region of the maxilla, support for nasal and orbital structures is required for maintaining nasal airway support and facial contour and esthetics for the nose.

Defects of the Mandible

Defects of the mandible can involve single subsets of the mandible, several segments, or the entire mandible. Marginal defects involve loss of the mandibular bone with the inferior and posterior portions left intact. In marginal defects the continuity of the mandible is intact, and reconstructive efforts are focused on maintaining bulk and contour. Segmental defects involve loss of mandibular bone and either the posterior or inferior border and confer a continuity defect of the mandible. Descriptions of the size of the defect are usually expressed in centimeters, measured at the inferior border. This measurement will serve as a guide in estimating the amount of bone necessary to reconstruct the defect. Segmental defects can cause a wide variety of reconstructive challenges, depending on their anatomic location. Small lateral continuity defects are surprisingly well tolerated, and following ablative procedures, it was not unusual to defer or omit reconstructive techniques. Segmental defects of the anterior mandible, however, are not well tolerated because of unfavorable anatomic and biomechanical features. Maintenance of tongue position and interramal width are severely compromised with large anterior segmental defects. The defects need to be interpreted not only in terms of their relationship to the rest of the mandible but also in relation to the opposing maxillary structures, both dental and nondental.

Identifying and categorizing defects of the mandible in terms of both size and extent represent the first step in bony reconstruction of the lower jaw.

Defects of the Maxilla

Defects of the maxilla can be divided into those that disrupt partitioning of cavities and those that represent inadequate bulk or position of bone in one of the subsets. Partitioning disruptions need to be evaluated in terms of both size and location. Small defects in the bone interfering with partitioning can be managed by soft tissue procedures only and may not necessarily need to undergo bony reconstruction. Larger defects in bone interfering with partitioning can be successfully obturated by maxillofacial prostheses and, similarly, may not need bony reconstruction. Many reconstructive options exist for these types of defects. The demands of occlusal restoration or stability of the upper jaw represent the majority of needs for bony reconstruction. Positioning of the upper jaw segments can be managed through orthognathic surgery, which is not the focus of this chapter. With defects in the alveolar portion of the jaws, evaluation of adequate bone in terms of height, width, and relationship to bone in the opposing mandible is the critical first step in reconstruction of the upper jaw.

Limitation of Bony Reconstruction

Bony reconstruction of the jaws depends largely on the amount of soft tissue available. Soft tissue coverage and recipient bed nourishment need to be addressed prior to any bony reconstruction. The soft tissue evaluation and management should precede any efforts at bony reconstruction. The limitations of bony reconstruction lie largely in the imagination and skills of the practitioner. Host limitations relate to the existing soft tissue envelope in terms of both bulk and blood supply and systemic factors in the patient. Identification of all

factors influencing outcome will be a critical step in determining choice of best methods for bony reconstruction.

Bone Biology

The hallmark of reconstruction of the jaws is the grafting of bone into sites of loss or need. Bone, unlike most other tissues of the body, heals not by formation of scar tissue but by regeneration of bone. Advances in the understanding of bone physiology, immunologic concepts, and technology have made successful reconstruction of the jaws possible and somewhat predictable. The success of jaw reconstruction today is several times what it was only three decades ago. Bone reconstruction on a physiologic level is accomplished by combinations of three processes: osteogenesis, osteoconduction, and osteoinduction. Osteogenesis is the formation of new bone from osteocompetent cells. Osteoconduction is the formation of new bone along a scaffold from the host's osteocompetent cells. Osteoinduction is the formation of new bone from the differentiation and stimulation of mesenchymal cells by the bone-inductive proteins.

The understanding of the basic biologic processes in bone has blossomed over the past thirty years. Key discoveries in the bioactive molecules began with the findings of Urist and Strates relating to the bone morphogenetic proteins (BMPs).^{5,6} BMP is not a single protein but a family of proteins belonging to the transforming growth factor- β superfamily (TGF- β). At least 13 BMPs have been identified (BMP-1 does not belong to the TGF- β superfamily). The ones that are of clinical interest and are involved in human bone metabolism are BMP-2, BMP-4, and BMP-7 (also called osteogenic protein 1 [OP-1]).⁷ As with most biologic systems, antagonists to these molecules exist for biologic regulation.⁷⁻¹⁴ These antagonists called noggin, chordin, gremlin, dan, and cerberus are proteins that bind to BMPs and thus govern cartilage and skeletal morphogenesis.¹⁵

BMPs 2, 4, and 7 have effects on stem cells and osteoblast precursor cells to convert them to mineralizing osteoblasts. BMPs bind and initiate a cell signal through a transmembrane receptor complex and generate an intracellular response involving Smad proteins that promotes osteoblast differentiation. The Smad proteins function as inducible transcriptional activators associated with a component that binds deoxyribonucleic acid (DNA) when they enter the osteoblast nucleus. Research into the specific genes activated is an active area of work and definitive elucidation of the mechanisms is ongoing.

Bone Grafting Biology

Axhausen initially described the repair of bone and divided it into two phases.¹⁶ The first phase consists of cellular proliferation and production of osteoid in a disorganized fashion. The second phase is characterized by resorption of the osteoid and replacement by more organized lamellar bone. During the first phase of bone regeneration the transplanted cells within the graft proliferate and form new osteoid over the course of a few weeks. The amount of bone regeneration is dependent on the amount of bone cells that survive the transplantation procedure. These cells' survival is integrally related to the nourishment from the recipient bed. For the first 3 to 5 days diffusion by plasmatic circulation is the source of nutrients; by day 5, capillary ingrowth from the surrounding soft tissue and bone edges penetrate the graft.¹⁷

Free grafts of bone can be either cancellous, cortical, or corticocancellous blocks (Table 39-1). Within a graft, cancellous bone revascularizes sooner than cor-

ticocancellous or cortical block grafts. Endosteal osteoblasts proliferate and form osteoid on the surface of cancellous bone trabeculae.¹⁸ Those cells within the trabeculae may die as a result of their encasement in mineralized matrix and impaired diffusion through it. Osteocytes within their lacunae appear to survive if they are less than 0.3 mm from the surface.¹⁹ In cortical grafts, revascularization is much slower because the process follows preexisting haversian systems from the periphery into the interior.²⁰ A histologic difference in cortical grafts is the initiation of osteoclastic rather than osteoblastic activity. The osteoclasts will enlarge the haversian systems peripherally, then centrally. The haversian systems of a cortical graft will undergo significant resorption before osteoblastic activity will fill in the resorbed areas. The process of osteoclastic resorption followed by osteoblastic deposition is termed "creeping substitution." New bone may be deposited throughout the graft, leaving areas of necrotic bone covered by viable bone. The necrotic bone areas may persist indefinitely.²⁰ The osteoid from the transplanted cells and from the endosteum fuse in a process called consolidation.

A second phase of bone growth follows the initial consolidation and begins at about 2 weeks. Fibroblasts and other mesenchymal cells differentiate into osteoclasts and begin a resorption of the osteoid. This differentiation of cells is accomplished by BMPs found in the transplanted bone. New bone is laid down in a more orderly fashion. The two-phase theory of bone healing applies to all types of autogenous grafts. In summary: (1) cancellous grafts are revascularized more rapidly than cortical grafts, (2) cancellous bone incorporates by an appositional phase followed by a resorptive phase but cortical grafts incorporate by a resorptive phase followed by an appositional phase, and (3) cancellous grafts tend to repair completely whereas cortical grafts remain a mixture of necrotic and viable bone.

Table 39-2 Bone Grafts

Autogenous grafts: free grafts, composite grafts
Homologous grafts (allografts)
Heterogeneous grafts (xenografts)

Bone grafts improve in their mechanical properties over time. Cancellous bone grafts tend to be strengthened over time with the addition of new bone. As the necrotic cores are replaced, the strength of the bone returns to normal. Cortical grafts have a different time course and actually undergo a weakening of the bone during the osteoclastic phase. Cortical grafts have been shown to be 40 to 50% weaker than normal bone from 6 weeks to 6 months following transplantation, a period in which the porosity of the graft increases approximately 15%.²¹ After 1 to 2 years the mechanical strength becomes equal to normal bone.

Other sources of bone are available for grafting, but none has surpassed autogenous grafts (Table 39-2). Grafts can be either homologous grafts (Table 39-3) (allografts) or heterografts (xenografts). The ability to obtain grafted bone without donor site morbidity to the patient has been a longtime goal of reconstructive surgeons. Autogenous bone grafts have been shown to be superior to allogeneic bone, xenogeneic bone, bone substitutes, and alloplasts in terms of the function, form, and adaptability.²² The superiority is due to the transfer of a greater number and density of osteocompetent cells.²³ Homologous grafts, also known as allografts or allogeneic grafts come from another person. Allogeneic grafts are genetically dissimilar and to avoid tissue rejection

phenomena must be rendered nonantigenic. These grafts serve a purpose merely as a scaffold for reconstruction and do not transfer osteocompetent cells. Grafts of the mandible can be used in conjunction with an autogenous cancellous graft with the allogeneic bone used as a scaffolding with desired contour, size, and shape.²⁴ There are many methods for rendering an allograft less antigenic including boiling, deproteinizing, merthiolating, freezing, freeze-drying, irradiating, and dry heating. The most common method used is freeze-drying (lyophilization). The major source of antigenicity in allografts is the cellular elements of bone. Boiling, drying, or chemically treating the bone will kill the cells but has a deleterious effect on coagulation of organic elements, reducing or eliminating their inductive effects and making their removal by host cellular processes difficult.²⁵ Heat in excess of 80°C destroys the biologic properties of the bone matrix.²⁶

Allograft materials have been used in several jaw reconstructive procedures, but their volume and lack of osteocompetent cells make their use limited.²⁷⁻³⁰

Alloplastic graft materials include hydroxylapatite crystals, bioactive glasses, calcium sulfate, beta tricalcium phosphate, and biphasic calcium phosphate.³¹⁻³³ Hydroxylapatites are the most commonly used alloplasts. Porous nonresorbable hydroxylapatite found in coral has been used but with only limited success. New bone can grow into the pores, but the nonresorbable coral matrix shields the new bone from stress and prevents it from maturing as well as might be desired.

Bone Morphogenetic Proteins

BMPs are an attractive restorative material. Although technically a graft, this material derives its ultimate effect by bone formation in the host. The role of BMPs in reconstruction of the jaws, indications for and limitations of their use, and the ideal carrier to deliver the material have yet to be

defined.³⁴⁻³⁷ The safety of BMPs has been studied extensively in orthopedic applications, with most of the studies having been conducted with grafting to the spine and reported in the orthopedic literature.³⁸⁻⁴⁰ With a goal to increase the available bone for placement of endosseous implants in the maxilla, BMPs have been placed into the maxillary sinus with collagen sponges as a carrier to induce new bone formation.^{41,42} With a similar goal in mind BMP-7 has been placed in fresh extraction sites prior to the placement of dental implants in dogs showing greater amount, density, and degree of remodeling of bone.⁴³ They have been placed in alveolar ridges with a resorbable collagen sponge as a carrier; however, safety and feasibility was assessed in only one study.^{44,45} They have also been placed with a poly(α -hydroxy acid) carrier into alveolar cleft defects in dogs with equivocal results.⁴⁶ Large mandibular defects (3 cm segmental) in animal studies have been reconstituted with BMPs.⁴⁷⁻⁴⁹ Only two human BMP studies have been published.^{42,50}

Autogenous Bone Grafting Sites

Intraoral Bone Grafts

Grafts that can be obtained from a local or regional site are attractive in that they are easily obtained, often in the same surgical field (Figure 39-3). They are, however, usually limited in size, quality, or cancellous bone content. Intraoral donor sites include the symphysis (chin), ramus, mandibular inferior border, mandibular body, coronoid process, and zygoma.⁵¹⁻⁶⁴ Limited amount of bone is available from these sites, and the amount of cancellous bone is sparse.

For harvesting of grafts from the chin either an intrasulcular or vestibular incision can be made. The periosteum and mentalis muscle are stripped from the chin region, and osteotomies are performed on the buccal surface beginning below the apices of the teeth. Alternatively a trephine can be used to obtain the graft. The mid-

line is usually left intact, and grafts can be harvested from the right and left sides simultaneously if necessary; graft volumes of 1 to 3 cc have been reported.³ A mild pressure dressing is applied to the chin region for 5 days. Temporary paresthesia of the chin has been reported in at least 43% of cases.⁶⁵

For harvesting of ramal grafts, several incisions can be used. In the edentulous patient a crestal incision is used extending posteriorly to the ascending ramus at the level of the occlusal plane. With healthy natural teeth, an intrasulcular incision is used, extending it posteriorly to the ascending ramus. When prosthetic crowns are present, consideration should be given to a submarginal incision along the mucogingival line, again extending to the ascending ramus. Following any of these incisions, a full thickness mucoperiosteal flap is developed along the lateral aspect of the mandible, exposing the lateral ramus of the mandible. A rectangular block of cortical bone up to 4 mm in thickness, up to 3.5 cm in anteroposterior dimension, and up to 1 cm superoinferiorly can be harvested. The medialmost osteotomy cut is lateral to the teeth and 4 to 6 mm medial to the external oblique line. The osteotomies can be cut with burs, saws, or a small diamond wheel (especially useful for the inferiormost cut). Using osteotomes and chisels the block can be

FIGURE 39-3 Intraoral bone graft donor sites.

removed. Alternatively, trephines can be used to obtain bone. Morbidity from this procedure includes fracture of the mandible, lingual or inferior nerve neurosensory disturbance, bleeding, and incision dehiscence, although these events are considered rare.⁶⁶

Cranial Bone Grafts

Cranial bone is a time-honored site for obtaining bone for grafting. Initially described for use in facial reconstruction by Tessier and refined by Jackson and colleagues, the technique can yield considerable amounts of cortical bone but limited amounts of cancellous bone.^{67,68} There is an age-dependent relationship of the development of diploic space in the calvarial bones: 80% of children have a diploic space by the age of 3 years, and when present it is less than 50% of its adult thickness.⁶⁹ The grafts can be harvested from either the inner or outer cortical tables and the procedure is well tolerated by patients. Fearon looked at postharvest magnetic resonance imaging (MRI) of the brain in 20 patients and did not detect any abnormalities, even though 3 of the patients had a full thickness breach.⁷⁰ The thickness of the bone should be at least 6.0 mm to consider in situ harvesting. Koenig and colleagues recommend not performing in situ bone graft harvesting from this site prior to 9 years of age.⁶⁹ Selection of the side of the head to use should be in the nondominant hemisphere. Grafts from the areas of the parietal bone are the most useful; although harvest from the frontal or occipital regions has been described, the temporal region should be avoided. The incision through the scalp for obtaining the graft can be either coronal (full or partial) or sagittal (Figure 39-4). The dissection of the scalp flap should proceed in the subgaleal plane, and then the pericranium of the calvaria should be incised sharply. The area of the graft is marked out with a bur staying at least 2 cm from the sagittal suture to avoid overlying the sagittal sinus

FIGURE 39-4 Exposure for cranial bone graft harvest.

or arachnoid granulations. The graft donor site should also be chosen to avoid other sutures.

For harvest of small areas of bone, a single block can be obtained (Figure 39-5). A bur is used to make initial cuts through the outer cortex of the calvaria. One side is beveled to allow insertion of a curved osteotome in a plane parallel to the outer surface and at the diploic level. For larger block grafts (Figure 39-6) it is advisable to bevel two or more sides to avoid inadvertent perforation of the inner cortex. When larger amounts of graft are needed it may be safer to harvest the bone as several strips, rather than a single block (Figure 39-7). Once the graft has been harvested the donor bed is checked to assure integrity of the inner cortex, and a piece of gelatin foam is placed over the site. The periosteum is reapproximated and the scalp closed in layers, with the galea being

FIGURE 39-5 A and B, Harvest of small cranial bone graft.

reapproximated. The skin can be closed with either staples or sutures.

For grafts from the inner table of the skull (internal table of calvaria), a formal craniotomy is performed and the bone flap is handled ex vivo (Figure 39-8). The graft is obtained from the inner cortex, and the flap is replaced after resuspending the dura then fixated.

In a series of 212 in situ cranial bone graft harvests, Zins and colleagues noted a 0.5% incidence of dural tear and a 2.4% incidence of dural exposure without tear.⁷¹ No infections, seromas, or bleeding were encountered in his series. In a large series of 12,672 cranial bone graft harvests, the total complications comprised only 0.18%.⁷² Inadvertent exposure of the dura (not reported as a complication) occurred in 11%.

Costochondral Grafts

Grafts from the rib are useful in that they contain both bony and cartilaginous tissues. The cartilaginous component is useful for providing an articular surface for the temporomandibular joint and for providing a growth center in growing patients. This source of bone, however, is limited by the size, curvature, and strength of the rib. For reconstructing the temporomandibular joint the contralateral rib usually has the more favorable contours. Ribs from either side can be harvested, but most surgeons prefer to use the right side over the left side

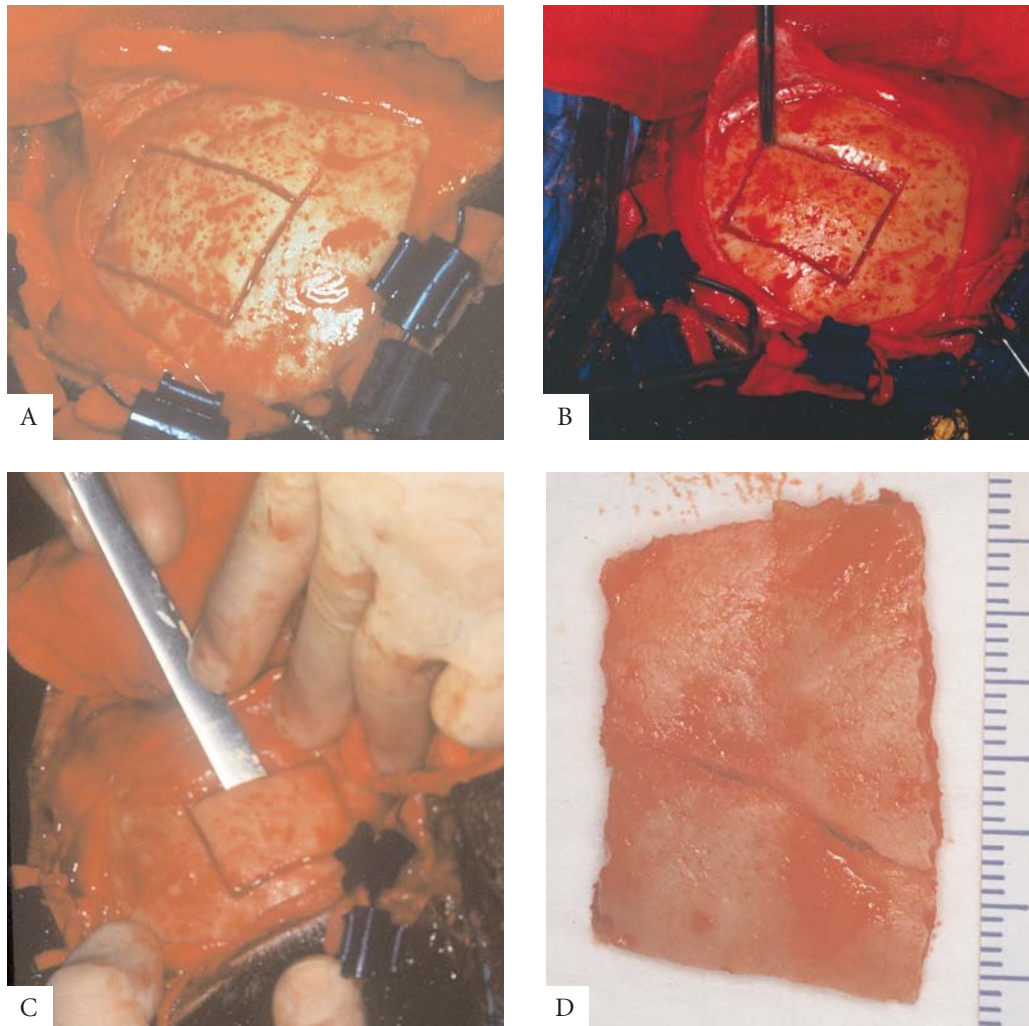

FIGURE 39-6 A to D, Harvest of a larger cranial bone block graft.

because of the position of the heart. An incision is used that corresponds to the submammary crease (Figure 39-9). This incision is well hidden in women and is a minor concern in men. The incision will

usually overlie the sixth rib. A curvilinear incision is used and the skin is incised sharply; sharp dissection is used to enter the plane overlying the ribs from the costochondral junction to the midaxillary line.

Either the fifth or sixth rib can be harvested. The sixth rib is usually the inferiormost origin of the pectoralis major muscle, and its use will entail the least amount of stripping of the muscle. A longitudinal incision is made over the bony portion of the rib, and a careful subperiosteal dissection is performed circumferentially around the rib. Care is to be used at the inferior and deep aspect of the rib to avoid the neurovascular bundle. Either saws or rib cutters can be used to divide the rib. The rib can be harvested with a variable amount of cartilage attached to the end. Once the rib is harvested the cut edge of the residual rib remaining in the patient is rounded to avoid sharp edges. Sterile saline is placed in the donor site, and the patient's lungs are inflated to assess for pneumothorax. The wound is closed in layers and a long-acting local anesthetic is administered to the harvest site.

Iliac Crest Bone Grafts

The ilium is the most preferred donor site for bone grafting. Grafts may be obtained from either the anterior or posterior portions of the bone. It contains the greatest absolute cancellous bone volume and has the highest cancellous-to-cortical bone ratio. Greater amounts of bone can be obtained from the posterior ilium. From a single side, the maximum amount of obtainable bone approaches 50 cc. From the posterior ilium, the maximum obtainable bone approaches 90 cc. Documented

FIGURE 39-7 A to C, Harvest of several cranial strip grafts.

FIGURE 39-8 A and B, Inner table cranial bone graft (arrow).

donor site complications include hematoma, seroma, nerve and arterial injuries, gait disturbances, fractures of the iliac wing, peritoneal perforation, infection, sacroiliac instability, and pain. Major complications have been reported to be less common (0.7–25%) than minor ones (1.8–15.4%). The reported prevalence of complications following anterior or posterior iliac crest bone grafting has varied.⁷³

Harvest of the anterior iliac crest bone graft begins with site selection. Harvesting of the graft from the ipsilateral or con-

tralateral side from the recipient site is largely determined by positioning of the patient relative to the rest of the operating room team. A separate field is used to avoid contamination of donor and recipient sites, and the contralateral side is usually preferred. The anatomic landmarks of the anterior superior iliac crest and relative position of nerve structures are marked (Figure 39-10). The nerve branches that are most at risk are the lateral cutaneous branch of the subcostal nerve (T12) and the lateral cutaneous branch of the iliohy-

pogastric nerve (L1). The lateral femoral cutaneous nerve is located anterior and medial to the anterosuperior iliac tubercle; careful delineation of landmarks will avoid damage to this nerve. Anesthesia or paresthesia of the skin following harvesting of iliac crest bone grafts has ranged from 8 to 38% of patients.^{73–78} The skin overlying the iliac crest is gently pulled superiorly and medially to allow the incision to rest in a position inferior and lateral to the prominence of the bone. The resultant scar should be in a position where it is not rubbed or chafed afterward by a belt or clothing (Figure 39-11A). The incision is made parallel to the crest of the iliac bone and approximately 2 cm posterior to the anterosuperior iliac tubercle. A 3 cm incision is usually adequate to gain access to the iliac bone. The skin is incised sharply down to the subcutaneous fat. Using electrocautery, the subcutaneous tissue is incised down to the fascia overlying the fascia lata and external oblique muscles. An incision is made along the crest of the bone down to and through the periosteum. This incision can usually be made with minimal cutting into the muscle fibers. Once the incision is made through the periosteum, the subperiosteal dissection can proceed onto the medial or lateral surfaces of the ilium, depending on the approach used and the need for a multilaminar graft. In the anteromedial approach the subperiosteal dissection continues onto the medial side of the bone (Figure 39-11B). Care is taken not to strip muscle from the lateral surface of the ilium. Keeping the tendons of the tensor fascia lata attached to the ilium minimizes gait disturbances and pain. Acute ambulation difficulty has been reported in as many as 50% of patients immediately following iliac crest bone harvest, with long-term ambulation difficulty ranging from 3 to 12.7%.^{75,78,79} A Bennett retractor is helpful to protect the iliacus muscle and peritoneal contents.

In the anterolateral approach, the periosteum is stripped from the lateral

surface of the ilium for easier access but at a cost of increased incidence of gait disturbance. Once the ilium is exposed by any approach, the bone can be harvested as a corticocancellous block graft, a cortical graft,

or a cancellous graft (Figure 39-11C–F). The size of the graft is outlined, and using saws, osteotomes, or a bur, osteotomies are performed. The cancellous graft can be harvested with curettes, gouges, or trephines.^{74,79–82} Hemostasis is obtained with the use of gelatin foam or other hemostatic agents if necessary. Use of drains at the donor sites of either posterior or anterior approaches is not indicated; and no difference has been shown in wound healing.⁸³ Injection of a long-acting local anesthetic agent into the overlying soft tissue provides some comfort in the immediate postoperative period.⁸⁴

Harvest of the posterior iliac crest is another well-documented source for bone.^{85–88} Patient positioning in the supine position for most maxillofacial procedures involves a patient repositioning when posterior iliac crest bone is harvested. Larger amounts of bone available from this approach may make it worthwhile to consider this option. The patient is positioned in the prone position with a small amount of flexion and placement of a hip roll. The

landmarks identified are the spinous processes of the vertebra and the posterosuperior iliac crest and spine. A 5 cm curvilinear incision is made through the skin overlying the iliac crest. Nerves at risk are the superior and middle cluneal nerves (L1 to S3). Using sharp and blunt dissection through the subcutaneous tissues, the posterosuperior crest is identified and the fascia divided between the abdominal and gluteal muscles. A subperiosteal dissection proceeds, and the tissue is reflected laterally. Care is used to avoid the sacroiliac ligaments. Bone can be harvested as a corticocancellous block graft, a cortical graft, or a cancellous graft similar to the approach to the iliac crest. Complication rates for posterior iliac crest bone harvest are, in general, lower than those for anterior harvest.^{73–77,79}

Tibial Bone Graft

The tibial metaphysis is another important source of autogenous bone. O’Keefe and colleagues reported the first large series (230 cases) using the tibia as a donor site.⁸⁹ They found adequate bone for grafting

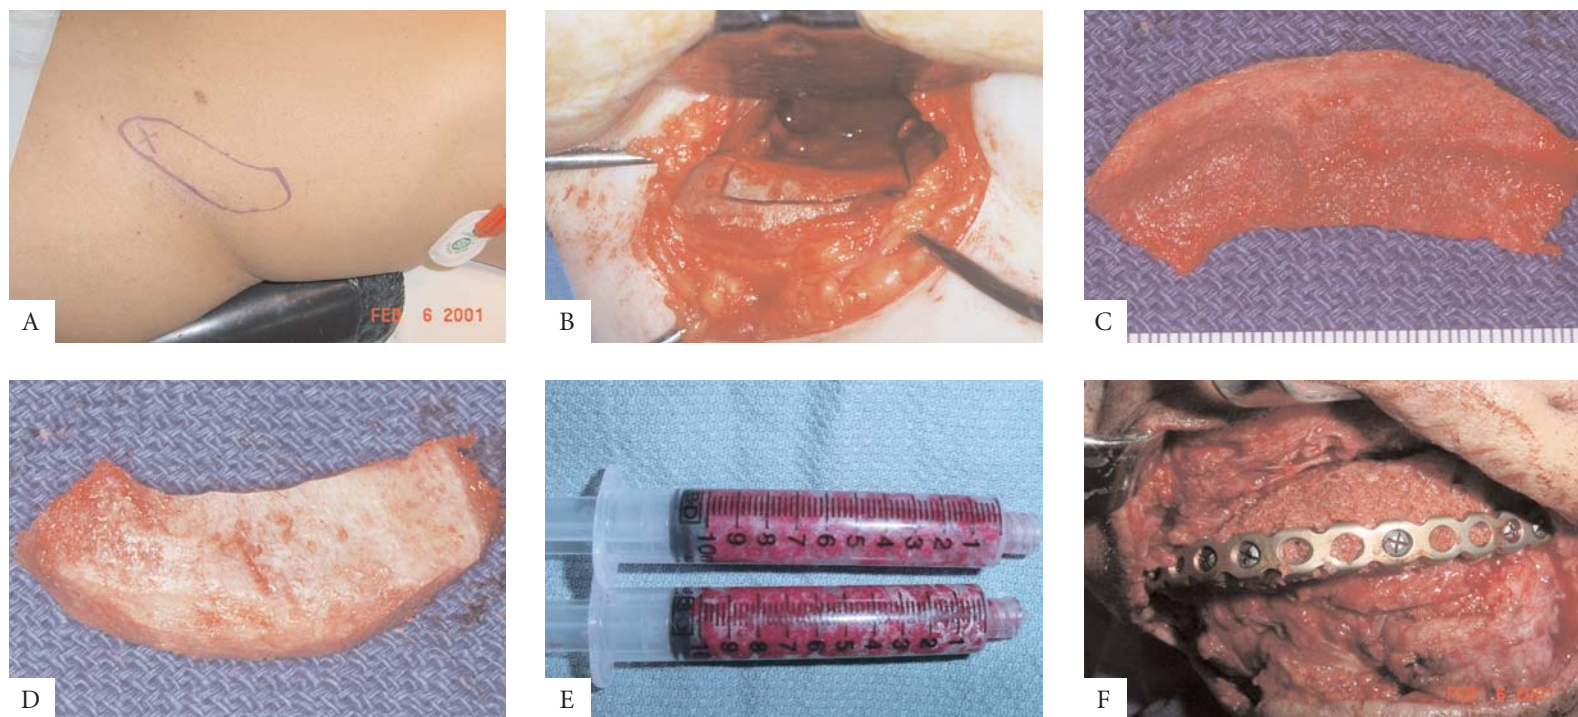

FIGURE 39-11 A, Landmarks for obtaining graft. B, Osteotomies for harvest. C, Corticocancellous grafts. D, Cortical surface of graft. E, Cancellous graft. F, Cancellous graft applied.

and a low incidence (1.3%) of complications, none of which were long-term. The tibial region heals exceptionally well, but radiographic findings in the donor site may persist indefinitely.⁹⁰ The use of this site is relatively contraindicated in growing patients because of the risk of disturbance to a growth center site, although its use has been reported in the repair of alveolar clefts.⁹¹ Catone and colleagues described the use of tibial bone in maxillofacial surgery and was able to obtain up to 42 mL of uncompressed cancellous bone per site.⁹² Bone from the tibial site was successfully used to graft mandibular nonunions, in orthognathic surgery, as a sinus augmentation, and in mandibular reconstruction. Comparison of tibial grafts against iliac crest grafts in secondary alveolar clefts shows similar bone densities at 6 months.⁹¹

The graft is usually harvested with the patient in the supine position, although the graft can be harvested with the patient in the prone position.⁸⁹ A 3 cm longitudinal and slightly angled incision (Figure 39-12) is made through the skin overlying Gerdy's tubercle. Gerdy's tubercle is a prominence of bone on the anterior surface of the proximal end of the tibia located lateral to the tibial tuberosity. It is the distalmost insertion of the iliotibial tract. Sharp dissection is used to obtain a suprapariosteal dissec-

FIGURE 39-12 Incision for tibial bone graft.

tion overlying and inferior to Gerdy's tubercle. The dissection should be medial to the tibialis anterior muscle and lateral to the patellar ligament. If a cortical graft is desired, the dissection can proceed in a subperiosteal plane, exposing Gerdy's tubercle.⁸⁹ If no cortical bone is required, an osteoperiosteal flap can be created by incising through the periosteum in a "U" shape, leaving periosteum attached to the cortex.⁹² A cortical window is made with burs, saws, or osteotomes measuring 1 cm by 1 cm. The window should incorporate the crest of the tubercle at the superior portion of the window. The crest represents a simple and reliable landmark to avoid the articular surface of the tibia and the joint space. It is recommended to keep at least a 2 cm distance from the articular surface of the tibia to avoid damage.⁹³ A medial approach to the tibia has also been advocated that avoids the insertion of the iliotibial tract and several other anatomic landmarks.^{94,95} In the medial approach, the landmarks are two lines: one vertical line drawn through the patella and tibial tuberosity and the other perpendicular to the first, through the tibial tuberosity. It is recommended that an oblique skin incision be made centered over a point 15 mm superior to the horizontal line and 15 mm medial to the vertical line.⁹⁵ Dissection continues through the periosteum overlying the bone underneath the incision. A bone window is made to provide access to the cancellous bone. Regardless of the approach (medial vs lateral) used, once the window has been removed or elevated, the cancellous bone can be harvested with curettes. Equal amounts of bone are available from either lateral or medial approaches.⁹⁵ For larger volumes of grafts, bilateral grafting can be done, with some possible impairment to early ambulation. No attempt is made to fill the metaphyseal dead space, and no drains are used. The wound is closed in layers. If smaller amounts of bone are needed (< 15 cc), the procedure can continue through a small stab incision and with use

of a trephine or curettes.^{92,96} van Damme reported up to 40 cc of cancellous bone obtained through this method.⁹⁶

Microvascular Free Flaps

Many microvascular free flaps have been described for reconstruction of the mandible and maxilla, including the fibula, iliac crest, and scapula. Free microvascular flaps have the advantage of having their own blood supply independent of the local tissue bed, and they behave as a microvascular transfer of tissue, except where they interface with the existing recipient bone. In areas of poor vascular supply they have superiority over other bone grafts. Additionally they may be transferred as composite grafts including soft tissue components. A detailed discussion of microvascular free flap reconstruction is presented in Chapter 40, "Microvascular Free Tissue Transfer."

Platelet-Rich Plasma

With the advent of blood factor fractionation in hematology and the search for hemostatic agents, interest has increased in platelet-rich plasma (PRP) fractions. PRP is a volume of autologous plasma that has a platelet concentration higher than normal. In general, PRP contains $> 1 \times 10^6$ platelets/ μL . In clinical practice, PRP is applied to the site of a bone graft to deliver a high concentration of growth factors from platelets.⁹⁷ Once the PRP-containing high concentrations of fibrinogen and platelets are mixed with thrombin and calcium, a gel is formed resulting in the release of growth factors from the platelet (α) granules. Within 10 minutes the platelets secrete 70% of their stored growth factors and close to 100% within the first hour.⁹⁸ The platelets then synthesize additional amounts of growth factors for about 8 days until they are depleted and die. The precise content and concentration of growth factor has yet to be fully elucidated. The α -granules of platelets release at least seven growth factors, including platelet-derived growth factor, TGF- β , platelet-

derived epidermal growth factor, platelet-derived angiogenesis factor, insulin-like growth factor-1, and platelet factor-4.⁹⁹ There is a complex interplay between the growth factors that depends on their concentration, local microenvironment, and interactions with other molecules. Many of these growth factors can have effects that are in opposite directions depending on the context of expression.¹⁰⁰ The PRP constellation of growth factors allows the complex interplay of these agents to be exploited to better advantage than relying on a single growth factor agent.

PRP is an autologous preparation; therefore, the risk of disease transmission from its use should theoretically be nil. There has been some concern about the antigenicity of the bovine thrombin used, although this has not been a problem in maxillofacial applications.¹⁰¹ It is believed that some of the antigenicity attributed to thrombin results from contamination from bovine factor V in the thrombin preparation. Another gelling agent, ITA, has been used in place of bovine thrombin but its constituents are proprietary and unknown.¹⁰²

There are several systems for preparing PRP (Figure 39-13) ranging from the simple to the complex, from those that require whole units of blood to those that require only 50 mL. The most complex are the general-purpose cell separators that are widely used by blood banks and hospitals. Using a plasmapheresis technique, 450 mL of whole blood is drawn off into a collection bag containing an anticoagulant, usually citrate phosphate dextrose. Other anticoagulants are available; anticoagulant citrate dextrose-A is also used and may be preferred.⁹⁸ Edetic acid is avoided since it fragments the platelets.¹⁰² The preparation is then centrifuged first at high speed to separate the plasma from the red cells and the buffy coat. The centrifuge is then slowed down and run for a period of time to further separate the PRP and the platelet-poor plasma (PPP). Approx-

FIGURE 39-13 A, Machine for harvest of platelet-rich plasma. B, Fractionated sample containing platelet-rich plasma.

mately 30 cc of PRP can be obtained from the sample in about 30 minutes. Platelet counts of 0.5 to $1.0 \times 10^6/\mu\text{L}$ can usually be attained with this method. It is recommended that the PRP be used within 6 hours of being procured. Once developed, PRP is stable and remains sterile in the anticoagulated state for 8 hours.⁹⁸

In a quest to achieve a concentrated delivery of platelets at a reasonable cost, several systems were developed that use smaller procurements of whole blood, are faster, produce more concentrated product, and are less expensive.^{97,102,103} Two of the units that are currently approved by the US Food and Drug Administration are the Harvest SmartPrep Platelet Concentrate System and the 3i Platelet Concentrate Collection System. These systems both use tailored centrifuge containers to manipulate the blood cells to achieve the separation and sequestration of platelets. They both have long and short spin cycles. Average platelet counts of 1.4 to $1.8 \times 10^6/\mu\text{L}$ are obtained in a 5 mL sample.⁹⁹ Run times for the preparation are usually 15 to 20 minutes.

Once the PRP has been prepared, the coagulation process is initiated using a mixture of 100 US units of topical bovine

thrombin (TBT) powder suspended in 10 mL sterile saline and 10% calcium chloride. In a 10 cc syringe, 6 mL of PRP is mixed with 1 mL of 10% CaCl_2 , 1 mL TBT, and 1 mL air for mixing. The mixture is applied to the bone grafts in a layered fashion. Some of the newer systems have special syringe tips that combine the constituents from several syringes simultaneously. Once applied, the mixture sets in a matter of minutes.

There is a paucity of strong clinical data to support many of the claims being made for PRP in the jaws; only one prospective trial is published.¹⁰⁴ The majority of the publications are case series or case reports. Marx and coworkers evaluated the effect of PRP on bone graft reconstructions of mandibular continuity defects 5 cm or greater, showing a maturity index of about twice actual maturity at 2 and 4 months.⁹⁷ In a case series of 15 patients, PRP has been added to freeze-dried demineralized bone to augment the maxillary sinus and alveolar ridge.¹⁰⁵ The authors posit that use of PRP may allow for earlier implant placement and loading, but this conclusion will require further study to be supported. In another cases, 24 maxillary sinuses were

augmented with a combination of PRP and deproteinized bovine bone along with simultaneous insertion of endosseous implants.¹⁰⁴ In three of these cases bone density measurements made at 4 months showed increased density compared with the surrounding native bone. Only preliminary data are available to date on the histologic evaluation of the PRP-augmented sinuses.^{106,107} A case report of use of PRP with autogenous bone and a titanium mesh for a large anterior maxillary defect has also been described.¹⁰⁸ Fourier and fractal analysis of radiographs of maxillary alveolar ridge repair using PRP and inorganic bovine bone showed trabecular patterns of the regenerated bone similar to but lower in complexity than the native bone, which the authors attributed to the PRP.¹⁰⁹

Hyperbaric Oxygen Therapy

After success with treating osteoradionecrosis of the mandible with hyperbaric oxygen therapy, the modality was applied to patients undergoing mandibular reconstruction.¹¹⁰ Applying fairly stringent success criteria, a rate of 94% was reported. Hyperbaric oxygen therapy consists of breathing 100% O₂ at 2.4 atm for 90 minutes, commonly referred to as a dive. Protocols for reconstructive procedures differ from those used to treat osteoradionecrosis and consist of 20 dives preoperatively and 10 dives postoperatively.

The mechanisms by which hyperbaric oxygen therapy exerts its effects are biochemical, cellular, and physiologic.¹¹¹ During a dive, arterial oxygen tensions in excess of 2,000 mm Hg, and tissue oxygen tensions of almost 400 mm Hg have been attained. Physiologically at 2.4 atm, oxygen not only saturates the available hemoglobin but dissolves in the plasma to more than 10 times the amount at sea level (0.3 mL/dL). Tissue irradiated beyond 5,000 cGy exhibits hypoxia, hypovascularity, and hypocellularity. This predisposes the tissue to infection and poor wound healing in addition to making it a poor donor bed for a bone

graft. Hypoxia inhibits and decreases the neutrophil-mediated killing of bacteria by free radicals. Tissue PO₂ levels in irradiated patients have been documented as low as 5 mm Hg and often range between 5 and 15 mm Hg. During hyperbaric oxygen therapy the tissue PO₂ rises to between 100 and 250 mm Hg but falls to baseline within 10 minutes following a dive in the initial period of therapy. Improved collagen formation and fibroblast proliferation occur when the tissue oxygen tension is raised over 20 to 30 mm Hg.¹¹² Capillary proliferation occurs along collagen laid down following hyperbaric oxygen exposure. As this neovascularization spreads, tissue oxygenation improves between 20 and 35 mm Hg in the hours after treatment. The improvement plateaus after 10 to 20 dives; dives beyond this time do not marginally improve the host bed.

Complications of hyperbaric oxygen therapy include reversible myopia; barotrauma to the middle ear, lungs, teeth, and sinuses from rapid pressure changes; seizures (self-limited and causing no permanent damage); claustrophobia; reversible tracheobronchial symptoms (chest tightness, substernal burning sensation, and cough). No evidence of a tumorigenic effect of hyperbaric oxygen has been found to date.¹¹³

Reconstruction of the Mandible

Reconstruction of the mandible can occur immediately at the conclusion of an ablative procedure of the jaw (primary reconstruction); delayed (secondary), after an appropriate time of primary soft tissue healing; or, in the case of developmental or gradually acquired defects, at the time of recognition of the need for reconstruction. The first step in reconstruction is to classify the defect determined by its size, location, and functional or cosmetic impairment. The size of the defect in three dimensions will define the magnitude of the reconstruction. Small defects of the alveolus may require limited bone grafting, while larger defects may require more extensive or

staged procedures. Some defects may not necessarily be restored to the original size and bulk of the missing part. Loss of a significant portion of a ramus may be adequately managed by providing continuity from the condyle to the body of the mandible without restoring a coronoid process or several centimeters of anteroposterior width. The bulk of the bone need only be enough to provide for adequate strength to manage the functional loads. Location is important as some defects may not need to be restored, such as the very posterior of the body of the mandible (distal to the first or second molar) where no plan is made for restoration of the dental occlusion of the mandible or opposing dental arch. The functional deficits that exist and those that are to be addressed play a role in the choice of reconstruction.

Once the area of bony defect has been defined and the assessment of how much bone to reconstruct has been determined, attention should be directed to how to best achieve these goals. The available soft tissue in terms of quantity and quality is paramount in choosing a reconstructive method. Indeed the soft tissue will determine to a large extent the available options. If the soft tissue is adequate in both of these parameters, the options will be many. If, however, the soft tissue is inadequate in size or bulk, efforts will need to be made to provide adequate soft tissue before undergoing bony reconstruction. This can be accomplished by introducing more soft tissue through local flaps, pedicled flaps, or microvascular free flaps. Composite flaps are an option for simultaneous hard and soft tissue reconstruction. Techniques such as distraction osteogenesis can provide increased bone and soft tissue simultaneously like the composite grafts. If the quantity of soft tissue is adequate but the quality of the soft tissue is poor, the reconstruction will be compromised or the options limited. Tissue that has been irradiated or has extensive scarring will provide a poor host bed for any

grafting procedures. Adjunctive procedures such as hyperbaric oxygen therapy or soft tissue flaps may be necessary to provide an adequate donor bed.

The functional and esthetic requirements will dictate the goal to be accomplished; multiple-stage procedures are the norm rather than the exception.

Reconstruction of the Maxilla

The same general parameters in approaching the mandibular reconstruction are operative in the maxilla. Identification of the goals of reconstruction will dictate the course of reconstruction to take. Once the goal has been delineated, attention is first given to the soft tissue envelope to support bony reconstruction of the maxilla. Appropriate grafting procedures are undertaken, and provision is made for interim prosthetics. The following cases illustrate specific points of consideration in reconstruction of the areas of the jaws.

Case Example 1: Reconstruction of Large Traumatic Mandibular Defect

The patient is a 17-year-old man who suffered a gunshot wound to the anterior mandible with loss of both hard and soft tissue (Figure 39-14). The maxilla was unaffected. The first step in this case is to define the defect in terms of both hard and soft tissue and decide on a strategy for reconstruction. As this is a contaminated

FIGURE 39-14 Gunshot wound to mandible.

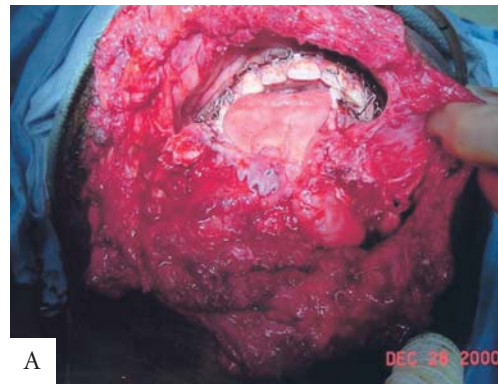

FIGURE 39-15 A and B, Débridement of nonviable hard and soft tissues.

wound with ill-defined areas of vital hard and soft tissue, delayed reconstruction is the preferred option. Débridement of free bone fragments and grossly nonperfused soft tissue will enhance the rapidity of primary healing (Figure 39-15). Once the débridement is complete, the bone components are aligned using available dental landmarks (Figure 39-16) and soft tissue components are reapproximated (Figure 39-17). To aid the ease of reconstruction, anatomic relations are maintained and stabilized with fixation devices (Figure 39-18) to preserve interramal width. At this time a more accurate assessment of soft tissue and bone deficits can be appreciated in three dimensions. There is a segmental mandibular defect with inadequate soft tissues and an opposing dental arch. The functional requirements for reconstruction include (1) restoration of continuity of the mandible, (2) adequate bone height and width to allow restoration of the occlusion, and (3) restoration of mandibular morphology for esthetic and functional requirements. Because of the avulsive nature of the defect, the soft tissue is inadequate in terms of quality and quantity. A period of weeks to months may be required for the soft tissues to mature and heal. Before bony reconstruction can begin, soft tissue must be brought in to provide for an adequate recipient bed for grafting and restoration of contours. In this otherwise healthy individual, autogenous grafting will most effectively supply the adequate bulk and form nec-

essary to achieve the goals. A pedicled myocutaneous graft (pectoralis major) with a skin paddle will provide the blood supply to nourish the graft and to provide adequate bulk of skin in the chin region. The residual bilateral condyle-ramal complexes will be stabilized with a titanium reconstruction plate (Figure 39-19). An appropriately sized skin paddle will restore

FIGURE 39-16 Alignment using dental landmarks.

FIGURE 39-17 Reapproximation of skin and mucosa.

FIGURE 39-18 A and B, Stabilization with external fixator.

FIGURE 39-19 Stabilization of mandible with titanium reconstruction plate.

the missing skin over the chin (Figure 39-20). The muscle is positioned to restore bulk to the region and to approximate the area of the future bone graft. The soft tis-

ues are then allowed to heal over several weeks prior to definitive bone grafting (see Figure 39-20D). Both allografts and autografts will be used, with a cadaveric mandibular crib (Figure 39-21) secured to the reconstruction plate used to maintain the proper morphology of the mandible. A cancellous marrow graft is obtained to provide adequate bulk (Figure 39-22). Restoration of the contours and functionality of the mandible results at the completion of the reconstruction (Figure 39-23).

Case Example 2: Delayed Reconstruction of an Ablative Defect of the Mandible

A swelling with associated radiolucency of the mandible is noted (Figure 39-24). Both

the medial and lateral cortices have been destroyed in the area of the lesion. Because of the location and size of the defect, reconstruction of the defect is indicated to restore bulk and strength of the residual mandible following treatment. After adequate soft tissue healing, an anterior iliac crest cancellous bone graft is obtained and placed in the defect (see Figure 39-24B). One year following reconstruction, the bone graft has matured with a normal trabecular pattern. The graft is maintained and the bone is adequate for oral rehabilitation 2 years after grafting (see Figure 39-24E).

Case Example 3: Reconstruction of the Anterior Maxilla

A 37-year-old man had undergone avulsive trauma to the anterior maxilla during a motor vehicle accident. The residual defect was from the loss of anterior maxillary teeth and a large portion of the alveolus (Figure 39-25A). Dental models were obtained, and a diagnostic wax-up was prepared to assess the ideal position of the restored teeth. The bony reconstructive effort is therefore guided by the prosthetic plan so that adequate bulk and position of the grafted bone can be assured. The defect in the upper jaw consisted of inadequate bone in terms of height and width and inadequate soft tissues. No oral–nasal cavity partitioning defect existed. A wide pedicled flap is raised

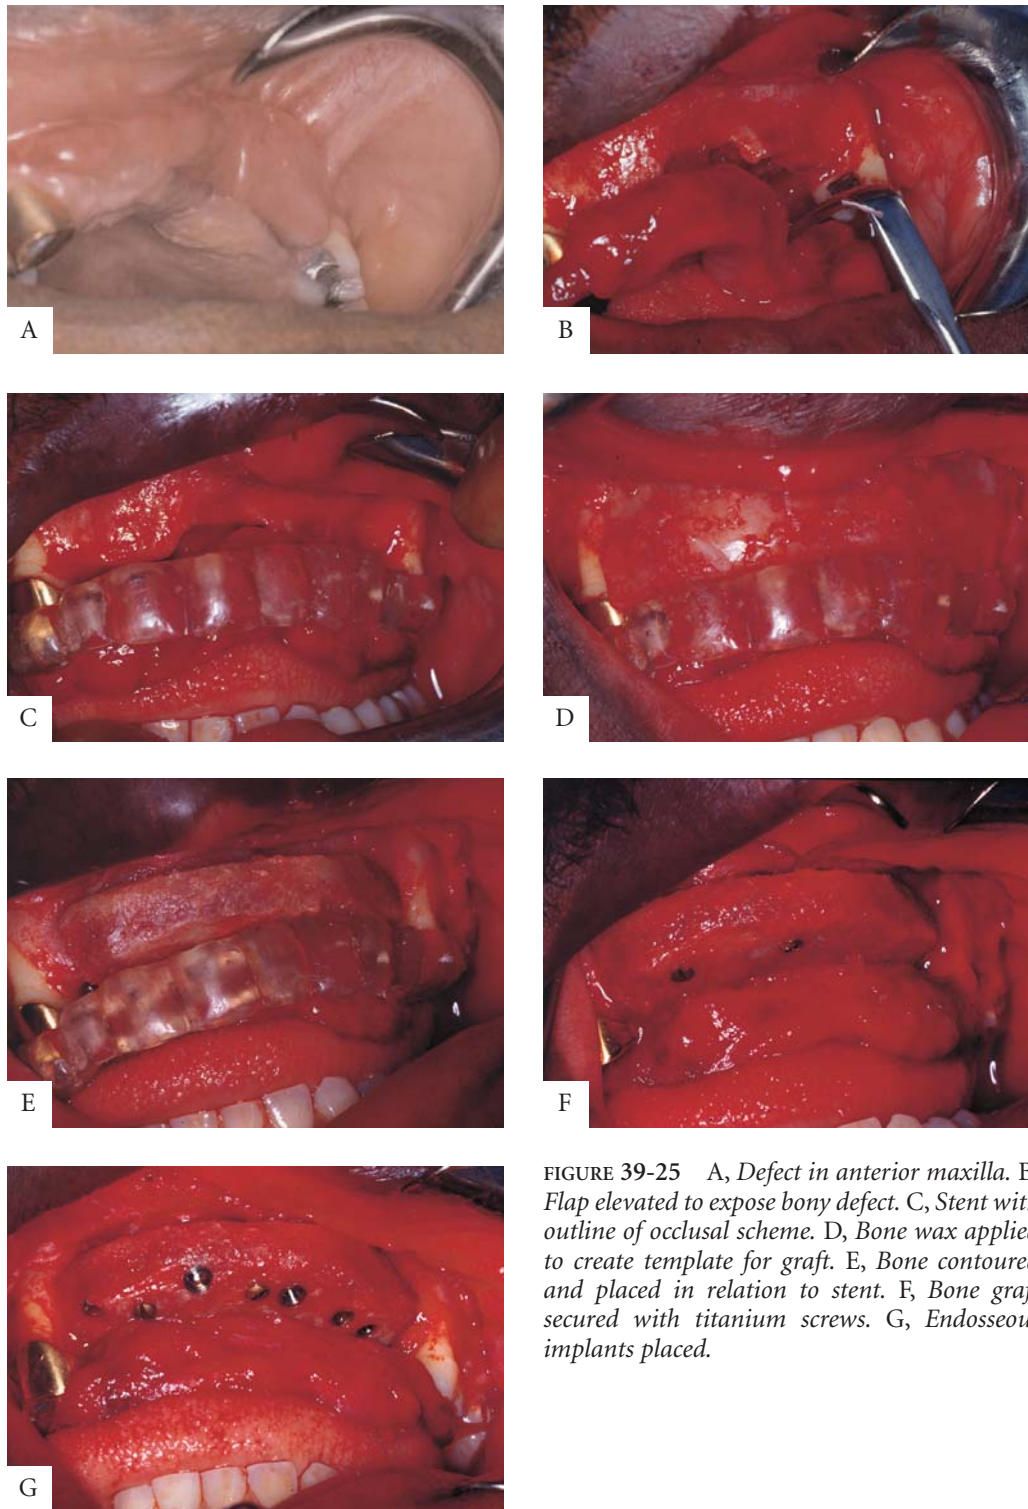

FIGURE 39-25 A, Defect in anterior maxilla. B, Flap elevated to expose bony defect. C, Stent with outline of occlusal scheme. D, Bone wax applied to create template for graft. E, Bone contoured and placed in relation to stent. F, Bone graft secured with titanium screws. G, Endosseous implants placed.

(Figure 39-25B) to expose the bony defect, and a stent prepared from the diagnostic wax-up is used to assess the bony defect more accurately (Figure 39-25C). Sterile bone wax is used to prepare a template for the graft dimensions (Figure 39-25D). A

corticocancellous graft is obtained from the anterior iliac crest, contoured from the template and secured with titanium screws (Figure 39-25E and F). Using the stent as a guide, endosseous root-form implants are placed in the graft (Figure 39-25G).

Microvascular Free Tissue Transfer

Joseph I. Helman, DMD

Remy H. Blanchaert Jr, MD, DDS

Reconstruction of the maxillofacial region has been a challenge due to the significant complexity of function and esthetics. The introduction of free tissue transfer to the armamentarium of available techniques has facilitated this task, and therefore allowed for a better quality of life for our patients. Following the description of the history of free flaps in this chapter, the surgical techniques are reviewed and discussed along with the most common specific donor sites: the radial forearm flap, the free fibula flap, and the iliac crest with the deep circumflex iliac vessels.

History of the Surgical Microscope

The development of microsurgical free tissue transfer resulted in a dramatic evolution in head and neck reconstruction, allowing for a significant increase in the available choices of anatomic and functional rehabilitation. There is no doubt that the availabilities of surgical loupes and intraoperative microscopes have been the facilitating factors to performing microvascular and microneurosurgical anastomoses.

In 1590 Dutch opticians Zacharias and Hans Janssen aligned two lenses within a sliding tube, thereby inventing the microscope. Galileo Galilei independently developed the same device a decade later by inverting his “tubum opticum” or telescope.

From the sixteenth to the nineteenth centuries many technical advances were

made, including the mathematical formulas of Ernst Abbe who predicted and standardized optical qualities, allowing Zeiss to mass produce high-quality microscopes. Operating spectacles were introduced in the 1860s and surgical loupes were used for the first time in surgery by the German physician Saemisch in 1876. The first surgical microscope was built by Dr. Carl Nysten, a Swedish otolaryngologist who used it for the first time in the operating theater in 1921.¹

History of Free Tissue Transfer for Head and Neck Reconstruction

Early attempts to achieve free tissue transfer resulted in few successes. Carrel first reported free vascularized transfer of intestine into the cervical region of experimental animals in 1907.² In the late 1950s and early 1960s Jacobson and Suarez performed successful anastomosis of carotid arteries in dogs and rabbits with a 100% patency rate.³ When Jacobson presented the outcome of his research at a national meeting, a leading surgeon at a prestigious institution stated in front of the audience, “This is very nice work, but it is simply ridiculous to bring a microscope into the operating room.”¹ During the 1960s the art of microsurgery was promoted by neurosurgeons and plastic surgeons with encouraging results.

New flaps were designed for reconstruction of the head and neck based on the ability to transfer distant tissues and provide immediate viability through a vascular anastomosis.

In 1975 Taylor and colleagues described the free fibula flap, while Hidalgo applied the technique for mandibular reconstruction in 1989.^{4,5} In 1981 Yang developed the radial forearm flap, while Soutar and colleagues popularized the technique for intraoral reconstruction with and without the addition of a portion of the radius in the mid-1980s.⁶⁻⁸ In 1978 Taylor described the transfer of the iliac crest as an osteomyocutaneous flap based on the blood supply from the circumflex artery and vein.^{9,10}

Free flaps became popular in the head and neck region due to the ability to transfer vascularized bone and soft tissue in one stage at the time of the resection, with predictable high success rates. It is also obvious that they increased the choices of tissue availability, as well as pliability, texture, color, etc, in the quest to achieve an ideal reconstruction and a functional rehabilitation of the patient.

Principles of Microvascular Anastomosis

Instrumentation

The microsurgery instruments require the following specifications:

1. Their weight must not exceed 15 to 20 g. Titanium instruments usually have less weight.
2. They must be at least 10 cm long so that they lie loosely in the hand.
3. The closing pressure of some instruments such as forceps or scissors should lie between 50 and 60 g. Tremor increases with higher closing pressure.
4. The vascular clamps must exert an evenly distributed pressure over the whole length of the jaw of the clamp. The jaws must lie parallel with each other.
5. Microscissors should have an opening of less than 4 mm. They can be either straight or curved, but it is imperative that they cut tissue in a clean fashion in order to reduce the risk of a thrombosis in a vascular anastomosis or the formation of a neuroma in a crushed nerve.
6. Watchmaker forceps are extremely useful, either straight or angled. They can be used as needle holders as long as there is no need to exert a significant force on the needle, in which case a microneedle holder would be the instrument of choice.
7. Microsurgical bipolar coagulation allows for concentrated coagulation between the two ends of the forceps, avoiding unnecessary devitalization of tissues.
8. Microscope and/or loupes. Surgical microscopes were developed by Zeiss in the early days and presently there are several similar microscopes manufactured by other companies. A magnification of 10× is usually enough for anastomosis. The zoom allows for regulation from a magnification of 10× while performing the anastomosis, to a lower magnification (4× to 6×) while the suture is being knotted.¹¹

Anastomosis Technique

The suture (usually 9-0) is passed at a distance from the margin of the vessel similar to that of the thickness of the wall. It is rec-

ommended to apply a counterforce while passing the needle through the vessel by holding the forceps open inside the lumen (Figures 40-1A and B) instead of grasping the vessel wall which may damage the edge of the vascular structure (Figure 40-1C). After the suture has passed through both ends of the vessel, a small “tail” of 2 to 3 mm is left in order that the knot can be performed while seeing the suture end within the field of the surgical microscope (Figures 40-1D and E).

After the first suture is placed the second suture is usually placed 180° from the first. The third suture is placed in between the first and the second, and two more interrupted sutures are placed on the same side. After finishing one side the vascular clamps are turned to expose the other side of the anastomosis. The sutures should always be at the same distance as the edges of the vessel as well as the same distance between each one of the sutures (Figure 40-2).

When the vascular anastomosis cannot be performed “end-to-end” due to very significant differences in the diameter of

the lumen, an “end-to-side” anastomosis is a viable alternative (Figure 40-3). An oval excision of the wall of the large-diameter artery is performed, and the sutures are executed in a similar fashion as explained in the end-to-end anastomosis.

Radial Forearm Free Flap

Many types of free flaps have been used in head and neck reconstruction. The radial forearm flap is perhaps the most commonly used soft tissue microvascular flap for intraoral and oropharyngeal defects. It has gained wide acceptance because of its reliability, adaptability, ease of harvest, and the thin pliable nature of the flap. The flap allows restoration of the complex three-dimensional anatomy inherent in oral and oropharyngeal defects. This is demonstrated by the commonplace reconstruction of combined tongue and floor-of-mouth defects. Folding the flap on itself to simultaneously reconstruct the tongue and floor of mouth creates redundancy and allows the residual tongue to retain outstanding mobility (Figure 40-4).

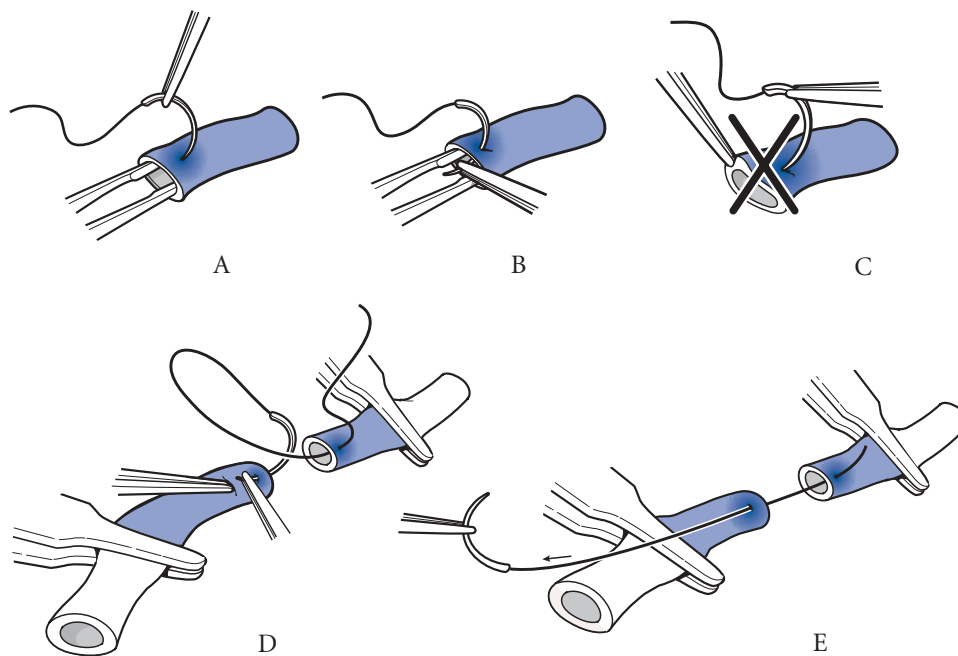

FIGURE 40-1 A and B, It is recommended to apply counterforce while suturing by holding the forceps open inside the lumen. C, Grasping the vessel with the forceps may damage the edge of the vessel. While passing the needle the motion should be circular, following the needle shape in order to avoid a tear of the vascular structure. D and E, A small “tail” of 2 to 3 mm should be left at the end of the suture to perform the knot within the microscope surgical field. Adapted from Medhorn HM and Muller GH.¹¹

FIGURE 40-2 The first and second sutures are performed 180° from each other. The third suture is placed between the first two while holding the vessel on both sides with the tails of the first and second sutures. After interrupted sutures are placed on one side of the vessel, the microvascular clamps are turned to expose the other side of the anastomosis and proceed in a similar fashion as on the first side. Adapted from Medhorn HM and Muller GH.¹¹

Clinically the skin paddle of the radial forearm flap often takes on an appearance similar to that of oral mucosa following its transfer to the oral cavity. This change in appearance has been shown to be reactive in nature and does not represent true metaplasia.¹²

Development

The history of the spread of understanding of the flap is interesting. Soutar and colleagues reported and referenced the introduction of the flap to German surgeons visiting China in 1980.⁷ Subsequently these surgeons published in the German language literature on the use of the radial forearm as a donor site for the creation of neurofasciocutaneous and osteocutaneous flaps in neck and in hand reconstructions.

Soutar and colleagues reported the use of the radial forearm flap in primary mandibular reconstruction in 1983.⁷ Corrigan and O'Neill published a report of the cases outlining the technique of osteocutaneous flap harvest and transfer, and included a description of complications encountered.¹³ The most devastating of these complications is distal radius frac-

ture, which results in significant deformity. Vaughan documented extensive experience with 120 radial forearm flaps, praising the adaptability and applicability of the flap in head and neck reconstruction.^{14,15} Published reports have demonstrated it to be possible to perform defini-

tive mandibular reconstruction using the osteocutaneous radial forearm flap and dental implants.¹⁶ The volume and height of the bone compare poorly to those of other flaps. The fibula and deep circumflex iliac artery flap appear to have the most suitable bone stock to facilitate dental implant-based mandibular rehabilitation and are therefore more popular when bone is necessary.¹⁷

Refinement and adaptation of the radial forearm flap continued throughout the early 1990s. Urken and colleagues reported on the use of the neurofasciocutaneous radial forearm flap in head and neck reconstruction.¹⁸ This report included a means of monitoring buried or poorly accessible flaps that could be facilitated by the inclusion of a skin paddle on the proximal fascial/subcutaneous element of the flap. Protection of the flap vessels and augmentation of the contour deformity created by neck dissection are additional advantages of this modification.^{19,20} The literature abounds with descriptions of suitable adaptations of the radial forearm flap to specific sites within the head and neck. Urken and Biller published a

FIGURE 40-3 A–F, The end-to-side anastomosis is performed after excision of an oval segment of the “side” donor vessel. The sequence of suturing is similar to the technique described in Figure 40-2. Adapted from Medhorn HM and Muller GH.¹¹

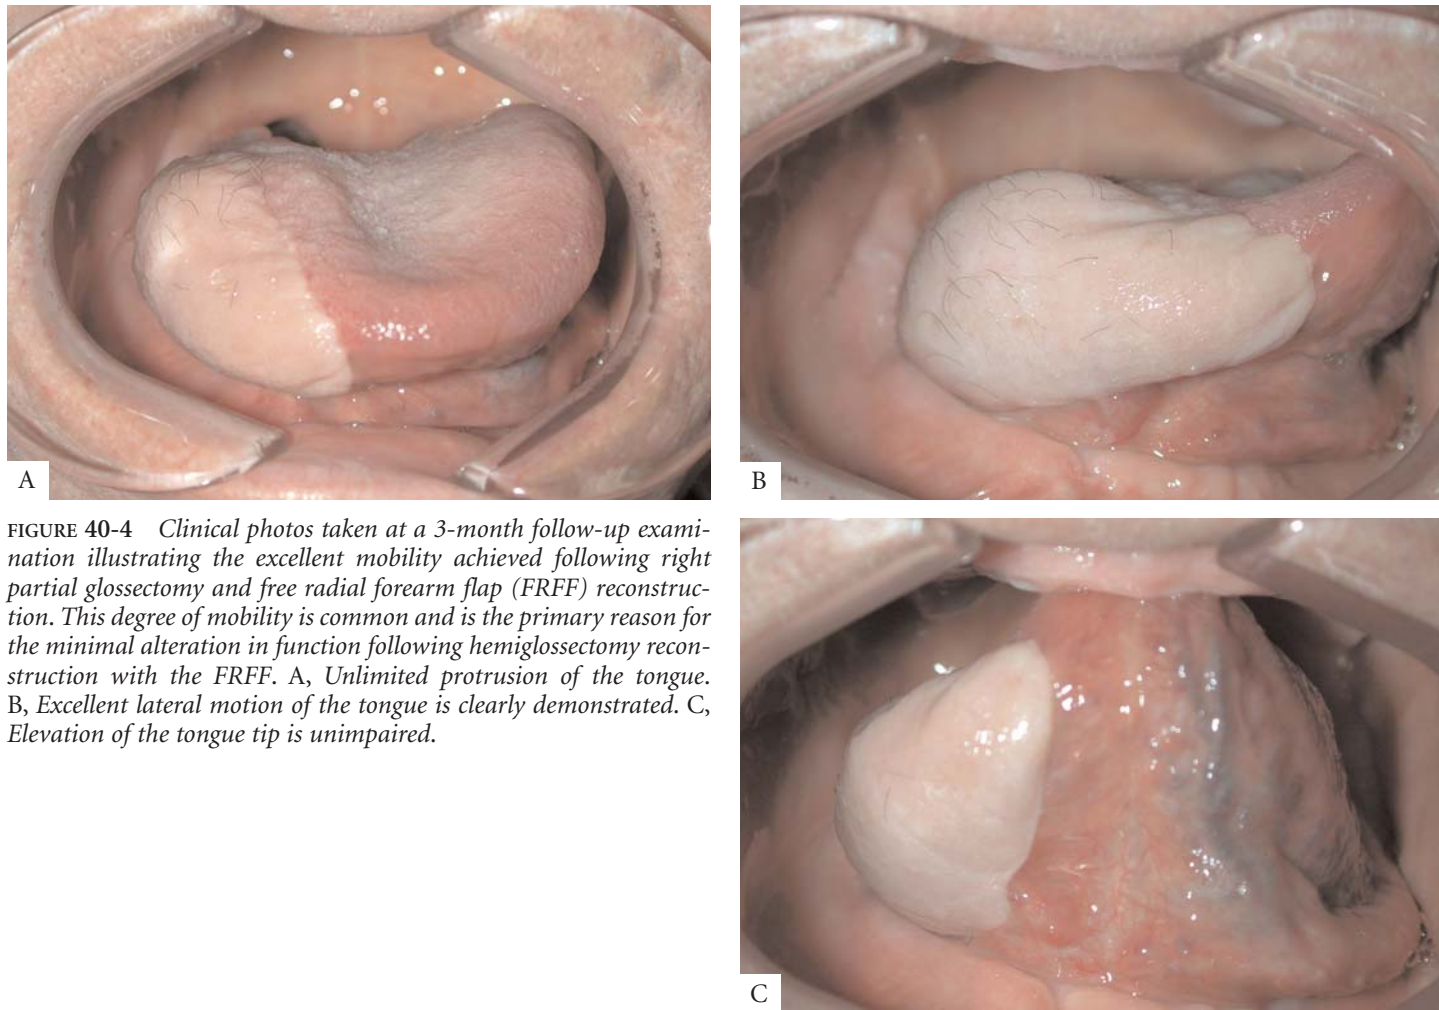

FIGURE 40-4 Clinical photos taken at a 3-month follow-up examination illustrating the excellent mobility achieved following right partial glossectomy and free radial forearm flap (FRFF) reconstruction. This degree of mobility is common and is the primary reason for the minimal alteration in function following hemiglossectomy reconstruction with the FRFF. A, Unlimited protrusion of the tongue. B, Excellent lateral motion of the tongue is clearly demonstrated. C, Elevation of the tongue tip is unimpaired.

description of a bilobed neurofasciocutaneous flap for hemiglossectomy defects that allows preservation of residual tongue function.²¹ Oromandibular reconstruction has been reported using the free radial forearm flap alone or in combination with a fibula free flap.^{7,13,22,23} Lower lip reconstruction has been described wherein the palmaris longus tendon provides support and suspension to the flap.^{24,25} Simultaneous lip and cheek, full-thickness cheek, and soft palate reconstruction have also been described.²⁴⁻²⁸ Oral cavity and pharyngoesophageal reconstruction with the radial forearm flap has advantages over other reconstructive modalities, demonstrating good functional outcomes.^{29,30} Reconstruction of facial defects (forehead, nasal) has also been described as an appropriate use of the radial forearm flap.^{31,32}

Extreme uses of the flap include reports of the creation of hybrid flaps, wherein the cephalic vein remains pedicled for use in cases with inadequate venous outflow and the simultaneous use of bilateral flaps.^{33,34}

Throughout the development of the free radial forearm flap, reinnervation of the flap has received considerable attention. Many authors have discussed the role of sensory reinnervation in functional outcomes in oral cavity and oropharynx reconstruction.^{17,18,21,35,36} Recall that some of the earliest descriptions of the use of the flap were neurofasciocutaneous flaps.⁷ The neurofasciocutaneous radial forearm flap is typically designed to include only the median antebrachial cutaneous nerve (see Figure 40-6). Sensory nerve mapping accomplished by cadaveric microdissection and selective nerve block technique

in 8 forearms of 4 human subjects has revealed that much of the skin territory harvested with the flap is supplied by either the lateral antebrachial cutaneous nerve or the superficial radial sensory nerve.³⁷ This brings into question the means by which the radial forearm flap achieves reinnervation. Many authors have postulated that reinnervation occurs by ingrowth of nerve fibers from the recipient bed and peripheral or adjacent tissues.^{27,36,38-41} Close and colleagues compared spontaneous sensory recovery in myocutaneous pectoralis major flaps and radial forearm fasciocutaneous flaps and found the forearm flaps to exhibit significantly better sensation.³⁵ This supports the idea that the characteristics of both the flap and the recipient bed influence the sensory recovery within non-reinnervated

soft tissue flaps. Netscher and colleagues studied 12 patients who underwent free radial forearm flap reconstruction of the tongue and floor of mouth.³⁹ Seven patients received reinnervated flaps and 5 received flaps without intentional neural anastomosis. Improved sensory recovery in the patients who received reinnervated flaps was documented, but no statistically significant difference in function could be found.

Santamaria and colleagues reported objectively evaluated sensory recovery in reinnervated flaps to be near normal when neural anastomosis was accomplished to the lingual or inferior alveolar nerve.³⁶ Sensation was found to be poor if the anastomosis was carried out to other recipient nerves (posterior auricular nerve, cervical plexus, hypoglossal nerve). The study also found the recovery of sensation to be significantly diminished in patients who received postoperative radiotherapy. In summary the decision to perform the radial forearm flap as a neurofasciocutaneous flap must be made on a case-by-case basis dependant on the defect characteristics and location, recipient bed, and the ability to accomplish anastomosis to the lingual or inferior alveolar nerve.

Anatomic Considerations

Blood Supply The arterial blood supply of the radial forearm fasciocutaneous flap is based on perforators of the radial artery. The fascial plexus supplied by these perforators supplies the skin of nearly the entire forearm. There are discrete groups of these perforators. The most clinically relevant is the small number of perforators at the site where the flexor carpi radialis and brachioradialis muscles overlap. One particularly relevant implication of this is the ability to develop multiple skin flap elements based on a single vascular pedicle without the requirement of preservation of the entire fascial element.^{42,43} The bone element of the flap is supplied by branches of the radi-

al artery within the lateral intramuscular septum. Branches that form a longitudinal plexus within the periosteum pass through the insertion of this fascia.⁴⁴

The venous drainage of the radial forearm flap occurs through the interconnecting superficial (cephalic vein) and deep (venae comitantes) systems. Thoma and colleagues published an excellent description of the variation on the pattern of venous drainage identified in 40 clinical cases.²² Five distinct patterns were described. The type I pattern, found 20% of the time, exhibits wide communication of an anastomosing vein of the venae comitantes and the cephalic vein, which split to separate cephalic median and basilic median veins. The type II pattern existed 43% of the time and was similar to type I, with the exception that no division of the fusion of vessels occurred. The type III pattern, seen 18% of the time, displayed an anastomosis of the paired venae comitantes that remained separate from the cephalic vein. The type IV pattern occurred 5% of the time and exhibited no fusion of the venae comitantes of near equal size. Although pattern V, seen 15% of the time, also exhibited no fusion of the two systems, there was clearly a dominant venae comitantes.⁴⁵ Thoma and colleagues made a strong recommendation for completing multiple venous anastomoses. Their view appears to be common in early free flap and replant experiences. However, a single venous anastomosis has been shown to be adequate in the more recent literature. Futran and Stack compared outcomes and operating time in 43 consecutive radial forearm flaps.⁴⁶ Two anastomoses were performed in 16 patients and one anastomosis was performed in 23 patients. They reported no difference in flap survival and no flaps were re-explored for venous complications. Twenty-one to 36 minutes less surgical time was documented in cases in which a single venous anastomosis was completed. Surgeon preference and individual patient and flap

characteristics determine the most appropriate vein for anastomosis. Clearly in cases with a superficial venous system compromised by trauma or extensive venipuncture, the deep system (venae comitantes) must be used. The reliability of the deep system has been well documented.⁴⁷ Netscher and colleagues used dye injection to study the venous drainage system.⁴⁸ They found that careful mapping of the cephalic vein was necessary to ensure its capture within the flap, occasionally necessitating localization of the flap skin paddle over a portion of the dorsum of the forearm. Venae comitantes vessel diameters were found to be less than 2 mm in several specimens. The study also concluded that selection of the site for venous anastomosis significantly alters the vessel diameter. In order to obtain the greatest diameter, the confluence of the venae comitantes must be identified. This may result in venous pedicle redundancy and kinking. The superficial venous drainage system exhibits a larger diameter throughout its entire length and is significantly easier to elevate, and its separation from the arterial pedicle increases options for recipient vein selection with acceptable vessel geometry.

Vascular Abnormalities Preoperative evaluation of the arterial supply to the hand is required prior to harvest of the free radial forearm flap. This is traditionally accomplished by an Allen's test. Accurate performance of the test involves exsanguination of the hand by clenching and releasing the fist multiple times while both the radial and ulnar arteries are compressed. Return of color to the blanched thenar eminence and thumb following release of the ulnar artery confirms adequate communication between the superficial (ulnar) and deep (radial) palmar arches. Thus harvest of the flap would not compromise the blood supply to the hand. A single published report of acute ischemia to the hand following radial forearm flap

harvest despite a “normal” Allen’s test initiated further investigation into forearm vascular anatomy.⁴⁹ The subjective nature of the Allen’s test has led to the use of adjunctive clinical aids such as Doppler and pulse oximetry to ensure adequate perfusion of the thumb with radial artery occlusion. In their description of a method for preoperative vascular assessment, Nukols and colleagues reported the use of an “objective Allen’s test” in a clinical series of 65 patients.⁵⁰ Twenty-five patients were thought to have inadequate flow by subjective testing, 18 of whom were found to have acceptable flow by objective testing. The authors concluded that objective testing was more reliable in identifying potential problem donor sites. Color flow duplex assessment of 18 patients revealed 5 with unilateral or bilateral arteriopathy. This finding impacted the site selection of the radial forearm harvest or resulted in the use of alternate reconstructive modalities in those 5 cases.⁵¹ Interestingly, color flow duplex quantifications of the flow rates in the upper extremities of 11 patients preoperatively and 4 to 5 months postoperatively revealed overall increased flow rates (mean 162 mL/min to 215 mL/min). The increased flow resulted from dramatic increases in blood flow through the anterior and posterior interosseous arteries. In fact the anterior interosseous artery was found to take on a flow rate (33% of the total) that was nearly equal to that of the radial artery before flap harvest (39%).^{51,52}

Many authors have published case reports of vascular abnormalities of the radial artery.^{39,53–57} Funk and colleagues published a review of the literature on forearm vascular anomalies that included clinical correlation based on 52 patients.⁵⁸ The paper described six types of anomalies, the most common of these being a high origin (proximal to the antecubital fossa) of the radial artery occurring in approximately 15% of all upper extremities. The majority of radial arteries in these patients originate from the brachial artery,

but 10 to 25% were reported to arise directly from the axillary artery. This anomaly poses no problem for safe radial forearm flap harvest. The second most common anomaly reported was a superficial ulnar artery. The superficial location of the ulnar artery places the vessel at risk in flaps involving the entire volar surface of the forearm. Surgeons are strongly encouraged to palpate the entire antecubital fossa and volar forearm in order to rule out this anomaly. The abnormal vessel course is typically best palpated overlying the flexor carpi muscle. The superficial ulnar artery anomaly reported in 2.5% of upper extremities should prompt the surgeon to preferentially use other sites for flap harvest because of the risk incurred in selection of such a donor site. The flap can be done safely with this anomaly if the flap is positioned more to the radial side of the ventral forearm. Distal takeoff of the radial artery has been reported once. No risk of vascular insufficiency is incurred with this anomaly, and there is no reason to believe it could be identified prior to flap elevation. The other anomalies reported result in significant risk of vascular insufficiency to the hand in the case of radial artery flap harvest and should be easily identified on the basis of abnormal Allen’s tests (Figure 40-5).

Complications In general, patients with head and neck defects tend to be less than ideal surgical candidates because of medical comorbidities. Comorbidities are common and are related to advanced age, alcohol abuse, and tobacco abuse. Complications can occur at the operative sites directly or they may be medically related. Singh and colleagues analyzed a cohort of 200 consecutive patients with head and neck defects who had undergone free tissue transfer, to determine factors that influence both surgical site and medical complication rates.⁵⁹ Successful free tissue transfer was accomplished in 98% of cases. Complications occurred in 56 cases (28%) with 21 (10.5%)

FIGURE 40-5 An abnormal Allen’s test. Note the clearly delineated vascular territory of the ulnar artery.

patients developing multiple complications. Using univariate analysis, statistically significant factors that increased the risk of complication included prior radiation therapy, anesthesia time >10 hours, and advanced Charlson comorbidity grade. However, after multivariate analysis only advanced Charlson grade proved significant. Prior radiation therapy appeared to have no significant effect on flap survival, as reported in other studies, although significant alteration in technique including vein grafting may be required.^{60,61} Surgical time has also been shown to correlate significantly with increased rates of surgical site infection, which is the most common factor in late vascular compromise of free tissue transfers through direct effect on the vascular pedicle.^{62,63}

The free radial forearm flap is a very reliable reconstruction. The international microvascular research group published a multi-institutional prospective study of 493 free flaps.⁶⁴ In a subgroup of the report, 84 free radial forearm flaps exhibited a thrombosis rate of 8.3% and a flap failure rate of 3.6%, indicating a significant role for flap monitoring and flap salvage surgery in head and neck reconstruction.

Monitoring of the radial forearm flap is required in order to identify early compromise of the flap vasculature. Conventional techniques of monitoring have been shown to be adequate for this purpose. These

techniques include visual inspection for color, capillary refill assessment, Doppler probe assessment, and needlestick test. Flap design for deep or buried flaps in which direct observation is not possible should include either a monitor skin paddle that can be directly evaluated or an implantable Doppler probe.^{20,65} An extensive review of 750 consecutive microvascular flaps demonstrated a re-exploration rate of 8.5% and a flap loss rate of 2.3%.⁶⁵ The majority of those flaps salvaged were re-explored at < 48 hours due to observed changes in the parameters monitored. Late re-exploration at > 72 hours was most commonly the result of wound infection causing compromise of the vascular pedicle by pressure or thrombosis. Late re-exploration is associated with high rates of flap loss.

Several assessments of donor site morbidity of the radial forearm flap harvest have been carried out.⁶⁶⁻⁷⁰ Complete or partial failure of split thickness skin graft at the donor site is the most common complication encountered. This can lead to flexor tendon exposure and prolonged healing. Many methods have been devised to decrease the incidence of this complication including coverage of the defect with rotation/advancement flaps, preoperative tissue expansion and primary closure, full-thickness grafting, suprafascial dissection, and the use of vacuum-assisted wound care.⁷¹⁻⁷⁹

A devastating complication of osteocutaneous radial forearm flap harvest is postoperative radius fracture. Prophylactic plating is strongly recommended when bone is included in the flap.^{80,81} Selection of an alternative donor site seems a more prudent alternative provided that one is available. Overall, with the exception of cases in which a radius fracture occurs, donor site function, though objectively altered, is subjectively insignificant.^{62,66,68}

Flap Technique

Simultaneous clinical evaluation of the tumor defect site by both the ablative and

reconstructive surgeons is particularly useful in design of the radial forearm flap and allows planning for the most appropriate vessel geometry. Careful examination of the proposed donor site is required to verify the patency of the superficial venous system and to document the arterial anatomy of the hand. An Allen's test is mandatory and should be supplemented with Doppler or pulse oximetry whenever the examination is inconclusive. Palpation of the entire forearm to determine the vascular anatomy should be done without a tourniquet (arterial assessment) and with the use of a venipuncture tourniquet and dependant positioning of the upper extremity (venous anatomy).

Preliminary planning is supplemented by the intraoperative examination of both the resection specimen and the defect site. Occasionally modifications are required due to extension of the planned resection to achieve tumor margins or due to vascular insufficiency identified in access flaps following a lip split-mandibulotomy procedure. Accurate determinations of the pedicle length required allow further tailoring of the flap harvest to the specifics of the defect site. This facilitates flap harvest because the surgeon need not dissect the entire available vascular pedicle length. This also facilitates the anastomosis procedure because the surgeon can skeletonize the region of the pedicle at which the anastomosis will be completed during a non-ischemic period.

The donor site is prepared for surgery by removing hair in the surgical field with clippers. The radial artery is outlined along its length with a surgical marker. A venipuncture tourniquet is applied to distend the veins and the superficial venous system is outlined with a surgical marker. A preliminary outline of the flap is then marked on the wrist that will be refined following the completion of the resection and identification of the most appropriate recipient vessels. For most cases a fascio-subcutaneous segment of the flap proxi-

mal to the skin paddle can be included to optimize the blood supply, resist vessel kinking, and protect the vascular pedicle. The surgical site is prepared with a chlorhexidine surgical scrub and isolated using extremity drapes. A standard arm-board is sufficient for support of the extremity throughout surgery. Care is taken to ensure absolute isolation of the arm from the head and neck field. Cross-contamination has been implicated in causing suppurative tenosynovitis resulting in a frozen hand.⁸²

Upon completion of the resection or refining of the defect site, the neck is carefully explored to identify likely recipient vessels. The selected vessels should be checked for patency, presence of atherosclerosis, and intimal injury. Loupe magnification facilitates this process. Although any suitable vessel can be used as a recipient vessel, the facial artery and common facial vein are most commonly selected as recipient vessels in intraoral reconstruction. Because these vessels lie central in the lateral neck, less alteration of the flap vessel geometry occurs on extreme head movement when these vessels are used. The reader is reminded of the transverse cervical artery (a branch of the thyrocervical trunk) because of its similar diameter to the radial artery. Because of the position of the transverse cervical artery low in the neck, it is commonly available and in good condition following prior selective neck dissection or radiotherapy. Although the available pedicle length allows for use of neck vessels, when performing an upper facial reconstruction the superficial temporal artery and vein or the facial artery and vein are often used.

Daily aspirin therapy to decrease platelet aggregation is initiated on the evening of surgery and continued for 6 weeks. Flap harvest is accomplished following exsanguination of the upper extremity and inflation of a tourniquet to 250 mm Hg. Tourniquet control facilitates the flap harvest by maximizing visualization. This

creates an excellent environment for teaching the microvascular flap harvest technique. Enough cannot be said about the crucial role that gentle tissue/vessel handling plays in the ultimate viability of the microvascular transfer. The distal flap is elevated first, requiring ligation of the distal radial artery and cephalic vein. A subfascial plane of dissection allows capture of all available communications between the elements of the vascular supply of the flap without significantly increased morbidity (Figure 40-6).

The superficial radial nerve is resected to avoid violation of the fascial compartment. This can be used as a free nerve graft of 4 to 6 cm length if needed. The sensory defect is limited to the dorsal portion of the thumb and index finger. We have found that skin graft placement over a preserved dorsal radial nerve provides insufficient protection. Severe pain can result from stimulation of the nerve by a sleeve or wristwatch.

Continued dissection around the circumference of the designed flap is accomplished deep to fascia laterally and deep to the dermis proximally. Skin flaps are then elevated proximally coincident with the

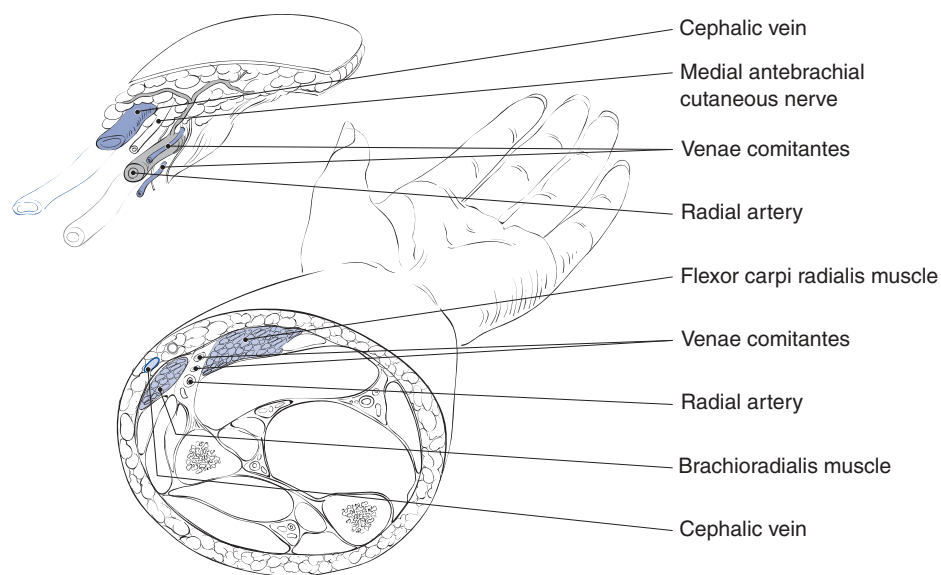

FIGURE 40-6 Cross-sectional anatomy of the radial forearm free flap donor site. The harvested flap demonstrates subfascial dissection of the flexor compartment. Adapted from Urken ML.⁹⁹

FIGURE 40-7 The harvest of the flap. Note the retraction of the brachioradialis muscle required to dissect the radial artery.

volume of the planned fasciosubcutaneous element of the flap. Proximal to this the cephalic vein and antebrachial cutaneous nerve are isolated. Proximal dissection of the arterial vascular pedicle requires the separation of the fascia joining the flexor carpi radialis and brachioradialis muscles and the lateral retraction of these muscles (Figure 40-7).

The venae comitantes are dissected from the radial artery for a few centimeters either side of the planned arterial

anastomosis and are preserved. Where one of the venae comitantes is clearly dominant, only this vessel is preserved. Numerous interconnections exist between these two vessels and careful dissection is required to achieve their separation. With the vascularity assured the flap is then elevated distal to proximal. This requires identification and ligation of deep branches of the radial artery. We prefer to use titanium vessel clips to accomplish this. These facilitate rapid flap harvest and are excellent markers of the pedicle position in the event that the neck must be explored at a later date. After completion of the flap harvest, the tourniquet is released. Careful examination of the flap during this reperfusion interval should be accomplished to ensure absolute hemostasis because access following inset and reanastomosis will be limited. The surgeon should examine the hand for adequate perfusion. Tourniquet time less than 45 minutes is the norm following familiarity with the flap harvest. This can be significantly less with increased surgical experience.

The vascular pedicle is then transected following a suitable period of reperfusion (30 minutes on average). The flap vessels should be occluded with appropriately sized microvascular clamps during completion of the inset. The flap is then transferred

to the defect site. Care must be taken to avoid rotation or kinking of the flap vessels, particularly when the flap must be passed through a tunnel to the defect site. Insetting should be accomplished completely prior to microvascular anastomosis to allow accurate determination of the vascular pedicle geometry. Meticulous closure with gentle eversion to achieve a watertight seal is necessary because of the deleterious effects of saliva on the flap vessels. Care is taken to achieve a flap vessel–recipient vessel geometry that contains only slight curves to prevent vessel kinking. We prefer end-to-end interrupted sutured anastomoses with the vessels secured in Acland frame clamps. The artery is approximated first because the recipient artery is generally deeper than the venous structures. Heparinized saline (500 U/100 cc NS) is used to irrigate during the anastomosis. Papavarine is occasionally used if arterial spasm is noted. It should be recognized that gentle handling is the best defense against spasm. Following the release of the approximator clamps, the flap should be carefully evaluated. Evaluation of color and capillary refill is generally adequate for flap monitoring. In situations wherein this is difficult or the status of the flap is unclear, pricking the flap with a 25-gauge needle confirms flap perfusion. Color and character of the bleeding are important. A venous-compromised flap will bleed dark blood that does not clot as well as serous fluid.

Closed-suction drains are used in the neck with care taken to prevent them being displaced onto the vascular pedicle. The proximal skin flaps at the donor site are approximated over a closed-suction drain. The distal skin elements are sutured to the muscle to fixate them. A split-thickness skin graft is placed over the donor site defect and secured. A compressive dressing and volar splint or vacuum-assisted closure dressing are applied. These remain in place for 5 days. Active and passive range-of-motion exercises are initiated at 2 weeks post flap harvest.

The free radial forearm fasciocutaneous flap is extremely useful in head and neck reconstruction. The flap's reliability, adaptability, ease of harvest, and the similar character of the thin pliable skin to the lining tissues of the oral cavity make its use commonplace in modern maxillofacial reconstruction.

Free Fibula Flap

Anatomic Considerations

The fibula is ideal for large bony defects since it offers up to 25 cm of vascularized cortical bone. If we view the fibula in a cross section, we can identify a triangular shape established by three borders. The anterior border is the area of attachment of the anterior intermuscular septum, and the interosseous or medial border is the point of attachment of the interosseous membrane that binds the fibula to the tibia. The posterior intermuscular septum attaches to the posterior border (Figure 40-8).

In the proximal aspect the fibula articulates with the tibia and the knee joint, whereas in the distal aspect it articulates with the tibia and the talus.

Above the knee the popliteal artery divides into the anterior and posterior tibial arteries. Distal to the knee the posterior

tibial artery has a collateral branch, the peroneal artery. The blood supply to the fibula is delivered through perforators originating in the peroneal artery which is usually between 2 and 4 mm in diameter. The venae comitantes provide the venous drainage; these are paired vessels that run along the artery (Figure 40-9).

A significant limitation of the free fibula flap is the common presence of peripheral vascular disease in the lower extremities. In population-based studies that evaluated the incidence of arterial disease in the lower extremity in patients older than 55 years, the parameter was an ankle-brachial index lower than 0.9.⁸³ The value was obtained by dividing the systolic blood pressure measured at the ankle by that obtained at the brachial artery. A Danish study that included 700 individuals aged 60 years showed a prevalence of lower extremity arterial disease of 16% in men and 13% in women.⁸⁴ A similar study from Edinburgh showed an overall incidence of 17%.⁸³

Unfortunately the same risk factors (age and tobacco) are a common denominator for head and neck cancer patients as well as patients with peripheral vascular disease; therefore, it is indicated to perform either a conventional angiography or

FIGURE 40-8 Cross-sectional view of the tibia and fibula with the surrounding anatomic structures. Adapted from Serafin D.⁹³

FIGURE 40-9 Vascular anatomy of the fibula, view from a posterior view of the leg. Adapted from O'Leary MJ et al.⁸⁸

a magnetic resonance angiography to establish the safety of harvesting the flap.

In a recent retrospective study Smith and colleagues reviewed 17 potential free fibula flap candidates (34 legs) evaluated by both a color flow Doppler (CDF) and angiography. Sixteen legs were normal by both studies, 18 legs showed abnormal CFD study results, and the angiogram revealed anatomy that was considered to represent a high risk for fibula flap harvest in 16 legs and considered safe in the other 2 legs.⁸⁵

The free fibula flap can be raised with or without a skin paddle. The skin paddle had a poor prognosis, based on the original series by Hidalgo who harvested the attached skin based on septocutaneous perforators.⁵ Schusterman and colleagues later performed an anatomic study that showed more soleus musculocutaneous

perforators than septal perforators.⁸⁶ Furthermore the clinical success of the skin paddle is above 90% when the musculocutaneous perforators are incorporated in the flap, whereas the viability of the skin is only 33% when the flap is based on septal branches.

Neurosensory potential to the skin paddle was described by Hayden and colleagues by incorporating the lateral cutaneous nerve of the calf (LCNC) and/or the sural communicating nerve (SCN) in order to restore intraoral sensation by anastomosis of the lingual nerve to the LCNC and/or the inferior alveolar nerve to the SCN.^{87,88}

Flap Technique

The patient is placed in the supine position, the hip and the knee are slightly flexed, and a pneumatic tourniquet is placed in the proximal aspect of the leg. A line is drawn from the lateral malleolus to the fibular head. If a skin paddle is included, it should be centered more posteriorly than the axis of the fibula in order to include both the septocutaneous and the musculocutaneous perforators.

The dissection is carried down to the crural fascia that is incised. The dissection continues through the anterior border of the peroneal muscles while maintaining a cuff of 2 to 3 mm of muscle surrounding the bone. The extensor digitorum longus and the extensor hallucis longus are elevated anteriorly, exposing the interosseous septum that connects between the fibula and the tibia. The peroneal vessels and the anterior tibial vessels are located posterior to the interosseous septum; therefore, careful dissection with fine dissecting scissors should be performed in order to avoid damage to the vascular structures or to the deep peroneal nerve. At this stage, two horizontal incisions are performed in the proximal and distal aspects of the fibula where the osteotomy is being planned. The bony cuts are performed with a Gigli, a reciprocating, or an oscillating saw while the medial aspect is protected with a malleable

retractor. The peroneal vessels are ligated in their distal aspect and the vascular pedicle is carefully dissected superiorly until the branching of the peroneal artery from the posterior tibial is identified. The flexor hallucis longus muscle and part of the soleus muscle are included in the flap, especially if a skin paddle is planned (Figure 40-10).

It is recommended to perform the osteotomies to shape the fibula while pedicled to the proximal vessels in order to minimize the ischemia time as well as preparation of the vessels in the recipient site before ligation of the proximal aspect of the peroneal artery.

The skin defect in the leg can be closed primarily or through the addition of a split-thickness skin graft.

An example of the application of this technique is as follows:

A patient presented with a large mass in the anterior aspect of the mandible with an obvious clinical deformity due to significant buccal expansion of the buccal cortical bone, with a progressive growth during the 3 years previous to his clinical evaluation (Figure 40-11). Panoramic radiography showed a multilocular lesion extending from tooth no. 21 to tooth no. 31 (Figure 40-12).

A histopathologic diagnosis of ameloblastoma was obtained through an incisional biopsy of the lesion. A magnetic resonance angiogram was obtained which showed a normal vascular pattern in both lower extremities. A segmental resection of the lesion was performed along with the mental and inferior alveolar nerves (Figure 40-13).

The defect was immediately reconstructed with a free fibula flap without the need for a skin paddle since residual mucosa was available for primary closure. Two osteotomies were performed in the fibula to allow for appropriate contour, resulting in three bony segments that were fixated to the recipient mandible by means of a reconstruction plate (Figure 40-14). A postoperative panoramic radiograph was obtained

FIGURE 40-10 Elevation of the free fibula flap after the osteotomy of the distal and proximal attachments. The ligation of the feeding vessels is obvious in the distal aspect of the flap, while the proximal blood supply is maintained until the osteotomies are performed. Adapted from Serafin D.⁹³

which showed good continuity of the bony segments (Figure 40-15). In a previous retrospective study it was reported that radiographic bony healing was achieved in 93% of osteotomy sites of free fibula flaps.⁸⁹

The amount of bone available in free flaps in order to place osseointegrated implants has been investigated in an anatomic study in 28 cadavers evaluating the most commonly employed donor sites.⁹⁰ Implantability was established based on measurements of height, width, and cross-sectional area. The results showed that the iliac crest was the most implantable donor site (83%), followed by the scapula (78%), the fibula (67%), and the radius (21%).⁹⁰

A retrospective analysis of patients treated with a free fibular flap for mandibular reconstruction was performed by Disa and colleagues evaluating the long-term bone mass of the fibula.⁸⁹ Only patients with at least 24 months of follow-up were included in the study. The comparative measurements of fibular height revealed that central segments underwent a mean decrease in height by 4%, body segments decreased by 7%, and ramus segments decreased by 5%. The findings were not affected by the site of reconstruction, patient age, length of follow-up, adjuvant radiation therapy, or placement of osseointegrated implants.

Morbidity following Free Fibula Flaps

A retrospective analysis of donor site morbidity was performed by Shindo and colleagues on 53 consecutive patients who underwent fibula osteocutaneous free tissue transfer.⁹¹ Donor site wound complications occurred in 15 patients, 4 of whom (8%) had extensive wound breakdown,

FIGURE 40-14 Reconstruction of the surgical defect with a free fibula flap. The structures located superior to the reconstruction plate are the spared inferior alveolar and mental nerves. The vascular structures below the screws and the reconstruction plate at the level of the angle of the mandible are the peroneal vessels after microanastomosis to the facial vessels.

muscle necrosis, and/or exposure of tendon and/or bone, whereas the other 11 patients (21%) had only minor wound complications limited to superficial skin slough.

Shindo and colleagues recommended avoiding skin closure under tension since the group with the higher complication rate had primary closure of the donor site.⁹¹ Other reported complications have included weakness of great toe dorsiflexion, reduced spring action of the donor leg, ankle stiffness, and in a few cases, ankle instability. Despite the mentioned deficits, all patients were able to resume daily and recreational activities.⁹²

Iliac Crest Osteomyocutaneous Free Flap

Anatomic Considerations

The blood supply to the osteomyocutaneous iliac crest flap is based on the deep circumflex iliac artery (DCIA) and vein. The DCIA takes origin from the external iliac artery or femoral artery in the region of the inguinal canal (42% below the inguinal ligament from the femoral artery, 41% behind the inguinal ligament from the external iliac artery, and 17% above the inguinal ligament from the external iliac artery).⁹³

The artery courses a distance of about 5 to 7 cm between its origin and the anterior superior iliac spine, following thereon the inner aspect of the iliac crest. The DCIA provides an ascending branch that perforates through the transversus abdominis muscle giving blood supply to the transversus as well as the internal and external oblique muscles (Figure 40-16).

Through its pathway the artery provides multiple perforators to the bone, muscle, and overlying skin. The deep circumflex iliac vein follows the arterial course.

The lateral femoral cutaneous nerve crosses the DCIA near the anterior superior iliac spine. The nerve should be dissected, retracted, and protected during the harvesting of the vascular pedicle and the flap.

Flap Technique

The skin paddle is designed by drawing a line from the femoral artery to the inferior angle of the scapula. The skin paddle is then designed with an axis on the above-mentioned line and centered on the iliac crest, including the myocutaneous perforators which enter the skin along the inner aspect of the crest.

The external oblique muscle (with the attached overlying skin) is incised, leaving a cuff of about 3 cm of muscle attached to the inner aspect of the iliac crest. If a significant portion of the internal oblique muscle has to be harvested in order to cover soft tissue defects in the oropharyngeal region, then the muscle is divided in a horizontal fashion

FIGURE 40-15 Radiographic view of the reconstructed mandible with a free fibula flap.

FIGURE 40-16 Anatomy of the deep circumflex iliac artery (DCIA). Adapted from Strauch B, Yu HL, editors. *Atlas of microvascular surgery*. New York: Thieme Medical Publisher Inc.; 1993. p. 142–58.

below the costal margin, and the dissection is initiated in the superior, medial, and lateral aspects while incorporating the ascending branch of the DCIA. After identifying the ascending branch of the DCIA in the inner aspect of the internal oblique muscle, the deep circumflex iliac vessels are dissected proximally. The transversus abdominis muscle is incised parallel to the crest, leaving a cuff of about 3 cm attached to the inner aspect of the crest.

The peritoneum is then retracted medially and the iliacus muscle is identified. The transversalis fascia fuses with the iliacus fascia, and the deep circumflex vessels consistently travel lateral to this fascial fusion. A 1 to 2 cm incision is performed medial to the insertion of the iliacus fascia down to the periosteum.

The lateral or lower aspect of the skin paddle is incised, proceeding through the deep fascia of the thigh and the gluteus muscle, detaching them from the periosteum of the lateral aspect of the iliac crest until achieving the desired bone depth (Figure 40-17).

When both the medial and lateral cortices are exposed, the osteotomy is performed.

If additional osteotomies are necessary in order to contour the bone, it is recommended to proceed while the tissue is still pedicled to the feeding deep circumflex vessels.

After the flap is harvested the muscles are approximated in layers to prevent the potential complication of herniation of the abdominal contents. The transversalis fascia and transverse abdominis muscle are sutured to the iliacus fascia and the iliacus muscle. The fascia lata and the gluteus are sutured to the external oblique muscle. The inguinal ligament should be reattached if it had been divided.

FIGURE 40-17 Harvesting of a full-thickness iliac crest bone flap. Adapted from Strauch B, Yu HL, editors. *Atlas of microvascular surgery*. New York: Thieme Medical Publisher Inc.; 1993. p. 142–58.

In most cases the inner aspect of the iliac crest is sufficient to reconstruct a mandibular defect, having the advantages of a less deforming defect and avoiding the lateral dissection of the gluteus medius muscles (Figure 40-18).

Morbidity following Iliac Crest Free Flaps

Rogers and colleagues analyzed the associated morbidity and the quality of life of patients who had undergone harvesting of either a deep circumflex iliac or a fibula free flap.⁹⁴ They used the University of Washington Quality of Life questionnaire, which showed no statistical differences between the patients in their activity, anxiety, mood, pain, recreation, or shoulder function. Rogers reported that the patients reconstructed with free fibula flaps had lower scores for swallowing and taste. On the other hand, for maxillectomy defects, they preferred the deep circumflex iliac flap over the fibula free flap, the latter being almost exclusively used for mandibular continuity defects. The known incidence of inguinal hernia was about 10% for patients who underwent free iliac flap harvesting.

Overall the conclusion is that both flaps are viable options for complex reconstructive needs in the head and neck regions requiring bone and soft tissue coverage. Donor site morbidity should be presented to the patient with emphasis on the potential impact on their quality of life.

Discussion

The iliac crest provides a significant segment of bone that may reach 4 cm in height and 11 cm in length. The dimensions of the flap may allow for a reconstruction of a hemimandibulectomy or anterior mandibular defect.

There are two significant advantages to the iliac crest/internal oblique free flap: (1) the amount of bone available for potential reconstruction with osseointegrated implants; and (2) the availability of

FIGURE 40-18 Harvesting of a split-thickness iliac crest bone flap. Adapted from Strauch B, Yu HL, editors. *Atlas of microvascular surgery*. New York: Thieme Medical Publisher Inc.; 1993. p. 142–58.

a thin and broad muscle that can be left to heal by secondary epithelization intraorally. Brown and colleagues developed the concept of reconstruction of the maxillary alveolus with the iliac crest while the palate was reconstructed with the muscle.^{95,96}

The disadvantage of the flap is the relatively short vascular pedicle and the potential for herniation of the abdominal contents.

Versatility of Free Tissue Transfer

The flaps described in the current chapter are the most commonly used in head and neck reconstruction. The ability to transfer vascularized tissues allows for a significant variety of options.

The rectus abdominis free flap has been used mostly for base of skull reconstruction and tongue reconstruction. It is based on two vascular pedicles: the deep superior epigastric vessels, which are a continuation of the mammary vessels; and

the deep inferior epigastric vessels, which are branches of the external iliac artery. The deep inferior epigastric vessels have a larger diameter and a longer vascular pedicle which makes them the preferred choice for anastomosis to the recipient vessels with very high reliability and success.⁹⁷

The free scapular flap has been used for mandibular and maxillary reconstructions. The flap can be elevated together with the latissimus dorsi muscle, adding a large amount of soft tissue to large and complex defects of the maxillofacial region. The vascular supply to the scapular bone is provided by the scapular vessels, whereas the blood supply to the latissimus dorsi muscle is provided by the thoracodorsal vessels.

Urken and colleagues have described this combination of flaps as the subscapular system and specified some of its unique features⁹⁸:

- Long length and large caliber of the vascular pedicle
- Abundant surface area of thin skin that can be transferred
- Separation between the soft tissue and bony flaps which provides freedom for three-dimensional inseting
- The potential to combine the latissimus dorsi and the serratus anterior muscles with overlying skin and adjacent segments of rib

Other flaps have been used for oropharyngeal reconstruction, including free omentum for oral lining, gracilis muscle free flaps with the anterior obturator nerve for facial reanimation, and lateral thigh or lateral arm free flaps for pharyngeal reconstruction. Even free temporoparietal fascial flaps have been used based on the superficial temporal vessels for intraoral lining or combined with the overlying skin or underlying bone.

When the reconstructive options are maximized, the selection of the donor site may resemble most accurately the functional needs of the recipient site.

Microneurosurgery

Michael Miloro, DMD, MD

Injuries to the terminal branches of the trigeminal nerve may occur commonly following a variety of routine oral and maxillofacial surgical procedures, and the overwhelming majority of these injuries undergo spontaneous recovery without treatment. Third molar surgery is responsible for most of the injuries to both the inferior alveolar and lingual nerves. The reported incidence of nerve injury varies in the literature, but generally both temporary and permanent paresthesia must be considered. Nerve injury may occur following mandibular and maxillary orthognathic surgery, maxillofacial trauma, dental implant placement, endodontic therapy, facial fractures, and treatment of pathology. The anatomy of the trigeminal nerve system is unique since it carries, in some branches, both general sensory information and special (eg, taste) sensation. Injury to a nerve may result in neuroma formation, which can manifest in a variety of clinical signs and symptoms. Nerve injuries are classified by two popular classification schemes, which are based on the likelihood of an injured nerve recovering spontaneously. A basic understanding of nerve terminology (Appendix) and normal neural wound healing is essential to most appropriately manage clinical situations.

The initial evaluation of patients with nerve injuries must proceed in an orderly fashion, with several levels of testing to

determine most accurately the degree of individual nerve injury. A standardized clinical neurosensory test (CNT) may be employed for most patients; however, some advanced testing is available for special circumstances. A variety of nonsurgical and pharmacologic treatments are available for the patient with nerve injury. For most patients with dysesthesia, pharmacologic therapy is the mainstay of treatment.

Once the decision is made to proceed with microneurosurgery, a sequence of surgical steps must be followed meticulously. Specific surgical techniques depend on which specific nerve is involved, as well as the extent of the injury. In general, microneurosurgical repair of a trigeminal nerve injury involves neurolysis and preparation of the nerve stumps to perform neuroorrhaphy. The deleterious effects of tension on a nerve repair site have been well documented, so the inability to perform a primary tension-free repair warrants consideration for an autogenous nerve graft or another option for nerve gap management such as conduit repair. Following microneurosurgery, postoperative sensory re-education may play a role in the regenerative process. The overall success rates of microneurosurgical repair of the trigeminal nerve vary considerably; however, an important factor in determining success is the length of time from injury to repair since this impacts on the degree of ganglion cell death, wallerian degeneration, and cor-

tical somatosensory reorganization. The American Association of Oral and Maxillofacial Surgeons Clinical Interest Group on Maxillofacial Neurologic Disorders has promulgated certain treatment time recommendations for the patient who sustains a trigeminal nerve injury.¹

The field of microneurosurgery is in its infancy. As more surgeons become familiar with the diagnosis and management of patients with trigeminal nerve injuries, more laboratory, radiologic, and clinical information will become available to guide therapy. Also, residency programs will become more capable of training residents in the principles and practice of microneurosurgery and will thus foster access to this aspect of specialty care throughout the country and abroad.

Demographics

Trigeminal nerve injuries result from a variety of routine oral and maxillofacial surgical procedures, such as third molar odontectomy, management of facial trauma, orthognathic surgery, endosseous dental implant placement, salivary duct and gland surgery, treatment of benign and malignant lesions of the head and neck, preprosthetic surgery, and endodontic and periradicular surgery. Complications of third molar removal are responsible for the majority of nerve injuries.² These can occur during any phase of third molar surgery, including local anesthetic injection, incision

and flap design, the use of a high-speed drill for bone removal or tooth sectioning, elevation of the tooth with trauma to the lingual soft tissues, socket curettage with exposed neurovascular tissue, removal of remnants of an assumed “dental follicle” that may contain neural or vascular tissue, the use of medicaments in the extraction site to aid healing or prevent alveolar osteitis (eg, tetracycline-containing compounds^{3,4}), and the placement of sutures. The efficacy of lingual nerve retraction during lower third molar surgery has shown that although the incidence of temporary lingual nerve paresthesia is increased owing to a slight stretching or manipulation (6.4% with retraction vs 0.6% without retraction), the difference in long-term dysfunction is not significant (0.6% with retraction vs 0.2% without retraction).⁵ Other studies have indicated a temporary paresthesia rate of approximately 10 to 15% with lingual nerve retraction and protection, with a permanent rate of < 1%.

The incidence of trigeminal nerve injury may be estimated based on a review of the available literature. Overall the incidence of inferior alveolar nerve (IAN) injury from third molar surgery is 0.41 to 7.5% and from sagittal split osteotomy is 0.025 to 84.6%, whereas the lingual nerve is affected 0.06 to 11.5% of the time following third molar removal. However, the more important clinical distinction is to differentiate temporary from permanent paresthesia rates. For sagittal split osteotomies, temporary inferior alveolar paresthesia may be as high as 80 to 100%, but permanent rates are < 1 to 5%. For third molar surgery, both inferior alveolar and lingual nerve temporary paresthesias range from 2 to 6% each, whereas permanent rates are approximately 25% of the temporary rates, or 0.5 to 2% overall. Many risk factors for nerve injury during third molar surgery have been reported and include advanced patient age, female sex (recent animal studies indicate that

gender may play a role in spontaneous neurosensory recovery following injury), depth of impaction, mesiodistal angulation of the tooth (distoangular), lingual angulation of the tooth, integrity of the lingual cortex, the need for tooth sectioning, removal of bone distal to the third molar, and surgeon experience. Certainly the risk of an IAN injury may be influenced by so-called Rood radiographic predictors of potential tooth proximity to the inferior alveolar canal.⁶ These seven radiographic predictors on panoramic radiograph may indicate the potential for increased risk of injury to the IAN, and they are listed in Table 41-1. In cases with a high index of suspicion of nerve injury (eg, deep impaction, advanced age), intentional coronectomy with close observation should be considered.⁷ As opposed to the relatively consistent course of the IAN, the lingual nerve position is variable; and it is injured less often than the IAN following third molar surgery.⁸⁻¹² The position of the lingual nerve has been documented clinically,¹³ in cadaveric dissections,^{14,15} and radiologically.¹⁶ On average, in the third molar region, the lingual nerve lies 2.5 mm medial to the lingual plate of the mandible and 2.5 mm inferior to the lingual crest. The lingual nerve may be in direct contact with the lingual plate in 25% of cases (Kisselbach and Chamberlain reported 62%¹³) and may lie above the lingual crest in 10 to 15% of cases (Kisselbach and Chamberlain reported 17.6%¹³) based on an undisturbed radiographic assessment of the nerve.

Mandibular blocks may result in inferior alveolar and lingual nerve injuries; however, the incidence is unknown owing to unreported cases. An estimated 1 in 100,000 to 1 in 500,000 blocks result in paresthesia. Perhaps the largest study of its kind, Harn and Durham’s study of 9,587 mandibular blocks showed a 3.62% incidence of temporary paresthesia and a 1.8% incidence of long-term paresthesia lasting > 1 year.¹⁷ Several theories have

been proposed to explain the mechanism of injury. Direct neural trauma is unlikely owing to abundant interfascicular neural components resulting in separation of the fascicles by a needle or suture without direct neural disruption.¹⁸ The resultant edema may be responsible for the transient paresthesia that resolves spontaneously. Local anesthetic toxicity may be responsible for prolonged paresthesia following a mandibular block, especially if the solution is deposited within the confines of the epineurium. Recent reports indicate that prilocaine and articaine may be associated with an increased risk of long-term paresthesia compared with other local anesthetic solutions, but further investigation is warranted.¹⁹⁻²¹ The third potential mechanism of injury involves the formation of an epineurial hematoma. The epineurium and perineurium contain a vast plexus of vessels that nurture the neural elements, and a needle may cause disruption of one or more vessels. The localized bleeding most certainly tamponades itself owing to the surrounding epineurium, and the pressure may impinge on select groups of fascicles contained within the nerve. The resultant clinical signs and symptoms of localized paresthesia, not involving the entire distribution of the inferior alveolar/ mental nerve, nicely match the expected histologic situation, making this theory plausible. Also, lymphatic drainage of the localized hematoma over the few days to weeks

following surgery coincides with the clinical resolution of symptoms in most cases. The final theory is that of the needle-barb mechanism of injury.²² During a mandibular block injection, the needle may be advanced to the medial ramus where a small barb may form at the needle tip. On withdrawal, if the needle has passed through or in the vicinity of the lingual nerve or IAN, fascicular disruption may occur with potentially long-standing clinical consequences. Recent trends in our clinical understanding of injection-related nerve injuries are the following:

- These injuries are difficult to predict and prevent
- The classic electric-shock sensation is reported uncommonly by patients who sustain these injuries
- Injection injuries are more likely to result in dysesthesia than are other causes of nerve injuries
- There may be a nonanatomic distribution of nerve involvement (including the second and third divisions of the trigeminal nerve)
- Injection injuries occur more commonly in females
- The lingual nerve, which is stretched more upon mouth opening than is the IAN, is more commonly affected
- The majority of cases resolve within 8 weeks, and if paresthesia persists for > 8 weeks, then only one-third of those injuries resolve spontaneously

Microneurosurgery is a poor option for patients with injection-related nerve injuries because surgical access is difficult; therefore, most cases are managed with pharmacologic therapy. One of the difficulties for microneurosurgeons is differentiating a mandibular block injury from a third molar injury to the IAN. On rare occasions the third molar site of the IAN has been explored and found to be normal, with the assumption that the injury occurred as a result of injection rather than extraction.²³

It is well known that orthognathic surgery may result in nerve injury. The IAN is affected more often than is the lingual nerve, and rarely the facial nerve may be affected (0.67% with sagittal split osteotomy in one study²⁴). Certainly much is known about the risks of IAN injury associated with sagittal split osteotomy, as well as screw overpenetration injury to the lingual nerve.^{25,26} Unfortunately, the reported incidence of immediate and long-term neurosensory deficit varies considerably (from < 5% to > 90%) owing to poorly controlled factors inherent in the study designs, such as individual operator variability and surgeon experience, lack of standardization of neurosensory testing, lack of control sites for normal cutaneous facial sensibility, and variation in the periods of neurosensory testing. Several studies have examined the specific parameters of neurosensory recovery after bilateral sagittal split osteotomy by using objective and subjective assessment.²⁷ One study found a 39% incidence of neurosensory dysfunction following sagittal ramus surgery,²⁸ and others have shown < 15% dysfunction at 6 months.²⁹ Although the incidence of nerve dysfunction varies, there are well-known risk factors for nerve injury, including the following³⁰: patient age³¹; increased length of the surgical procedure; proximal or distal segment fracture (“bad splits”); concomitant third molar removal; concomitant genioplasty procedures; compression during fixation; inadvertent use of chisels; nerve entrapment in the proximal segment; nerve manipulation in the area of the osteotomy and, perhaps more significantly, in the lingual region during medial dissection (based on intraoperative recordings of IAN somatosensory evoked potentials)³²; the location of the inferior alveolar canal close to the inferior border; low corpus height and retrognathism (IAN closer to buccal cortex)³³; and frank nerve transection during surgery. Unfortunately, long-term neurosensory dysfunction following

orthognathic surgery is not generally amenable to surgical correction. However, most patients tolerate the paresthesia well following correction of a significant dentofacial deformity. Two caveats are that patients tolerate mild paresthesia following major surgery well (with informed consent) and that the magnitude of neurosensory dysfunction decreases as the time from injury increases. This certainly applies to orthognathic nerve injuries.

Maxillofacial trauma may result in injury to any of the terminal branches of the trigeminal nerve. Mandible fractures that violate the IAN canal result in temporary or permanent paresthesia. Treatment of mandible fractures with inadvertent placement of screws may cause iatrogenic nerve injury. In general, reduction of the fracture aids in realigning the natural conduit (ie, the IAN canal) that will help to guide spontaneous neurosensory recovery even with a transection injury.

Also, the presence and/or treatment of oral pathologic lesions may result in nerve injury. The use of Carnoy’s solution (ferric chloride 0.1 g/mL, absolute alcohol 6 mL, chloroform 3 mL, glacial acetic acid 1 mL) following treatment of pathology has been shown to have a critical exposure time in an animal model of 5 minutes, after which time there may be long-term irreversible neural injury.^{34,35} Following a resection procedure, consideration should be given to immediate or delayed neural reconstruction using autogenous nerve grafts.

Although preprosthetic surgery is performed less frequently today than in the past, procedures such as torus mandibularis reduction and vestibuloplasty place the terminal branches of the mental nerve and infraorbital nerve at risk of injury. Surgical repair of small terminal nerve fibers is difficult and often results in scarring and a poor chance of neurosensory recovery. The maxilla and mandible are excellent sources of autogenous bone grafts; however, they are not without potential morbidity. The majority of patients who undergo genial

bone graft harvest complain of desensitization of the mandibular anterior teeth. Depending on the specific technique employed for posterior mandibular ramus grafting, the IAN may be at risk of iatrogenic injury. Mandibular endodontic therapy and periapical surgery may result in an injury to the IAN, depending on the proximity of the root apex to the canal. Some endodontic filling materials may be neurotoxic, and to prevent irreversible paresthesia that in many cases results in dysesthesia, consideration should be given to prompt exploration and débridement of medications that have permeated through the root apex and are in direct contact with the nerve. Distraction osteogenesis of the mandible has been shown to induce transient changes in neuronal conduction without significant long-term nerve dysfunction.^{36,37} On a clinical level, a younger patient would certainly tolerate a “stretch-type” of injury to the nerve well. Recent data indicate that with a corticotomy and distraction rates of 1 mm/d neural changes are unlikely but that rates greater than this may be deleterious to nerve function; however, more studies are necessary.³⁸

Finally, implant-related injuries to the IAN are common (30–40%) and problematic to manage appropriately. Unfortunately there is a lack of data regarding appropriate patient assessment and management, with a lack of consensus on treatment protocols. In the posterior mandible the likely cause of nerve damage is that the initial pilot (depth) drill penetrates the superior cortex of the canal and violates the IAN vein (or artery, which is less likely). This results in some bleeding that, on placement of the implant, tamponades itself. The resultant increased pressure in the closed environment creates a compartment syndrome, with harmful effects on neurosensory function. This type of injury commonly results in long-term unpleasant altered sensation (dysesthesia) rather than simple decreased sensation (hypoesthesia). The recognition

postoperatively that the patient has paresthesia and that the implant is within the confines of the canal warrant the clinician to consider removal of the implant, with or without immediate replacement with a shorter implant. If, however, the injury was due to a compartment syndrome effect, then implant removal without replacement may be prudent. For patients with persistent paresthesia, referral to a microneurosurgeon may be warranted. The procedure of IAN repositioning (lateralization and transpositioning) is an option that theoretically would induce a “controlled” injury to the nerve and protect it during implant preparation. With lateral decortication of the mandible and nerve exposure, a compartment syndrome is not possible. Despite the potential advantages of nerve repositioning, there is a high incidence of long-term paresthesia ranging from 0 to 77%, with a mean of approximately 30 to 40%.³⁹ With appropriate surgeon experience, proper patient selection, and informed consent, this procedure remains a viable option in posterior mandibular reconstruction.

Trigeminal Nerve Anatomy and Physiology

A brief review of the trigeminal nerve is necessary to understand clinical diagnosis and management. The trigeminal nerve (Figure 41-1) is composed of a mesoneurium that suspends the nerve within the surrounding tissues and is continuous with the outer epineurium that defines and surrounds the nerve trunk. The epineurium contains a vast plexus of vessels called the vasa nervorum, as well as lymphatic channels. The epineurium is divided into outer and inner epineuriums, and the inner layer is composed of a loose connective tissue sheath with longitudinal collagen bundles that protect against compressive and stretching forces imposed on the nerve. Individual fascicles are defined by the perineurium, which is a continuation of the pia-arachnoid layer of the cen-

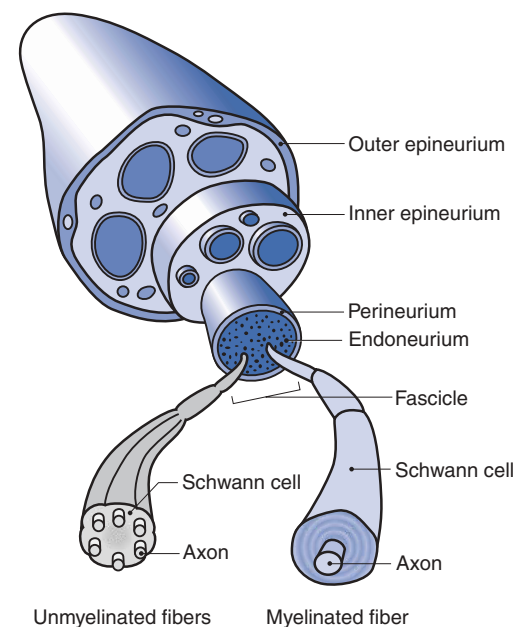

FIGURE 41-1 Trigeminal nerve anatomy.

tral nervous system. It functions to provide structural support and act as a diffusion barrier, similar to the blood-brain barrier that prevents the transport of certain molecules. The individual nerve fibers and Schwann cells are surrounded by the endoneurium, which is composed of collagen, fibroblasts, and capillaries. There are three types of neural fascicular patterns: monofascicular (one large fascicle), oligofascicular (2–10 fascicles), and polyfascicular (> 10 fascicles) (Figure 41-2). The inferior alveolar and lingual nerves are polyfascicular in nature. Polyfascicular nerves have abundant interfascicular connective tissue—the importance of which is that needle penetrations rarely cause direct neural trauma and that nerve repair with realignment of the fascicles is challenging. The nerve is composed of a functional unit with differing fiber types that transmit a variety of information (Table 41-2). The A alpha fibers are the largest myelinated fibers with the fastest conduction velocity; they mediate position and fine touch through muscle spindle afferents and skeletal muscle efferents. The A beta fibers mediate proprioception. The smallest myelinated fibers are the A delta

FIGURE 41-2 Three types of neural fascicular patterns: A, monofascicular; B, oligofascicular; C, polyfascicular. Adapted from Lundborg G. *The nerve trunk*. In: Lundborg G, editor. *Nerve injury and repair*. New York: Churchill Livingstone; 1998. p. 198.

fibers that carry pain (“first” or “fast” pain) and temperature information. The smaller-diameter and slower-conducting unmyelinated C fibers mediate “second” or “slow” pain and temperature sensations. The Schwann cells surround both myelinated (one Schwann cell per nerve fiber) and unmyelinated (one Schwann cell per several nerve fibers) nerves, and they play a major role in nerve survival and regeneration following injury. Although the myelin sheath may not survive a nerve injury, the Schwann cells do, and they provide a supportive role in the production of neurotrophic and neurotropic factors (such as nerve growth factor) that enhance neural recovery. The nodes of Ranvier are the 0.3 to 2.0 μm unmyelinated segments between the myelin sheaths that are responsible for the diffusion of certain ions that cause nerve depolarization and repolarization

and the saltatory conduction of a nerve impulse along the nerve.

Following nerve injury many changes occur, but the basic process of nerve healing involves both degeneration and regeneration (Figure 41-3).^{40,41} The nerve cell body responds with an increased metabolic phase with a heightened production of ribonucleic acid and breakdown of Nissl’s substance for export from the cell body. At the site of injury, there is edema and particulate cellular debris. In addition, there is a proliferation of phagocytes, and macrophages begin to clean the area. Within days there are axonal sprouts that extend from the proximal nerve stump. Each axon may have as many as 50 collateral sprouts. There is proliferation and a high level of activity of Schwann cells as well. These begin to lay down new myelin for the arrival of the new axons. Addition-

ally, nerve growth factors are produced that influence the direction of sprouting and guide the new axons into the newly

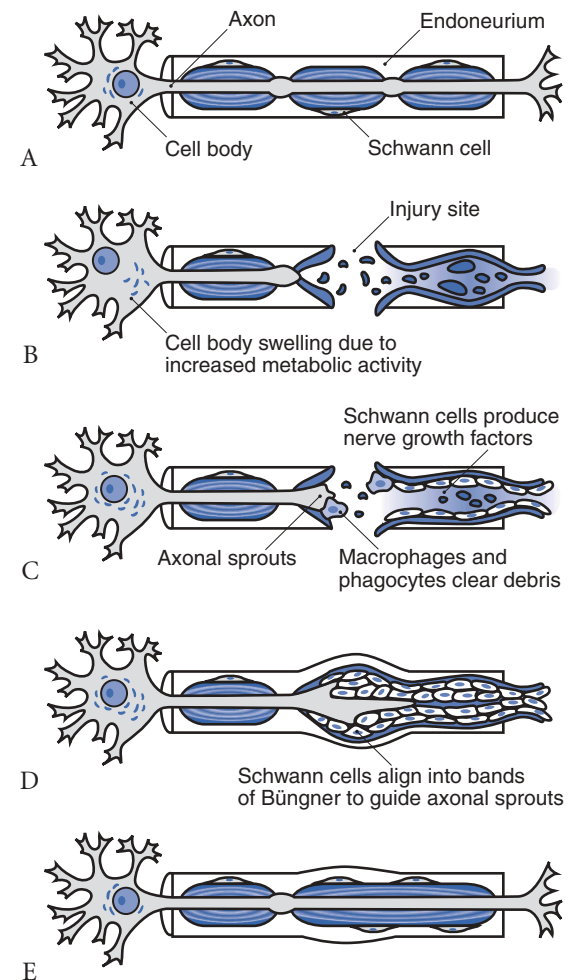

FIGURE 41-3 A to E, Neural wound-healing mechanisms.

Table 41-2 Trigeminal Nerve Fibers			
Fiber	Size (μ)	Conduction Velocity (m/s)	Function
A alpha (myelin)	12–20	70–120	Position, fine touch
A beta (myelin)	6.0–12	35–170	Proprioception
A delta (thin myelin)	1.0–6.0	2.5–3.5	Superficial (first) pain, temperature
C (unmyelinated)	0.5–1.0	0.7–1.5	Deep (second) pain, temperature

FIGURE 41-4 Neuroma types: amputation neuroma, neuroma-in-continuity, lateral exophytic neuroma, lateral adhesive neuroma.

formed myelin sheaths, known as the bands of Büngner. In the event that all of these interrelated processes occur appropriately, then spontaneous neural regeneration occurs. In the event that one or more of the reparative processes fail, there may be neuroma formation. A neuroma is simply a disorganized mass of collagen fibers and randomly oriented small nerve fascicles (sprouts). Neuromas are classified by gross morphology into the following types (Figure 41-4): amputation (stump) neuroma, neuroma-in-continuity (central or

fusiform neuroma), and lateral neuromas that are either lateral exophytic neuromas or lateral adhesive neuromas.

Nerve Injury Classification

There are two acceptable classification schemes used to describe the histologic changes that occur following nerve injury. Seddon described a three-stage classification system in 1943,⁴² and Sunderland revised and further subclassified nerve injuries into five grades in 1951 (Figure 41-5 and Table 41-3).⁴³ A neurapraxia (Seddon) or first-degree (Sunderland) injury is characterized as a conduction block from transient anoxia owing to acute epineurial/endoneurial vascular interruption resulting from mild nerve

manipulation (traction or compression), with rapid and complete recovery of sensation and no axonal degeneration. Damage is confined to within the endoneurium. Sunderland further subdivides first-degree injuries into types I, II, and III. Type I results from mild nerve manipulation with rapid (hours) return of sensation when neural blood flow is restored. Type II is due to moderate traction or compression with the formation of transudate or exudate fluid and intrafascicular edema, with return of sensation following edema resolution (days). Type III injuries result from more severe nerve manipulation that may result in segmental demyelination, with recovery within days to weeks. An axonotmesis (Seddon) corre-

FIGURE 41-5 Nerve injury classifications: A, Seddon classification; B, Sunderland classification.

Table 41-3 Nerve Injury Classifications: Seddon versus Sunderland

<i>Seddon</i>	<i>Sunderland</i>	<i>Histology</i>	<i>Outcomes</i>
Neurapraxia	First degree	No axonal damage, no demyelination, no neuroma	Loss of sensation, rapid recovery (days to weeks), no microneurosurgery
Axonotmesis	Second, third, and fourth degrees	More axonal damage, demyelination, possible neuroma	Loss of sensation, slow incomplete recovery (weeks to months), possible microneurosurgery
Neurotmesis	Fifth degree	Severe axonal damage, epineurial discontinuity, neuroma formation	Loss of sensation, spontaneous recovery unlikely, microneurosurgery

sponds to second-, third-, and fourth-degree (Sunderland) injuries, with the difference being the degree of axonal damage. Second-degree injuries are due again to traction or compression that results in ischemia, intrafascicular edema, or demyelination. This damage extends through and includes the endoneurium with no significant axonal disorganization. Recovery is slow and may take weeks to months, and it may not be complete. Third-degree injuries continue the spectrum of more advanced injury owing to more significant neural trauma with variable degrees of intrafascicular architectural disruption and damage extending to the perineurium. Recovery is variable; it may take months and be incomplete. Fourth-degree injuries result in damage to the entire fascicle that extends through the perineurium to the epineurium, but the epineurium remains intact. There is axonal, endoneurial, and perineurial damage with disorganization of the fascicles. Spontaneous recovery is unlikely, but minimal improvement may occur in 6 to 12 months. Finally, neurotmesis (Seddon) and fifth-degree (Sunderland) injuries result from complete or near complete transection of the nerve with epineurial discontinuity and likely neuroma formation. Spontaneous neurosensory recovery is unlikely. For completeness, in 1988 Dellon and Mackinnon described a sixth-degree injury, which recognizes that many nerve injuries exhibit features of different degrees of injury according to Sunderland (Table 40-4).⁴⁴ The Seddon and Sunder-

land classification schemes attempt to correlate histologic changes with clinical outcome (see Table 41-3).

Clinical Neurosensory Testing

The patient who sustains an injury to the trigeminal nerve may present with a variety of signs and symptoms. These may be divided into nonpainful anesthesia, hypoesthesia, hyperesthesia, or painful anesthesia (anesthesia dolorosa), hypoesthesia, or hyperesthesia (allodynia—pain from a nonpainful stimulus—or hyperpathia—increased pain owing to a painful or nonpainful stimulus). The history usually indicates the etiologic event, and the chief complaint may include the following descriptive terms: numbness, itchy, crawling, stretched, drooling, painful, tingling, tickling, pulling, burning, stinging, pins and needles, hot sensation, cold sensation, inability to feel food on lip, inability to taste, inability to shave, inability to smile, and loss of consortium. The history of present illness should be explored in depth

with a description of the onset and progression of symptoms, change in symptoms, treatment received and response, aggravating and alleviating factors, and present symptoms.

The McGill Pain Questionnaire (MPQ) may be used to assess pain and altered sensation, and it is a useful tool for monitoring progression of neurosensory recovery. The MPQ uses three classes of descriptive words to assess the level of dysfunction and interference with activity: sensory class (temporal, spatial, thermal, punctate, incisive, constrictive, traction pressure), affective class (tension, fear, autonomic properties, punishment), and evaluative class (patient perception). Perhaps the simplest and most reliable measure of subjective patient assessment is the use of a visual analog scale. Generally, this is a 10 cm five-degree scale, with a degree marked every 2.5 cm (Figure 41-6). This is a useful tool for monitoring subjective improvement. It must be remembered that subjective and objective nerve testings are

Table 41-4 Sunderland Grade and Recovery Patterns

<i>Degree of Injury</i>	<i>Recovery Pattern</i>	<i>Rate of Recovery</i>	<i>Treatment</i>
First degree	Complete	Fast (days to weeks)	None
Second degree	Complete	Slow (weeks)	None
Third degree	Variable	Slow (weeks to months)	Possible nerve exploration
Fourth degree	None	Unlikely recovery	Microneurosurgery
Fifth degree	None	No recovery	Microneurosurgery
Sixth degree*	Varies [†]	Varies [†]	Varies [†]

rarely at the same level. For example, in one study of nerve testing following sagittal split osteotomy, the subjective neurosensory deficit was 26.0%, whereas the objective tests revealed an 89.5% deficit.⁴⁵ Treatment planning decisions must be based on an assessment of both the subjective and objective testing results. Also, a radiographic assessment may reveal prior radiographic predictors of root proximity to the canal, retained root fragments, distal bone removal, or the presence of foreign bodies in extraction sites.

Clinical examination begins with inspection of the oral cavity, which may show signs of self-induced trauma, a lingually placed third molar incision scar, or atrophic changes of the tongue fungiform papillae.⁴⁶ Palpation may induce a Tinel's sign, which is a provocative test of regenerating nerve sprouts that it is performed by light palpation over the area of suspected injury. This maneuver elicits a distal referred "tingling" sensation at the target site. This sign is thought to indicate small-diameter fiber recovery; however, it is poorly correlated with functional recovery and is often confused with neuroma formation. To perform the CNT appropriately, the patient should be seated comfortably in a quiet room, and the specific testing procedures should be explained clearly to the patient, with confirmation that there is an understanding of what the patient is being asked to do and what possible responses are acceptable. The specific tests are performed

with the patient's eyes closed, and the contralateral uninjured side serves as the control, when appropriate.

The CNT is performed at three levels: A, B, and C (Table 41-5).⁴⁷ The CNT involves a dropout algorithm that attempts to correlate the results of the test with the level of nerve injury (Figure 41-7). If the results of level A testing are normal, then the CNT is terminated and the patient is considered normal; this would correspond to a Sunderland first-degree injury. An abnormal result at level A indicates the need to proceed to level B testing. If the results of level B testing are normal, then the patient is considered mildly impaired (Sunderland second-degree injury). If level B results are abnormal, then level C testing is performed. If level C results are normal, then the patient is moderately impaired (Sunderland third-degree injury). If level C results are abnormal, then the patient is considered severely impaired (Sunderland fourth-degree injury). If the patient's test results are abnormal at levels A, B, and C and there is no response to any noxious stimulus, the patient is considered completely impaired (Sunderland fifth-degree injury). Level A testing includes brush-stroke directional and static two-point discriminations. These tests assess function of the larger myelinated A alpha and beta fibers. These fibers are the most sensitive to compression and traction injuries; therefore, the CNT is terminated if level A is normal. Brush-stroke directional discrimination is performed with a fine sable or

camel hair brush. The brush is stroked gently across the area of involvement at a constant rate, and the patient is asked to indicate the direction of movement (ie, to the left or right) and the correct number of patient statements out of 10 is recorded. Two-point discrimination is performed in a static fashion (vs a moving two-point discrimination) and with blunt tips to avoid A delta and C fiber stimulation. This test can be performed with any device that is capable of allowing the distance between two points to be measured consistently (eg, a Boley gauge). The closest distance (in millimeters) at which the patient can consistently discern the two points is recorded. At level B testing, contact detection is performed with Semmes-Weinstein monofilaments or von Frey hairs, which, again, assess the A beta fiber integrity and function. These devices are acrylic resin or plastic transparent/translucent rods with nylon filaments of varying diameters. The stiffness of each filament determines the force necessary to deflect or bend the filament. The narrowest diameter filament that requires the least amount of force to deflect that is detected consistently is recorded. At level C testing, pinprick nociception and thermal discrimination assess the smaller A delta and C fibers, which are most resistant to injury. Pinprick nociception may be performed simply with a 30-gauge needle; however, a pressure sensitive device is more appropriate. Thermal discrimination may be performed with suprathreshold methods using ice or ethyl chloride or hot water on a cotton swab, but other options are

Table 41-5 Clinical Neurosensory Testing

Subjective assessment: visual analog scale

available. Minnesota thermal disks made of copper, stainless steel, glass, and polyvinyl chloride can be used.

Although the tests employed in the CNT are considered objective tests, they are, in reality, subjective since they require a patient response. There are few purely objective tests of nerve function available, and these include trigeminal somatosensory evoked potentials and magnetic source imaging.⁴⁸ Unfortunately, these tests are not readily available and are not considered a part of the routine assessment of a nerve-injured patient. Also, there is little data on the trigeminal nerve

and the patterns of responses based on specific injuries.

Finally, taste can be assessed by a variety of means, but generally it is performed as either whole-mouth or localized testing. Solutions such as 1 M sodium chloride (salt), 1 M sucrose (sweet), 0.4 M acetic acid (sour), and 0.1 M quinine (bitter) may be used. There are many difficulties with taste assessment in the patient with a lingual nerve injury. The perception of taste alteration is extremely variable and has little correlation with the degree of lingual nerve injury. For example, a patient with a fourth- or fifth-degree lingual nerve

injury may not report any taste alteration subjectively but may test abnormally with different solutions. The complex sense of taste is mediated not only by the chorda tympani branch of the facial nerve but also through feedback mechanisms in the nasopharynx, oropharynx, and hypopharynx, as well as the nucleus tractus solitarius in the brainstem.⁴⁹ Regarding lingual nerve repair, objective and subjective neurosensory recovery also is inconsistent.⁵⁰

Diagnostic nerve blocks can be a useful component of the patient evaluation when dysesthesia or unpleasant sensations predominate the clinical scenario. The primary purpose of the diagnostic block is to localize the source of pain and determine the prognosis for recovery following either pharmacologic or surgical therapy. The preferred local anesthetic solution is of a low concentration (eg, 0.25% lidocaine) to selectively block the smaller A delta and C fibers while not affecting the larger myelinated fibers. If the low concentration fails to relieve the pain, a higher concentration is used in the same location. Diagnostic blocks begin peripherally and proceed centrally with constant reassessment of the area of involvement both objectively and subjectively. If patients present with symptoms consistent with sympathetically mediated pain or causalgia, a stellate ganglion block may be performed. These symptoms indicate a problem not amenable to peripheral microneurosurgery. Other pain syndromes that generally are not relieved with diagnostic nerve blocks include anesthesia dolorosa and deafferentation pain; these also are not managed surgically but, rather, pharmacologically.

Nonsurgical Treatment

Pharmacologic management of peripheral nerve injuries is reserved for patients who present with unpleasant abnormal sensations or dysesthesia. In the majority of cases, pharmacologic treatment should be managed with a consultation from an experienced individual such as a neurologist or

Table 41-6 Systemic Pharmacologic Agents

facial pain specialist. Many systemic (Table 41-6) and topical (Table 41-7) medications are available.⁵¹ Whereas the systemic drugs may have significant side effects, topical agents offer the advantages of little systemic absorption, possibly only minor irritation (which can be relieved with a period of abstinence), and over-the-counter availability in many cases. There are also many combinations of topical agents that can be used, such as a eutectic mixture of local anesthetics (EMLA) that contains 2.5% lidocaine and 2.5% prilocaine. Many of the topical agents are prepared in a pleuronic lecithin organogel base. For most oral surgeons long-term pharmacologic management is not part of their routine practice, so the prompt referral to a microneurosurgeon or neurologist may offer the best chance for long-term success. Consideration may be given to a trial of a topical

Table 41-7 Topical Medications

Category	Example
Topical anesthetics	5% viscous lidocaine gel; 20% benzocaine gel; 2.5% lidocaine with 2.5% prilocaine
Neuropeptides	Capsaicin cream (0.025% or 0.075%)
Nonsteroidal anti-inflammatory drugs	Ketoprofen 10–20% PLO base; diclofenac 10–20% PLO base
Sympathomimetics	Clonidine 0.01% PLO base or patch
N-methyl-D-aspartate blocking agents	Ketamine 0.5% PLO base
Anticonvulsants	Carbamazepine 2% PLO base
Tricyclic antidepressants	Amitriptyline 2% PLO base
Antispasmodics	Baclofen 2% PLO base

PLO = pleuronic lecithin organogel.

agent such as capsaicin cream 0.025% tid and/or a systemic medication with few side effects, such as baclofen 10 mg tid or gabapentin 100 mg tid.

Some oral surgeons manage perioperative paresthesia following third molar removal or implant placement with a short course of corticosteroid therapy in an attempt to decrease perineural edema. Although there is little evidence to suggest that systemic steroids actually provide any effect, the use of steroids when a nerve injury occurs, indicates that the surgeon has recognized a problem and has taken an action to improve outcome, which is advantageous when considering medico-legal involvement issues.

Perhaps the most important consideration should be prompt referral, when indicated, to a specialist for pharmacologic or surgical management of the patient with a nerve injury. The indications for referral include but are not limited to those listed in Table 41-8.

In the past, prior to consideration of surgical management, a variety of neuroablative techniques have been used to manage painful neuropathies. Some of these include radiofrequency thermal neurolysis, cryoneurolysis, and alcohol and glycerol injections at the site of injury as well as at the gasserian ganglion. Based on the complications and recurrence rates of dysesthesia, caution should be employed when

Presence or development of dysesthesia

considering these options.^{52,53} The use of a low-level laser (gallium-aluminum-arsenide, wavelength 820 nm) has promise in the area of neural healing. Several studies have shown improvement in objective and subjective neurosensory recoveries with the use of laser therapy in some of the more difficult cases, such as long-standing injuries, orthognathic IAN paresthesia, and prolonged dysesthesia unresponsive to pharmacologic or surgical therapy.^{54–56} However, the current limited availability of the low-level laser and the lack of approval by the US Food and Drug Administration preclude its routine use for patients with nerve injuries.

Treatment Algorithms

The decision to proceed with microneurosurgery must be made following a careful patient assessment over a defined period of time. The dilemma is that sufficient time must be given to allow for spontaneous neurosensory recovery but that prompt surgical intervention may afford the best chance for recovery. Time is a critical issue for three main reasons. First, at the site of injury, distal nerve degeneration (wallerian degeneration—named for Augustus Waller in 1892) occurs owing to the interruption of axonal transport. This progressive loss of neural tissue may compromise future repair attempts. Second, at the nerve cell bodies there is ganglion cell death that occurs early following injury.⁵⁷ Third, as the time from nerve injury increases, there is a higher likelihood that central cortical changes may occur, and these would make peripheral repair ineffective.⁵⁸ As a result, if 30 to 50% of gan-

glion cells have undergone necrosis, the best possible success rate from surgical repair may also be 30 to 50%.

Microneurosurgery is indicated for persistent paresthesia that fails to improve over successive examinations. This includes both subjective and objective assessments. Surgery is not indicated if

there is continued improvement at each subsequent assessment. The current recommendations are to consider surgery for the lingual nerve within 1 to 3 months following the injury, and for the IAN within 3 to 6 months following the injury (Figure 41-8). The rationale for the difference in time is that the IAN lies within a bony

canal that can guide spontaneous regeneration, so more time is allotted for that process, whereas a lingual nerve injured within soft tissue does not have a “physiologic conduit” to guide regeneration. In general, the oral surgeon should have follow-up examinations with the patient over a period of approximately 4 weeks. If there is persistent paresthesia or a worsening of symptoms, referral should be made to a microneurosurgical specialist.

For an unobserved nerve injury, the plan should be to continue neurosensory testing for 1 month and then to refer for surgery in the 1- to 3-month (lingual nerve) or 3- to 6-month (IAN) time periods. For an observed nerve injury, treatment should focus on the specific etiology. For a suspected traction injury (Sunderland first-, second-, and third-degree injuries), the patient should be tested for 1 month for signs of expected spontaneous recovery. In the case of nerve compression, immediate decompression should be considered. This includes removal of a root displaced into the IAN canal, removal or replacement when there is evidence of implant impingement within the confines

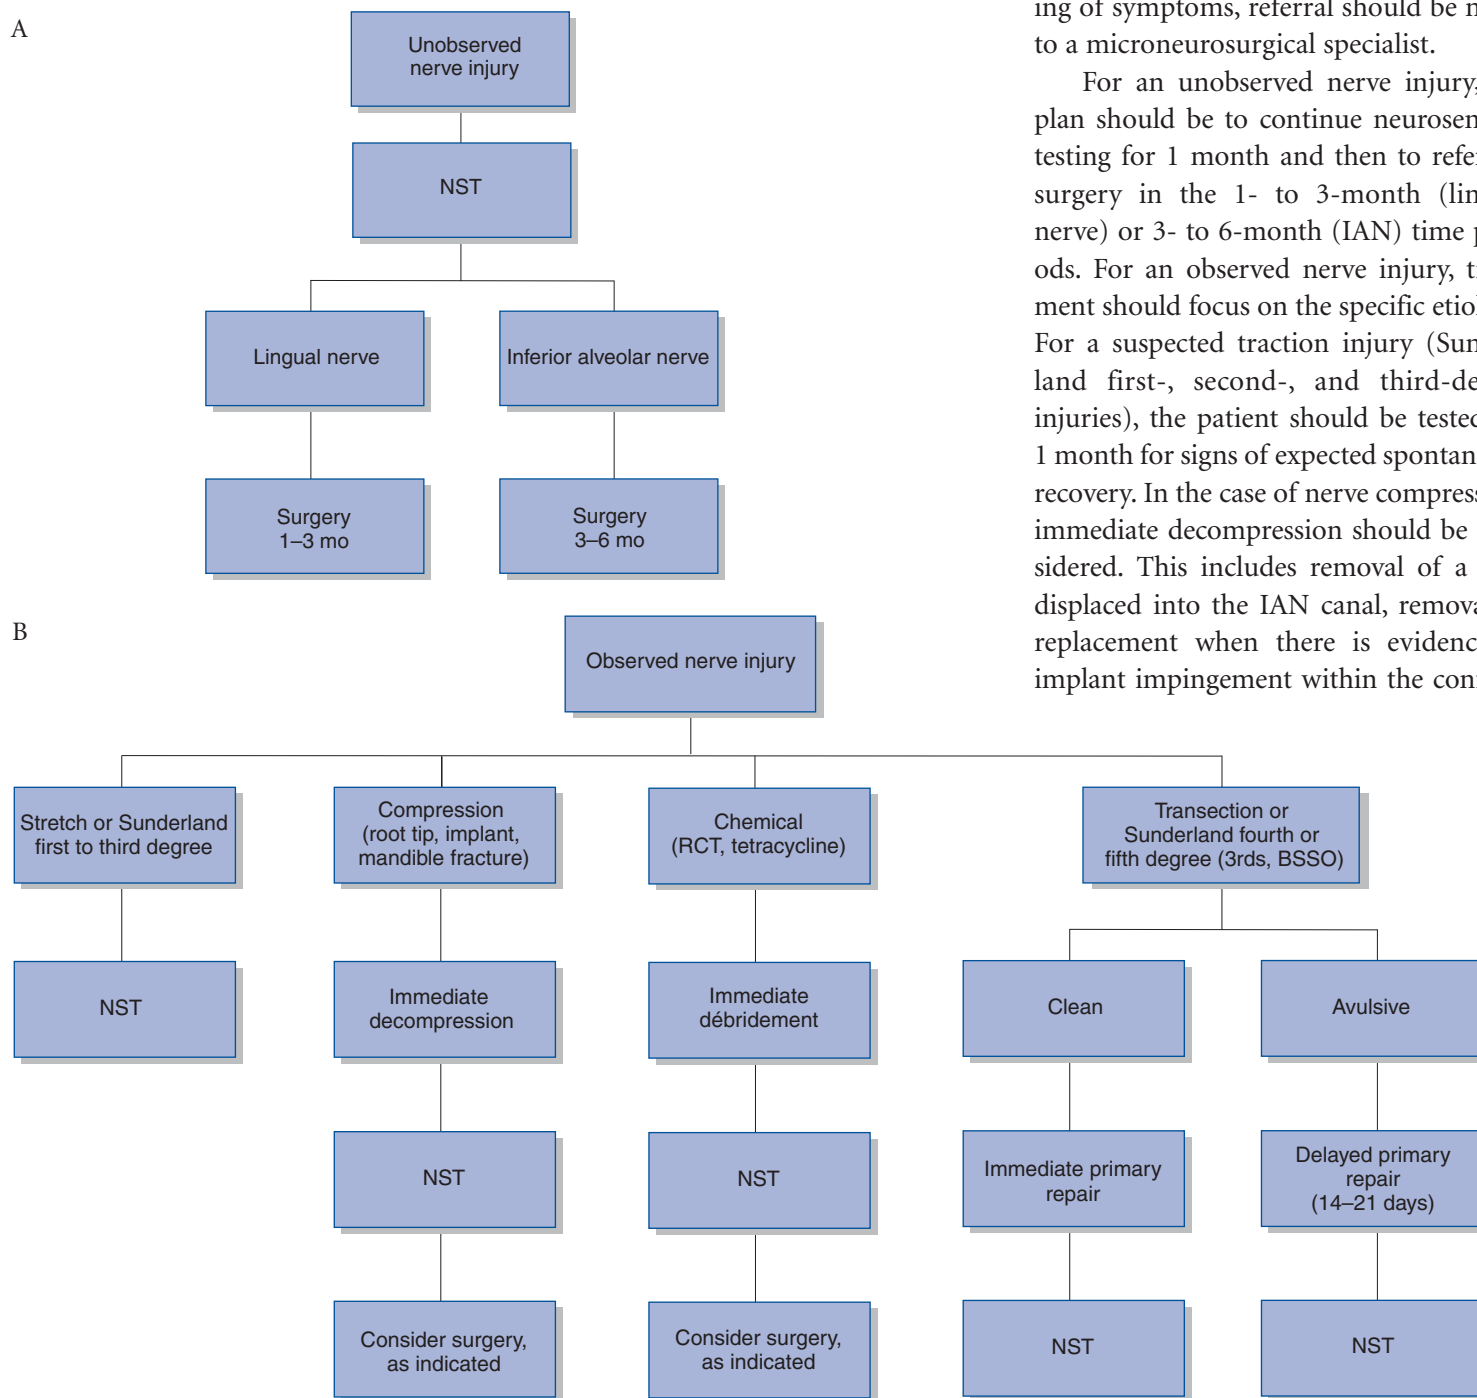

FIGURE 41-8 Nerve treatment algorithms: A, unobserved nerve injury; B, observed nerve injury. BSSO = bilateral sagittal split osteotomy; NST = neurosensory testing; RCT = root canal therapy.

of the IAN canal, or reduction and alignment of a displaced posterior mandible fracture including the IAN canal. Neurosensory testing should be performed following decompression, and microneurosurgery should be considered as indicated. Chemical injuries should be débrided promptly. For observed transection injuries (Sunderland fourth- or fifth-degree injuries), an immediate primary repair may be performed for a clean transection injury (eg, scalpel transection). For an avulsive injury (eg, lingual nerve entangled in a bur), consideration is given to a delayed primary repair performed at 3 weeks following the injury. This allows time for the proximal and distal nerve stumps to define the degree of injury, and to determine whether the surrounding environment is conducive to nerve surgery, when there are high levels of neurotropic and neurotrophic factors. After surgery, patients should be followed up with repeat neurosensory testing.

The success rates of microneurosurgical reconstruction following nerve injury are variable in the literature. This is due to many factors including the lack of standardization with the following⁵⁹: age, the etiology of injury, the time of delay from injury to repair, specific surgical techniques used, the length of the nerve gap, the method of neurosensory examination, the use of normative values for control sites, follow-up period variability, and criteria to define success (Table 41-9). A global review of the literature might indicate a success rate of 30 to 50% following microneurosurgery, including direct and gap repairs. In general, direct repair is preferred over gap repair (eg, using an autogenous nerve graft) and has higher reported success rates.⁶⁰ Perhaps the largest study to date indicates an overall “success” rate of 76.2% in 521 patients.⁶¹ The success criteria were defined as light touch detected > 80% of the time and a 30% decrease in postoperative pain level. The study results suggested some important trends in outcome.

Hypoesthetic injuries improved better following microneurosurgery than did hyperesthetic injuries, the lingual nerve recovered better than did the IAN overall, and there was a decrease in success associated with a delay of > 6 months. A recent report of 51 microneurosurgical reconstructions (direct and gap repairs) found that 10 patients subjectively reported good improvement, 18 patients some improvement, 22 patients no improvement, and 1 patient reported feeling worse following surgery.⁶² This indicates that 55% of patients showed some improvement. In another study of 53 surgical patients, with a mean follow-up of 13 months, light touch improved from 0 to 51% and pinprick nociception improved from 34 to 77%. Patients also experienced improved taste and an increased number of fungiform papillae, and there was a decrease in incidence of accidental tongue biting. Interestingly, there was no correlation of success with delay from time of injury to repair. No patient became completely normal, and there was no reduction in dysesthesia; however, most patients considered the surgery worthwhile. There is certainly a need for standardization in all aspects of evaluation and management of microneurosurgical patients.

Surgical Treatment

Microneurosurgical reconstruction involves a sequence of surgical procedures including exposure, dissection, assessment, manipulation, and repair. Many of the techniques of trigeminal nerve repair follow those of hand surgery and use similar instruments. In general, surgical loupe magnification ($\times 3.5$ magnification) is adequate. An operating microscope ($\times 12$ magnification) is cumbersome and difficult to use with a transoral exposure, although it may be more useful with a transfacial approach.

Exposure

Surgical access to the lingual or IAN may be accomplished transfacially or transoral-

ly. The transfacial approach affords wide exposure and access; however, it necessitates a facial incision with subsequent scar formation. The intraoral approach provides a more difficult surgical access and requires more diligence in microsurgery in the posterior regions of the oral cavity, but it avoids a facial incision. The decision regarding surgical access depends on an individual patient's anatomy, the site of nerve injury, planned surgical procedures, patient preference, and surgeon's skill and experience.

External Neurolysis

Microdissection of the nerve once exposed involves liberation of the nerve from the surrounding tissues to facilitate inspection. For the lingual nerve this procedure may involve the release of the nerve from a lateral adhesive neuroma in the area of the lingual plate in the third molar region, whereas for the IAN a corticotomy is generally required for external neurolysis. Sev-

Table 41-9 Classification of Sensory Recovery

Grade (Stage)	Recovery of Sensibility
S0	No recovery
S1	Recovery of deep cutaneous pain
S1+	Recovery of some superficial pain
S2	Return of some superficial pain and tactile sensation
S2+	S2 with over-response
S3*	Return of some superficial pain and tactile sensation without over-response; two-point discrimination > 15 mm
S3+	S3 with good stimulus localization; two-point discrimination = 7–15 mm
S4	Complete recovery, S3+; two-point discrimination = 2–6 mm

*S3 score indicates significant clinical recovery (Wyrick JD, Stern PJ. Secondary nerve reconstruction. *Hand Clin* 1992;8:587).

F, Wide exposure of the neurovascular bundle.

eral techniques have been described for lateral decortication in the area of the third molar for IAN exposure, and these range from a simple nerve transpositioning to a modified buccal corticotomy or a unilateral sagittal split ramus osteotomy (Figure 41-9).⁶³ The location of the injury and the surgeon's preference frequently dictate the specific approach used. The lingual nerve is usually exposed via a modified incision used for third molar surgery with a sulcular lingual extension (Figure 41-10). For the infraorbital nerve, external neurolysis may be performed secondary to reduction and fixation of a displaced zygomaticomaxillary complex fracture impinging on the neurovascular bundle at the infraorbital foramen. It has been suggested that external neurolysis may provide definitive treatment for a nerve injury if the nerve compression is < 25% of the normal diameter, if the paresthesia is of short duration (< 6 mo), and if there is no evidence of neuroma formation.⁶⁴

Internal Neurolysis

The term *internal neurolysis* refers to surgical manipulations within the epineurium to prepare the nerve for repair. Sophisticated maneuvers may compromise repair by unnecessary removal of tissue and

FIGURE 41-10 Lingual nerve exposure. A, Incision design via a distobuccal extension and lingual gingival sulcus approach. B, Right lingual nerve exposure with neuroma. C, Right lingual nerve repair with an interpositional nerve graft.

A and B adapted from LaBanc JP. *Reconstructive microneurosurgery of the trigeminal nerve*. In: Peterson LJ, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol 2. Philadelphia: J.B. Lippincott Company; 1992. p. 1067.

induction of cicatrix formation owing to excessive manipulation. Several types of internal neurolysis have been described, including epifascicular epineurotomy, epifascicular epineurectomy, and interfascicular epineurectomy (Figure 41-11). The first two prepare the epineurium for repair; any interfascicular surgery may cause further fascicular disruption and scarring. Extensive internal neurolysis procedures should be used with caution.

Nerve Stump Preparation

Perhaps the most critical portion of the surgical procedure involves the inspection of the proximal and distal nerve stumps via magnification. The preparation of the nerve stumps follows exposure; there may already be an existing discontinuity from a transection injury. When a neuroma is present, meticulous excision is required (Figure 41-12). It must be recognized that with any neuroma, the clinical appearance of neuronal edema or atrophy is less than the internal fascicular changes (see Figure 41-12A). Failure to resect enough nerve tissue to reach normal fascicles results in a failure of neurosensory recovery. Once the nerve is divided, if necessary, into proximal and distal stumps, care must be taken to resect small (1 mm) portions of the nerve trunk in both directions (see Figure

41-12B) until healthy glistening white mushrooming fascicles are seen to herniate through the edges of the epineurium (see Figure 41-12C).

Approximation

The trigeminal nerve is similar to other peripheral nerves in that it does not tolerate tension well; therefore, tension-free closure is mandatory.⁶⁵ The deleterious effects of tension result from vascular compromise and subsequent fibrosis at the nerve repair site. Approximation is the act of

bringing the nerve stumps into contact and assessing the degree of tension that is present. At the time of approximation a decision must be made regarding whether to use an interpositional graft. In general, mobilization with primary epineurial repair is possible for lingual nerve gaps < 10 mm and for IAN gaps < 5 mm.

Coaptation

Coaptation is the process of aligning the proximal and distal nerve stumps into the premorbid cross-sectional fascicular ori-

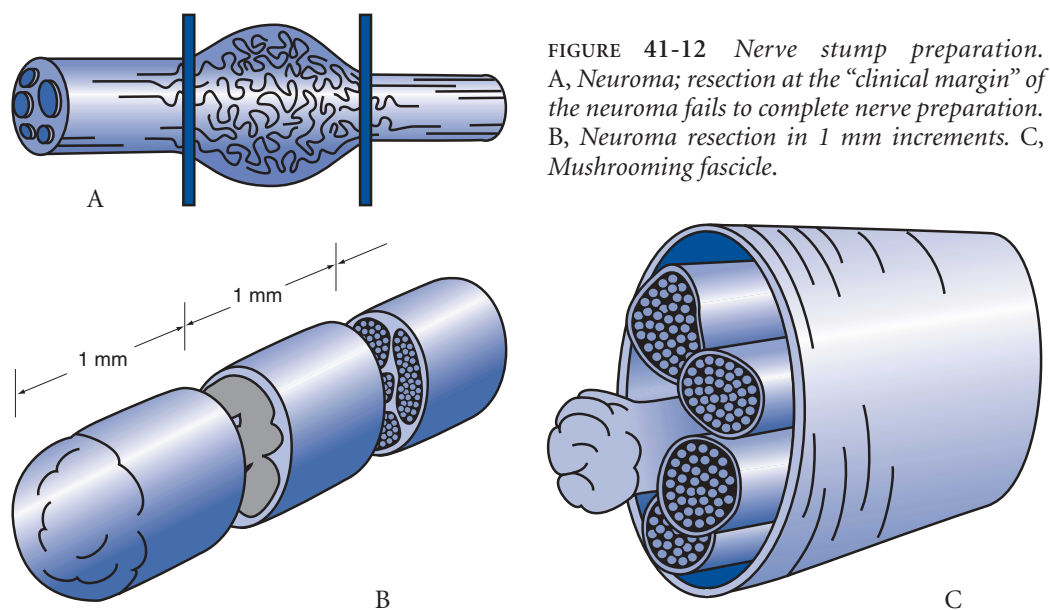

FIGURE 41-12 Nerve stump preparation. A, Neuroma; resection at the “clinical margin” of the neuroma fails to complete nerve preparation. B, Neuroma resection in 1 mm increments. C, Mushrooming fascicle.

entation. This is a difficult maneuver with a polyfascicular nerve that has undergone any degree of distal nerve changes in diameter or fascicular pattern. This step is usually not performed painstakingly in trigeminal nerve repair because of the complex polyfascicular pattern.

Neurorrhaphy

Neurorrhaphy is the act of nerve suturing for both direct and gap repairs. The trigeminal nerve is repaired using epineurial sutures, not perineurial sutures (Figure 41-13). Generally, an 8-0 monofilament nonresorbable nylon suture is chosen since a resorbable material would invoke inflammation and disturb the area of anticipated neural healing. At least two sutures are used per anastomosis site to prevent rotation, but not more than three or four sutures should be used per anastomosis. The first suture is placed on the medial side of the anastomosis since it is more difficult to access. The epineurium is pierced with the needle 0.5 to 1.0 mm from the edge of the nerve. The second suture is placed 180° from the first suture, and then an assessment is made regarding the need for more sutures.

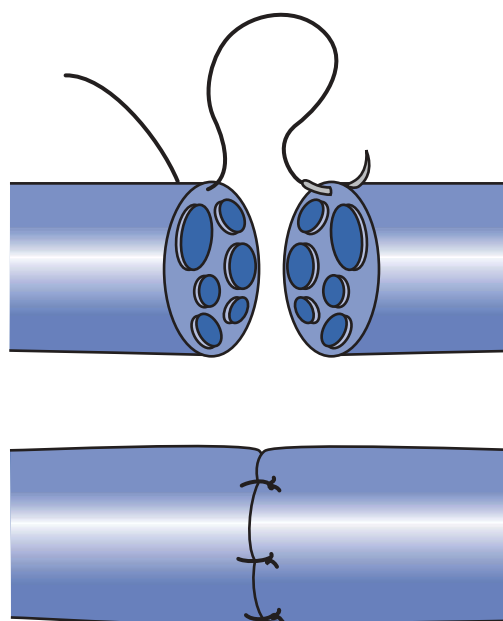

FIGURE 41-13 Direct epineurial neurorrhaphy.

Table 41-10 Size of Donor Nerve Grafts Relative to Injured Nerve

Injured Nerve	Donor Nerve		
	Sural (2.1 mm)	Greater Auricular (1.5 mm)	Greater Auricular Cable (3.0 mm)
Inferior alveolar (2.4 mm)	88%	63%	125%
Lingual (3.2 mm)	66%	47%	94%

Adapted from Brammer JP and Epker BN.⁶⁸

Nerve Grafts

When neurorrhaphy is not possible without tension and a nerve gap exists, an interpositional graft must be considered for indirect neurorrhaphy.⁶⁶ The options for autogenous nerve grafting include but are not limited to the sural nerve, the greater auricular nerve, and possibly the medial antebrachial cutaneous nerve.⁶⁷ The sural nerve is the preferred nerve for grafting since it most appropriately matches the nerve diameter and the fascicular number and pattern of the trigeminal nerve (Table 41-10).⁶⁸ The area of the nerve superior to the lateral malleolus exhibits less branching than at or below the lateral malleolus. The sural nerve, or medial sural cutaneous nerve, is a branch of the sacral plexus (S1, S2) and supplies sensory information to the posterior lower extremity and the dorsolateral foot. Sural grafts up to 20 cm in length are possible, and patients tolerate the donor site deficit well.⁶⁹ The greater auricular nerve is a poor choice for trigeminal repair. As a branch of the cervical plexus (C1, C2), the greater auricular nerve supplies sensation to the pre- and postauricular regions, the lower third of the ear, and the skin overlying the posteroinferior border at the angle of the mandible. Patients are generally not amenable to sacrificing one facial region for another. Additionally, the small diameter of the nerve makes it useful only when used as a cable graft (Figure 41-14). The sole advantage of a greater auricular graft over a sural graft is in situations when it can be harvested via the same incision for another procedure, such as the repair of an

extraoral mandibular fracture or management of pathology. The basic premise with graft repair is that the graft supplies the Schwann cells and growth factors necessary to support and encourage axonal sprouting through the graft toward the target site.

Entubulation Techniques

In an attempt to avoid donor site morbidity, a variety of entubulation techniques have been proposed to create conduits during nerve regeneration (Figure 41-15). These conduits involve both autogenous and alloplastic materials (Table 41-11). The autogenous options include vein,⁷⁰⁻⁷² collagen,^{73,74} and muscle grafts.⁷⁵ Alloplastic

materials include polyglycolic acid,⁷⁶ polymeric silicone,⁷⁷ and expanded polytetrafluoroethylene.⁷⁸⁻⁸¹ It appears that the use of these alloplastic materials has a high success in the animal model but poor clinical outcomes. Further investigation is warranted as new materials are developed.

Postsurgical Management

In the majority of cases, patients experience a variable period of complete anesthesia following nerve repair. In general, nerve regeneration progresses at approximately 1 mm/d (about 3 cm/mo) from the cell body to the target site. For example, with a direct IAN repair, the approximate distance from the trigeminal ganglion to the lower lip and chin is 10 cm; therefore, complete nerve regeneration takes about 100 days or 12 weeks following repair. With graft repair the time frame is lengthened owing to slowed regeneration through the graft site, but recovery is variable. A poor outcome following microneurosurgery may preclude future surgical options; therefore, the best chance for microneurosurgical success is at the first (and most likely, the last) surgical intervention.

Medicolegal Issues

Oral and maxillofacial surgeons currently practice during a time of “malpractice crisis,” and nerve injuries secondary to third molar removal account for a large propor-

tion of the complaints.⁸² Based on the information contained in this chapter and recent trends in malpractice, all oral and maxillofacial surgeons should have a minimum of understanding of the diagnosis and management of nerve injuries according to the so-called legal parameters of care.⁸³ These are summarized as follows:

- Spontaneous sensory recovery occurs in most but not all patients. It is difficult to predict early, it may not be “complete,” and it may not be to the patient’s satisfaction. Nerves in soft tissue (lingual nerve) have a lower rate of spontaneous regeneration than do those in bony canals (IAN)
- All nerve injuries should be documented and evaluated with a history, examination, and neurosensory testing (objective and subjective). The injury should be classified (Seddon or Sunderland). In cases of observed or known nerve injury, prompt referral for microsurgery provides the best opportunity for sensory recovery
- Repeat examinations at frequent intervals may be necessary. Patients should be followed up for at least 1 month. Complete recovery in 1 month indicates neurapraxia, and no further treatment is indicated. Neurosensory dysfunction that lasts > 1 month indicates a higher-grade injury with uncertain spontaneous neurosensory recovery. Microneurosurgical consultation should be considered
- Nerve injuries that show improvement (objective and/or subjective) may be followed up expectantly. Once improvement stops for a period of time, it usually does not begin again
- Most nerve injuries resolve within 3 to 9 months, but *only* if improvement begins prior to 3 months. Patients who are anesthetic at 3 months usually do not achieve significant neurosensory recovery. Prompt microsurgery is usually indicated
- Patients with partial sensory loss and/or painful sensations *that they find unacceptable* should be considered for microsurgery if objective and subjective findings have not improved or returned to normal by 4 months. Microsurgical delay decreases the chance of success because progressive distal nerve degeneration and/or the development of a central pain syndrome occur
- Some painful neuropathies may be managed nonsurgically under the supervision of a microneurosurgeon or other experienced individual (eg, neurologist)
- Angry uninformed patients with nerve injuries are less likely to improve with any treatment, surgical or nonsurgical. A discussion regarding options and the risk of nerve injury should be provided so that the patient can give informed consent. Local anesthetic injections carry a risk of nerve injury
- Early surgical intervention (ie, at 3–4 mo) is *more likely* to produce neurosensory improvement than is late intervention. Surgery delayed beyond 12 months is seriously compromised by distal nerve degeneration and the development of chronic pain syndromes
- Surgery is *more likely* to improve responses to objective sensory testing and/or to reduce functional impairment than it is to reduce pain or subjective feelings of numbness

APPENDIX Nerve Terminology Review*

allodynia: Pain due to a stimulus that does not normally provoke pain.

analgesia: Absence of pain in the presence of stimulation that would normally be painful.

anesthesia: Absence of any sensation in the presence of stimulation that would normally be painful or nonpainful.

anesthesia dolorosa: Pain in an area or region that is anesthetic.

atypical neuralgia: A pain syndrome that is not typical of classic nontraumatic trigeminal neuralgia.

axonotmesis (Seddon) or second- through fourth-degree injuries (Sunderland): Nerve injury characterized by axonal injury with subsequent degeneration and regeneration.

causalgia: Burning pain, allodynia, and hyperpathia after a partial injury of a nerve.

central pain: Pain associated with a primary central nervous system lesion (spinal cord or brain trauma, vascular lesions, tumors).

chemoreceptor: A peripheral nerve receptor that is responsive to chemicals, including catecholamines.

deafferentation pain: Pain occurring in a region of partial or complete traumatic nerve injury in which there is interruption of afferent impulses by destruction of the afferent pathway or other mechanism.

dysesthesia: An abnormal sensation, either spontaneous or evoked, that is unpleasant. All dysesthesias are a type of paresthesia but not all paresthesias are dysesthesias.

endoneurium: A connective tissue sheath surrounding individual nerve fibers and their Schwann cells.

epineurium: A loose connective tissue sheath that encases the entire nerve trunk.

fascicle: A bundle of nerve fibers encased by the perineurium.

hyperalgesia: An increased response to a stimulus that is normally painful.

hyperesthesia: An increased sensitivity to stimulation, excluding the special senses (ie, seeing, hearing, taste, and smell).

hyperpathia: A painful syndrome characterized by increased reaction to a stimulus, especially a repetitive stimulus. The threshold is increased as well.

hypoalgesia: Diminished pain in response to a normally painful stimulus.

hypoesthesia: Decreased sensitivity to stimulation, excluding the special senses (ie, seeing, hearing, taste, and smell).

mechanoreceptor: A peripheral nerve receptor preferentially activated by physical deformation from pressure and associated with large sensory axons.

mesoneurium: A connective tissue sheath, analogous to the mesentery of the intestine, that suspends the nerve trunk within soft tissue.

monofascicular pattern: Characteristic cross-section of a nerve containing one large fascicle.

neuralgia: Pain in the distribution of a nerve or nerves.

neurapraxia (Seddon) or first-degree injury (Sunderland): Nerve injury characterized by a conduction block, with rapid and virtually complete return of sensation or function and no axonal degeneration.

neuritis: A special case of neuropathy now reserved for inflammatory processes affecting nerves.

neurolysis: The surgical separation of adhesions from an injured peripheral nerve.

neuroma: An anatomically disorganized mass of collagen and nerve fascicles, and a functionally abnormal region of a peripheral nerve resulting from a failed regeneration following injury.

neuropathy: A disturbance of function or a pathologic change in a nerve.

neurotization: Axonal invasion of the distal nerve trunk.

neurotmesis (Seddon) or fifth-degree injury (Sunderland): Nerve injury characterized by severe disruption of the connective tissue components of the nerve trunk, with compromised sensory and functional recovery. Third-degree injury: Characterized by axonal damage and a breach of the endoneurial sheath, resulting in intrafascicular disorganization. The perineurium and epineurium remain intact. The mechanism is typically traction or compression.

Fourth-degree injury: Characterized by disruption of the axon, endoneurium, and perineurium, resulting in severe fascicular disorganization. The epineurium remains intact. Possible mechanisms include traction, compression, injection injury, and chemical injury. Fifth-degree injury: Characterized by complete disruption of the nerve trunk with considerable tissue loss. Possible mechanisms include laceration, avulsion, and chemical injury.

nociceptor: A receptor preferentially sensitive to a noxious stimulus or to a stimulus that would become noxious if prolonged.

oligofascicular pattern: Characteristic cross-section of a nerve containing 2 to 10 rather large fascicles.

paresthesia: An abnormal sensation, either spontaneous or evoked, that is not unpleasant. A global term used to encompass all types of nerve injuries.

perineurium: A thick connective tissue sheath surrounding fascicles.

polyfascicular pattern: Characteristic cross-section of a nerve containing > 10 fascicles of different sizes, with a prevalence of small fascicles.

protopathia: The inability to distinguish between two different modes of sensation, such as a painful and nonpainful pinprick.

sympathetically mediated pain: A general term that refers to a family of related disorders including causalgia, reflex sympathetic dystrophy, minor causalgia, Sudeck's atrophy, and postherpetic neuralgia, which may be sympathetically maintained.

synesthesia: A sensation felt in one part of the body when another part is stimulated.

wallerian degeneration: The distal degeneration of the axon and its myelin sheath following injury.

Cleft Lip and Palate: Comprehensive Treatment Planning and Primary Repair

Bernard J. Costello, DMD, MD

Ramon L. Ruiz, DMD, MD

The comprehensive treatment of cleft lip and palate deformities requires thoughtful consideration of the anatomic complexities of the deformity and the delicate balance between intervention and growth. Comprehensive and coordinated care from infancy through adolescence is essential in order to achieve an ideal outcome, and surgeons with formal training and experience in all of the phases of care must be actively involved in the planning and treatment.¹⁻³ Specific goals of surgical care for children born with cleft lip and palate include the following:

- Normalized esthetic appearance of the lip and nose
- Intact primary and secondary palate
- Normal speech, language, and hearing
- Nasal airway patency
- Class I occlusion with normal masticatory function
- Good dental and periodontal health
- Normal psychosocial development

Successful management of the child born with a cleft lip and palate requires coordinated care provided by a number of different specialties including oral/maxillo-facial surgery, otolaryngology, genetics/dys-

morphology, speech/language pathology, orthodontics, prosthodontics, and others.⁴ In most cases care of patients with congenital clefts has become a subspecialty area of clinical practice within these different professions. In addition to surgery for cleft repair, treatment plans routinely involve multiple treatment interventions to achieve the above-stated goals. Because care is provided over the entire course of the child's development, long-term follow-up is critical under the care of these different health care providers. The formation of interdisciplinary cleft palate teams has served two key objectives of successful cleft care: (1) coordinated care provided by all of the necessary disciplines, and (2) continuity of care with close interval follow-up of the patient throughout periods of active growth and ongoing stages of reconstruction. The best outcomes are achieved when the team's care is centered on the patient, family, and community rather than a particular surgeon, specialty, or hospital. The idea of having an objective team that does not revolve around the desires of one particular individual or discipline is sometimes impeded by competitive interactions between surgical special-

ties. Historic battles over surgical domains between surgical specialties and economic factors contribute to these conflicts and negatively affect the work of the team. Healthy team dynamic and optimal patient care are achieved when all members are active participants, when team protocols and referral patterns are equitable and based on the surgeons' formal training and experience instead of specialty identity, and when the needs of the child are placed above the needs of the team.

This chapter presents an overview of the concepts for reconstruction of the cleft lip and palate deformity. The surgical reconstruction of clefts requires that the surgeon undertaking this important work maintain a cognitive understanding of the complex malformation itself, the varied operative techniques employed, facial growth considerations, and the psychosocial health of the patient and family. The objectives of this chapter will be to present the overall staged reconstructive approach for repair of cleft lip and palate from infancy through the time of skeletal maturity, as well as a focused discussion of the specific surgical procedures involved in primary cleft lip and palate repair. Secondary revision procedures, bone

graft reconstruction of the cleft maxilla, and orthognathic surgery for cleft-related dysmorphology are discussed in Chapter 43, “Reconstruction of the Alveolar Cleft,” Chapter 44, “Reconstruction of Cleft Lip and Palate: Secondary Procedures,” and Chapter 61, “Orthognathic Surgery in the Patient with Cleft Palate.”

History of Cleft Lip and Palate Repair

The history of cleft lip and palate care has always been closely linked to dentistry and oral and maxillofacial surgery. The birth and roots of what is now the American Cleft Palate-Craniofacial Association are strongly rooted in dentistry.

The first documented cleft lip repair was performed in AD 390 on a patient who later became the Governor General of several regions in China, although nothing is known about the actual surgeon.^{5,6} Jehan Yperman is believed to have been the first to describe unilateral and bilateral cleft lip repair.^{6,7} The first diagrammatic representation of cleft lip repair and cleft palate obturator use is credited to Ambrose Pare in the fourteenth century.^{6,8} Much later the first documented successful cleft palate repair was performed by a dentist, Le Monnier, in 1766 in Paris.^{6,9} The concepts of cleft lip and palate repair have evolved from straight line repairs to a variety of techniques using various cutbacks, triangles, and Z-plasties.⁶⁻¹⁴ During the 1950s, Asensio, an oral and maxillofacial surgeon from Guatemala, developed a novel technique for cleft lip repair, which involved the rotation of the philtral segment inferiorly and advancement of the lateral segment medially using a quadrangular flap. Although he used this approach in Guatemala throughout the 1950s, he did not report it until much later.^{15,16} Ralph Millard of Miami described his classic rotational-advancement technique in the mid-1950s, and his concepts changed cleft repair forever.^{17,18} Millard is credited with perhaps the most important technical development related to cleft lip

repair, and today the majority of surgeons use his original technique or some close modification of it.

In the mid-nineteenth century, Hüllihen, recognized as the father of American oral and maxillofacial surgery, published a treatise on comprehensive care of cleft lip and palate deformities.¹⁹ Another pioneer, Truman Brophy, was the professor of oral surgery and dean of the Chicago College of Dentistry and contributed greatly to the care of many patients with clefts. Brophy published a text detailing his experiences with the management of various malformations of the mouth and their surgical repairs including the details of cleft repair.²⁰ One of his pupils was Chalmers Lyons who started a residency program in oral surgery at the University of Michigan in 1917.²⁰ Lyons developed the largest cleft practice in America and contributed extensively to the literature.²⁰

Many of the concepts related to interdisciplinary care with a cleft palate team care were introduced by Robert Ivy, an oral and maxillofacial surgeon who later became dually qualified in plastic surgery.²⁰ Robert Ivy trained both in dentistry and medicine at the University of Pennsylvania. After his training in dentistry, Ivy further developed his interests in maxillofacial surgery as an assistant to his uncle, Matthew Cryer, who was a professor in oral surgery at the University of Pennsylvania. Robert Ivy became interested in clefts during his training as the first dental intern at Philadelphia General Hospital at the University of Pennsylvania. His interests in maxillofacial injury led him to serve in France in World War I as an assistant to Vilray Blair. After the war Ivy and Blair's collaboration resulted in two landmark publications by Ivy, *Essentials of Oral Surgery* and *Fractures of the Jaws*. Through work with his state representatives in Harrisburg, Pennsylvania, he was able to start the very first cleft palate clinics in Lancaster, Pittsburgh, Philadelphia, Erie, and Scranton that provided interdisciplinary

care to children for cleft lip and palate deformities. When Reed Dingman put forth a resolution of the American Society of Maxillofacial Surgeons condemning oral and maxillofacial surgeons practicing in the hospital setting, Ivy resigned his membership and sent a letter of protest to the organization that he helped build in support of his dental colleagues.²⁰

In the 1950s the concept of primary or early bone grafting of the cleft maxillary defect was introduced by Schmid.²¹ Although the concept was initially met with enthusiasm from a number of surgeons, primary bone grafting was eventually abandoned due to unfavorable outcomes. During the decades that followed, the negative skeletal, dental, and growth-related consequences of primary bone grafting became better understood.^{22,23} During the early 1970s oral and maxillofacial surgeons Boyne and Sands were the first to publish their favorable outcomes using autogenous particulate bone grafts for reconstruction of the cleft maxilla/alveolus later in childhood during the mixed dentition rather than earlier in life.²⁴ Although their work and results represented a landmark discovery in the field of cleft reconstruction, cleft palate teams were slow to integrate his approach into their treatment protocols because of the negative associations that lingered following the days of primary bone grafting. Today their principles of secondary bone grafting represent the standard approach for almost all of the world's cleft centers.^{24,25}

Orthognathic reconstruction of the patient with cleft deformities has been discussed by many authors.²⁶⁻³⁶ Early techniques limited some surgeons' options to procedures centered on mandibular setback.³⁷ During the 1970s the use of total maxillary osteotomy was pioneered by Bell.³⁸ His novel ideas provided oral and maxillofacial surgeons with an understanding of the biologic basis for maxillary osteotomy, described the vascular supply that allowed the procedures to be performed safely, and as a result incorporated

the Le Fort I osteotomy into modern-day practice.³⁸ Since that time a number of technical refinements have been described for use of the Le Fort I osteotomy specifically in the cleft patient. Much of this work has been done by two of Bell's former pupils, Fonseca and Turvey, who went on to make substantial contributions to the skeletal reconstruction of patients with clefts.³⁹ Another dual qualified oral and maxillofacial surgeon, Posnick, has published the most complete descriptions of surgical technique modifications for patients undergoing midfacial advancement in the absence of prior bone graft reconstruction and his extensive experiences with the long-term stability of midfacial advancement after correction of various types of cleft deformities with orthognathic techniques.²⁶⁻³⁰ Distraction osteogenesis has gained recent popularity for correction of midfacial hypoplasia but has yet to show significant advantages over traditional techniques for the majority of patients.^{32,33,40-42}

Comprehensive and coordinated care has become more prevalent across the world, involving many different types of specialty care for children with clefts. Posnick has provided the most comprehensive, succinct, and evidenced-based discussions on the topic of cleft lip and palate reconstruction from infancy through adolescence.²⁶ These efforts as well as craniofacial training programs associated with oral and maxillofacial surgery have helped to solidify the role of oral and maxillofacial surgery in the comprehensive care of patients with clefts.

Embryology

To understand the goals of lip and palate repair from an anatomic standpoint the cleft surgeon must have an appreciation for the failure of embryogenesis that results in clefting. There are critical points in the development of the fetus when the fusion of various prominences creates continuity and form to the lip, nose, and palate. Anomalies occur when the normal developmental

process is disturbed between these components. Each of these prominences is made up of ectomesenchyme derived from neural crest tissue of the mesencephalon and rhombencephalon. Mesoderm is also present within these prominences as mesenchymal tissue. The prescribed destiny of each of these cells and tissues is controlled by various genes to alter the migration, development, and apoptosis and form the normal facial tissues of the fetus. At the molecular level there are many interdependent factors such as signal transduction, mechanical stress, and growth factor production that affect the development of these tissues. Currently only portions of this complex interplay of growth, development, and apoptosis are clear.

At approximately 6 weeks of human embryologic development the median nasal prominence fuses with the lateral nasal prominences and maxillary prominences to form the base of the nose, nostrils, and upper lip. The confluence of these anterior components becomes the primary palate. When this mechanism fails, clefts of the lips and/or maxilla occur. At approximately 8 weeks the palatal shelves elevate and fuse with the septum to form the intact secondary palate. When one palatal shelf fails to fuse with the other components, then a unilateral cleft of the secondary palate occurs. If both of the palatal shelves fail to fuse with each other and the midline septum, then a bilateral cleft of the palate occurs.

Fusion occurs when programmed cell death (apoptosis) occurs at the edges of the palatal shelves. The ectodermal component disintegrates and the mesenchyme fuses to form the intact palate. Soon after this the anterior primary palate fuses with the secondary palate and ossification occurs. At any point, if failure of fusion occurs with any of the above components, a cleft will occur of the primary and/or secondary palates. Clefts may be complete or incomplete based on the degree of this failure of fusion.

Genetics and Etiology

Clefts of the upper lip and palate are the most common major congenital craniofacial abnormality and are present in approximately 1 in 700 live births.⁴³ Although inheritance may play a role, cleft lip and palate is not considered a single-gene disease. Instead clefts are thought to be of a multifactorial etiology with a number of potential contributing factors. These factors may include chemical exposures, radiation, maternal hypoxia, teratogenic drugs, nutritional deficiencies, physical obstruction, or genetic influences. One prevailing theory relates the process of clefting as a threshold in which multiple factors come together to raise the individual above a threshold at which time the mechanism of fusion fails.^{44,45} Recently multiple genes have been implicated in the etiology of clefting.⁴⁶⁻⁴⁸ Some of these genes include the *MSX*, *LHX*, *gooseoid*, and *DLX* genes. Additional disturbances in growth factors or their receptors that may be involved in the failure of fusion include fibroblast growth factor, transforming growth factor- β , platelet-derived growth factor, and epidermal growth factor.

Clefts of the lip occur more commonly in males than in females.⁴⁹ In addition left-sided cleft lips are more common than right-sided cleft lips, and unilateral cleft lips are more common than the bilateral cleft of the lip.⁵⁰ Bilateral clefts of the lip are most often associated with clefting of both the primary and secondary palates. Cleft palate alone is seen in approximately 1 in 2,000 live births and this incidence is similar in all racial groups.⁵¹ Significant differences in the prevalence of clefts exist when specific ethnic/racial populations are examined. For example, African Americans have a birth prevalence that is less common than the total population, but Asians tend to have a higher prevalence.

In the majority of cases unilateral cleft lip and palate is an isolated nonsyndromic

birth defect that is not associated with any other major anomalies.^{43,52,53} By comparison a much greater proportion of patients with an isolated cleft palate will have an associated syndrome or sequence.^{43,53} Some of the more common syndromes seen in this group include Stickler's, Van der Woude's, or DiGeorge syndromes. It is important to identify the diagnosis early, as functional issues may arise early in life and go unnoticed. For example, patients with an isolated cleft palate should be evaluated early by an experienced pediatric ophthalmologist to evaluate the possibility of Stickler's syndrome. Patients with Stickler's syndrome may have ocular abnormalities that lead to retinal detachment. In an otherwise healthy-appearing child these findings may be difficult to diagnose and so early visual loss may go unnoticed. In many cases long-term genetics follow-up is necessary to make a definitive diagnosis and to provide genetic counseling.

The chances of a recurrence of clefting within a family are dependent on many factors, including family history, severity, gender, degree of relationship to

the affected individual, and the expression of a syndrome. Predicting the inheritance patterns of families who have a history of cleft lip and/or palate can be complicated. A skilled geneticist/dysmorphologist is best equipped to make these determinations based on pedigree analysis and genetic testing. Since most clefts are sporadic the chances of a family having another child with a cleft after having a child with a unilateral cleft lip and palate in which there was no family history of clefting is approximately 2 to 4%. The chances are higher if additional family history is present or if the cleft is bilateral.^{54,55} The nature of any genetic influence will have an effect on the presence of a cleft. Such is the case in patients with autosomal dominant syndromes such as Stickler syndrome where 50% of the children may express the syndrome if one of the parents carries the altered gene.

Classification

The typical classification system used clinically to describe standard clefts of the lip and palate is based on careful anatomic description. Clefts can be unilateral or

bilateral; microform, incomplete, or complete; and may involve the lip, nose, primary palate, and/or secondary palates (Figure 42-1). The presentation of clefts is extremely variable, and the individual repairs are custom-tailored to achieve the best symmetry and balance. More severe facial clefting is most commonly described using Tessier's orbitocentric system of numbering (Figure 42-2).⁵⁶ Other systems exist that are based on embryologic fusion planes, but these are cumbersome to use in routine clinical practice.⁵⁷

Prenatal Counseling

Recent advances in ultrasound imaging have revolutionized prenatal care and maternal-fetal medicine. Currently ultrasound images of clefts of the lip can be visualized as early as 16 weeks.⁵⁸⁻⁶⁰ Diagnostic images of the palate are more difficult to acquire, making the correct prenatal diagnosis of a cleft palate less predictable. Palatal structures may be visualized using sagittal and coronal views, but this currently requires the very latest technology and a skilled ultrasonographer with experience performing this type of study.

FIGURE 42-1 Cleft lips come in a variety of configurations, such that each repair must be customized to establish the most normal morphology. A, Microform left unilateral cleft lip only, not requiring primary repair. B, Minor left incomplete unilateral cleft lip only. C, Left incomplete unilateral cleft lip and palate with a Simonart's band. D, Wide left complete unilateral cleft lip and palate.

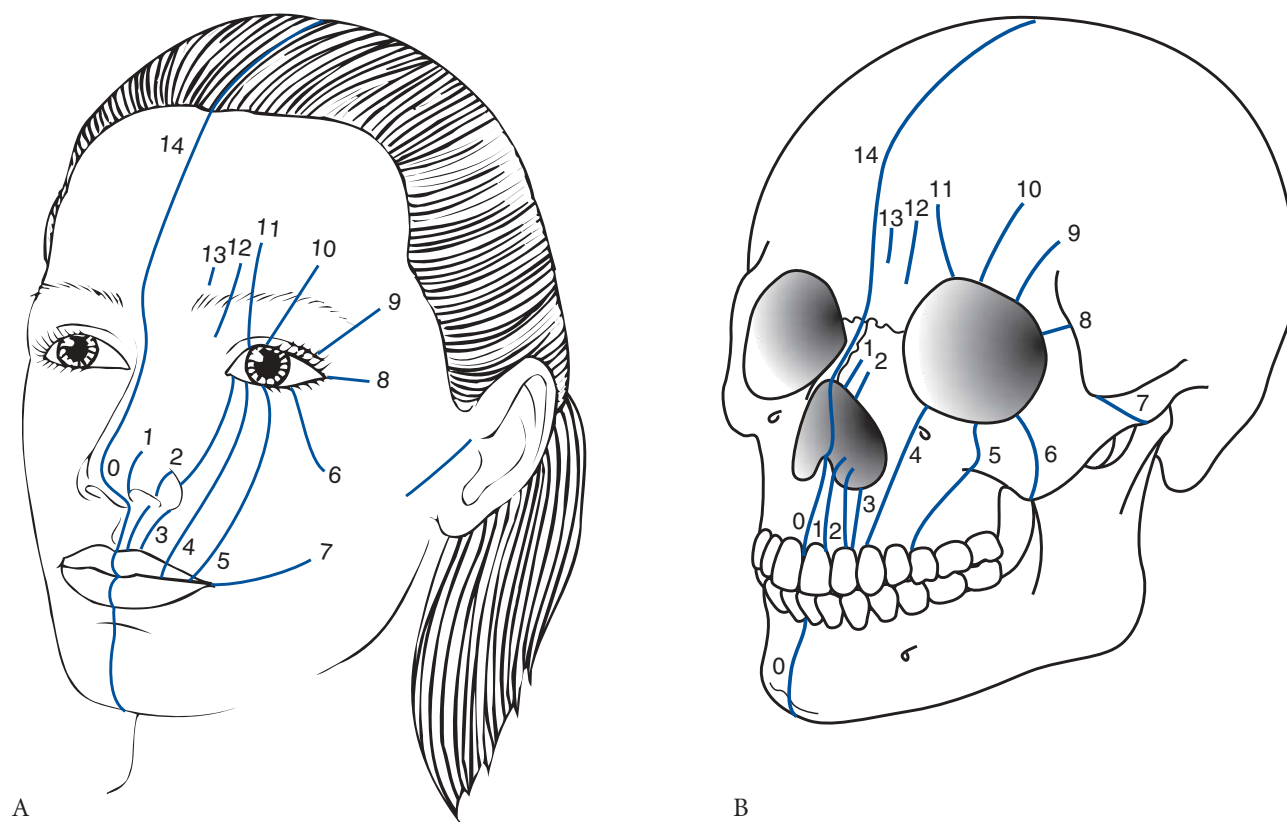

FIGURE 42-2 A and B, Complex facial clefts can be classified based on Tessier's original orbitocentric system of numbering. Clefts may involve all tissue planes including skin, mucosa, bone, teeth, muscle, brain, peripheral nerve, and other specialized tissues.

When the diagnosis of cleft lip is made during pregnancy the family can then be referred to an experienced surgeon for a prenatal discussion. A prenatal consultation provides an excellent opportunity to explain the diagnosis, review the different stages of cleft lip and palate reconstruction that may be necessary, and prepare the parents for practical considerations such as feeding of a child with a cleft palate. This gives the family the opportunity to ask questions, calm fears, and learn about feeding techniques that will be important during the first week of life for their baby. Parents are empowered with this new knowledge, and the preparations made during a prenatal consultation allow them to anticipate the delivery of their baby with a greater comfort level regarding the necessary care of the child during the early postnatal period. The family is then referred to a cleft and craniofacial team in order to undergo a more thorough interdisciplinary approach.

Critical to this process is consultation with a geneticist/dysmorphologist to further discuss the issues associated with the birth and the possibility of other associated deformities. Additional testing may be warranted to evaluate the possibility of associated deformities, syndromes, or sequences that could affect the birthing process. Exceptionally skilled ultrasonographers can visualize airway development and other abnormalities that may require early intervention with fetal surgery, exit procedures, extracorporeal membrane oxygenation, or surgical airway management (tracheotomy) at the time of delivery.

In some medical centers fetal diagnosis and treatment teams are in place to deal with issues associated with various deformities diagnosed in the prenatal period. These teams foster a cohesive environment where information is exchanged through consultation. Much like in the environment of a cleft and craniofacial team, fam-

ilies can get the best information available to consider their child's treatment decisions using an interdisciplinary care model that is patient (mother and fetus), family, and community oriented.

Feeding Concerns

Children born with isolated cleft lip can feed quite well and even have the opportunity to breastfeed in most instances. However, infants with cleft palate can have difficulty feeding due to the inability to form an adequate seal between the tongue and palate for creation of sufficient negative pressure to suck fluid from a bottle. Nasal regurgitation and inefficient handling of secretions and foodstuffs may also be observed during early development. Specialized nipples and bottles are necessary to improve feeding immediately after birth. The most useful devices combine oversized nipples with reservoir spaces and large openings, a squeezable bottle to push fluid

into the nipple assembly, and a one-way valve that allows the bolus of fluid to pass from the bottle to the nipple only in order to minimize the amount of work the child must perform to feed. These include a variety of nipples with reservoirs that collect a variable volume of liquid that can be expressed more easily when sucking is inefficient or not possible. Bottles that can be squeezed to allow for manual flow of liquid to the infant are helpful for improving feeding. No single bottle and nipple combination tends to work better than another, but trials with a variety of types using different techniques are helpful in optimizing feeding early in life. Close attention to weight gain is necessary for these children. Generally, in 24 hours each infant should have approximately 2 to 3 ounces of milk for each pound of weight. Feeding sessions should last no longer than 35 minutes as longer sessions are fatiguing and burn more calories than the baby can consume. Infants should be weighed at least weekly using the same scale, preferably at their pediatrician's office.

The subject of breast-feeding an infant with a cleft palate is controversial, with some practitioners encouraging the practice and others strongly opposed to it. There are clear advantages to breast-feeding a newborn, including passive immunologic contribution of the mother to the child in the form of secretory immunoglobulin A and an experience that enhances bonding between the mother and child during such a critical period.^{61,62} At the same time the infant's inability to create negative oral pressure will often make successful nursing difficult, if not impossible. It is relatively common to encounter an exclusively breast-fed infant with severe dehydration and failure to thrive secondary to these difficulties. This is especially a concern in infants that have a wide cleft of the secondary palate, where breast-feeding may not be possible. The authors' approach with regard to breast-feeding in the presence of a cleft palate is

to use a combined protocol that includes intermittent feeding with the use of a specialized bottle (as described above) and attempts at nursing. Breast milk may be pumped for use with the specialized nipple and bottle that will provide the nutritional and immunologic benefits desired. This also allows the parents to keep a more quantitative record of how many ounces have been ingested over the course of the day since this is normally difficult with breast-feeding alone. At the same time the mother and baby are not deprived of an opportunity to incorporate breast-feeding into the daily regimen. This approach obviously requires rigorous documentation of the child's weight, consultation with a lactation consultant and infant feeding specialist, and frequent follow-up evaluations through the surgeon and/or pediatrician.

Treatment Planning and Timing: Overview

The timing of cleft lip and palate repair is controversial. Despite a number of meaningful advancements in the care of patients with cleft lip and palate, a lack of consensus exists regarding the timing and specific techniques used during each stage of cleft reconstruction. Surgeons must continue to carefully balance the functional needs, esthetic concerns, and the issue of ongoing growth when deciding how and when to intervene. In no other type of surgical problem is the issue of early surgery's effect on growth more apparent than in the treatment of cleft lip and palate deformities. The decision to surgically manipulate the tissues of the growing child should not be made lightly and should take into account the possible growth restriction that can occur with early surgery. Nevertheless many patients with congenital deformities will benefit from surgical intervention based on functional or psychosocial reasons. Understanding the growth and development of the craniofacial skeleton is critical to the treatment

planning process.³³ In many cases waiting for a greater degree of growth to occur is advantageous unless compelling functional or esthetic issues are present that can not or should not wait.

Due to many different treatment philosophies the timing of treatment interventions is considerably variable amongst cleft centers. Therefore, it is difficult to produce a timing regimen that everyone agrees on. Each stage of surgical reconstruction and the suggested timing based on the patient's age are presented in Table 42-1. Special considerations may alter the sequencing or timing of the various procedures based on individual functional or esthetic needs.

Cleft lip repair is generally undertaken at some point after 10 weeks of age. One advantage of waiting until the child is 10 to 12 weeks of age is that it allows a complete medical evaluation of the patient so that any associated congenital defects affecting other organ systems (eg, cardiac or renal anomalies) may be uncovered. The surgical procedure itself may be easier when the child is slightly larger and the anatomic landmarks more prominent and well defined. Historically the anesthetic risk-related data suggested that the safest time period for surgery in this population of infants could be outlined simply by using the "rule of 10's." This referred to the idea of delaying lip repair until the child was at least 10 weeks old, 10 pounds in weight, and with a minimum hemoglobin value of 10 dL/mg.^{63,64} Today more sophisticated pediatric techniques, advances in intraoperative monitoring, and improved anesthetic agents have all resulted in the ability to provide safe general anesthesia much earlier in life.⁶⁵ Despite the ability to provide safe anesthesia earlier in life, there is no measurable benefit to performing lip repair prior to 3 months of age.^{64,66,67} Some surgeons have advocated that lip repair be carried out in the first days of infancy based on the idea of capitalizing on early "fetal-like" healing. Unfortunately these hoped-for benefits have not been

Table 42-1 Staged Reconstruction of Cleft Lip and Palate Deformities

Procedure	Timing
Cleft lip repair	After 10 weeks
Cleft palate repair	9–18 months
Pharyngeal flap or pharyngoplasty	3–5 years or later based on speech development
Maxillary/alveolar reconstruction with bone grafting	6–9 years based on dental development
Cleft orthognathic surgery	14–16 years in girls, 16–18 years in boys
Cleft rhinoplasty	After age 5 years but preferably at skeletal maturity; after orthognathic surgery when possible
Cleft lip revision	Anytime once initial remodeling and scar maturation is complete but best performed after age 5 years

observed, and problems with excessive scarring and less favorable outcomes have been encountered instead.^{68–70} Children may have more scarring at this early age, and their tissues are smaller and more difficult to manipulate. Consequently the esthetic outcomes may be worse if surgery is performed at an earlier age, and since there are no clear benefits to earlier repair the recommendations for repair stand at approximately 3 months of age.

Cleft palate repair is usually performed at approximately 9 to 18 months of age. In deciding the timing of repair the surgeon must consider the delicate balance between facial growth restriction after early surgery and speech development that requires an intact palate. Most children will require an intact palate to produce certain speech sounds by 18 months of age. If developmental delay is present and speech will not likely develop until later, then the repair can be delayed further. There is little evidence to suggest any benefit to palate repair prior to 9 months of age.^{71–73} Repairs prior to this time are associated with a much higher incidence of maxillary hypoplasia later in life and show no improvements in speech. For these reasons most surgeons will perform primary palate repair at approximately 9 to 12 months of age.

As the child continues to develop, approximately 20% of children will have inadequate closure of the velopharyngeal

mechanism (velopharyngeal insufficiency or VPI), and this may produce hypernasal speech.⁷⁴ These children are usually diagnosed at 3 to 5 years of age when a detailed speech examination can be obtained by a skilled speech pathologist familiar with clefts. When VPI is shown to be consistent and due to a definable anatomic defect, surgery is often helpful in correcting this problem. A pharyngeal flap or sphincter pharyngoplasty may be used to treat VPI, with the goal of improving closure between the oral and nasal cavities and reducing nasal air escape during the production of certain sounds. The details of assessment, diagnosis, and treatment of VPI associated with cleft palate are discussed in Chapter 44, “Reconstruction of Cleft Lip and Palate: Secondary Procedures.” Approximately 75% of patients with any type of cleft will present with clefting of the maxilla and alveolus.^{24–26} Bone graft reconstruction of this site is performed during the mixed dentition prior to the eruption of the permanent canine and/or the permanent lateral incisor. The timing of this procedure is based on dental development and not chronologic age. Based on work by Boyne and Sands, most surgeons reconstruct this area during the mixed dentition prior to eruption of the permanent canine. Earlier reconstruction of this area has been associated with a high degree of maxillary

growth restriction requiring orthognathic correction later in life in a much higher percentage of patients.^{22,24} The gold standard for reconstruction in this area is autogenous bone from the anterior iliac crest. Cranial bone, rib, tibia, symphysis of the mandible, zygoma, and allogeneic bone have all been studied, but none have been shown to be appreciably better than the iliac crest.^{26,75,76}

Orthognathic reconstruction of maxillary and mandibular discrepancies is performed at 14 to 18 years of age based on individual growth characteristics.^{26–36,38} This is done in conjunction with orthodontics prior to and after surgery. However, in some cases of severe maxillary hypoplasia, early Le Fort I osteotomy may be performed to optimize facial esthetics and occlusion with the supposition that revision osteotomies will likely be necessary. These early osteotomies may complicate later treatment. Early orthognathic correction is reserved for the most severe dysmorphology, and in most cases the authors prefer standard orthognathic techniques.^{31–33} Attempts at using distraction osteogenesis have been associated with a higher complication rate than with standard orthognathic techniques.^{32,42,77} Orthognathic correction of the deformities associated with cleft lip and palate defects is discussed in Chapter 61, “Orthognathic Surgery in the Patient with Cleft Palate.”

As with the timing of other interventions, lip and nasal revision is best reserved until after the majority of growth is complete. Most of the lip and nasal growth is complete after age 5 years. Lip revision can be considered prior to school age at about 5 years of age. However, this may be performed earlier if the deformity is severe. Nasal revision is performed after age 5 years as most of the nasal growth is also complete by this time. If orthognathic reconstruction is likely, then rhinoplasty is usually best performed after orthognathic surgery as maxillary advancement improves many characteristics of nasal

support. However, when nasal deformity is particularly severe, rhinoplasty can be considered earlier even if orthognathic surgery is expected. Multiple early revisions of the lip or nose should be avoided so that excess scarring does not potentially impair ongoing growth. Secondary revisions of cleft lip and palate deformities are discussed in Chapter 44, "Reconstruction of Cleft Lip and Palate: Secondary Procedures."

Cleft Lip and Palate Repair

Presurgical Taping and Presurgical Orthopedics

Facial taping with elastic devices is used for application of selective external pressure and may allow for improvement of lip and nasal position prior to the lip repair procedure. In the authors' opinions these techniques often have greater impact in cases of wide bilateral cleft lip and palate where manipulation of the premaxillary segment may make primary repair technically easier. Although one of the basic surgical tenets of wound repair is to close wounds under minimal tension, attempts at improving the arrangement of the segments using taping methods have not shown a measurable improvement.⁷⁸⁻⁸⁰

Some surgeons prefer presurgical orthopedic (PSO) appliances rather than lip taping to achieve the same goals.^{81,82} PSO appliances are composed of a custom-made acrylic base plate that provides improved anchorage in the molding of lip, nasal, and alveolar structures during the presurgical phase of treatment (Figure 42-3). Although the use of appliances probably makes for an easier surgical repair, there has been a lack of clinical evidence to demonstrate that there is any measurable improvement in esthetics of the nose or lip, dental arch relationship, tooth survival, or occlusion. Studies have looked at the dental arch relationship outcomes in patients who have infant presurgical orthopedic devices, and no improvement in dental arch relationship was seen.^{83,84} Addition-

FIGURE 42-3 Frontal and lateral views of the Grayson nasoalveolar molding appliance showing the nasal projections that help to theoretically mold the nasal cartilages and maxillary segments into a more appropriate configuration prior to repair.

ally no long-term improvement in speech outcome has been demonstrated in patients who had PSOs.⁸⁵ Furthermore concerns regarding potential negative consequences with these types of appliances have been raised.⁸⁶ PSOs also add significant cost and time to treatment early in the child's life. Many appliances require a general anesthetic for the initial impression used to fabricate the device. Frequent appointments are necessary for monitoring of the anatomic changes and periodic appliance adjustment.

The Latham appliance was popular for expanding and aligning the maxillary segments of the patient with a cleft palate.⁸⁷ It is a pin-retained device that is inserted into the palate with acrylic extensions onto the alveolar ridges. A screw mechanism is then used to manipulate the segments as desired. The Latham appliance has been shown to be associated with significant growth restriction of the midface when used in infancy to approximate the segments prior to definitive repair.⁸⁶ Children who have had Latham appliances have been shown to have significant midfacial growth restriction in adolescence 100% of the time whereas children who have not had the

Latham appliance have midface hypoplasia 25 to 35% of the time.^{42,80,86}

The nasoalveolar molding appliance has become popular with some surgeons in attempts to manipulate the segments without pin retention prior to lip and nose repair (see Figure 42-3). The appliance popularized by Grayson is adjustable by removing or adding acrylic and manipulating protrusive elements that attempt to mold the nasal cartilages. This device attempts to align the alveolar segments, lip structures, and nasal cartilages to optimize repair. Unfortunately the hoped-for advantages of this appliance have not been realized. Additionally no long-term data are available regarding growth in the craniofacial skeleton after using this protocol. The limited short-term data that are available cannot be extrapolated to determine the ultimate outcome on growth, function, or esthetics. Some surgeons use gingivoperiosteoplasty in conjunction with the PSO, using limited flaps to close the alveolus cleft during the primary repair of the lip or palate. Many surgeons who use this appliance in conjunction with their primary lip repairs will perform a gingivoperiosteoplasty in attempts to have bone form at the

alveolus. This is more easily performed with the segments aligned in close proximity as the flaps are small.⁸² Experiences with similar techniques in the 1960s involving primary bone grafting were poor with respect to growth.^{22,23} Additionally there has been no convincing long-term objective data showing improvement in either lip or nose esthetics.

In their current state of technical refinement there is no evidence that any of the PSOs offer an improved outcome with respect to esthetics, function, or growth in patients with cleft lip and palate. Coupled with the fact that appliances are time-consuming and have a high cost of fabrication and utilization, it is difficult to advocate their uniform use. As with other interventions considered for patients with clefts, costly and unproven interventions should be avoided, although they may prove to be helpful in some select cases.⁸⁸ Hopefully, long-term data will be forthcoming and positive to help determine which patients may benefit from PSO appliance treatment.

Lip Adhesion

Some surgeons attempt to surgically approximate the segments of the cleft lip prior to definitive lip repair in an attempt to achieve a better relationship of both the lip structures and the dental arches.⁸⁹⁻⁹¹ This is achieved by advancing small flaps of tissue across the cleft site. While some surgeons advocate the use of this technique in wide bilateral clefts, it is rarely performed in unilateral cases. When used, the lip adhesion is usually completed at 3 months of age. In most cases this will convert a wide complete cleft into a wide incomplete cleft as the scar will eventually be excised from the cleft site recreating a similar wide deformity. The definitive lip repair is then completed 3 to 9 months later by excising the scar and reapproximating the remaining lip structures. Furthermore at the second procedure there is usually less supple tissue to work with

when performing the definitive repair due to scarring. As with most endeavors in cleft surgery, repeated early interventions tend to complicate later refinements due to excessive scarring. In general adequate mobilization of the flaps in one stage will make tension-free skin closure possible in almost every case without the need for taping, presurgical orthopedic appliances, and/or lip adhesion.

Unilateral Cleft Lip Repair

Clefts of the lip and nose that are unilateral present with a high degree of variability, and thus each repair design is unique (see Figure 42-1).^{26,92} The repair technique preferred by the authors for cleft lip and nasal deformities is shown in Figures 42-4 and 42-5 and is usually performed after 10 weeks of age.^{17,18,26,63} The basic premise of the repair is to create a three-layered closure of skin, muscle, and mucosa that approximates normal tissue and excises hypoplastic tissue at the cleft margins. Critical in the process is the reconstruction of the orbicularis oris musculature into a continuous sphincter. The Millard rotation-advancement technique has the advantage of allowing for each of the incision lines to fall within the natural contours of the lip and nose. This is an advantage because it is difficult to achieve “mirror image” symmetry in the unilateral cleft lip and nose with the normal side immediately adjacent to the surgical site. A Z-plasty technique such as the Randall-Tennison repair may not achieve this level of symmetry because the Z-shaped scar is directly adjacent to the linear nonclefted philtrum (Figure 42-6). Achieving symmetry is more difficult when the rotation portion of the cleft is short in comparison to the advancement segment.

Primary nasal reconstruction may be considered at the time of lip repair to reposition the displaced lower lateral cartilages and alar tissues. Several techniques are advocated, and considerable variation exists with respect to the exact nasal reconstruc-

tion performed by each surgeon.^{93,94} The primary nasal repair may be achieved by releasing the alar base, augmenting the area with allogeneic subdermal grafts, or even a formal open rhinoplasty. Since lip repair is done at such an early point in growth and development, the authors prefer minimal surgical dissection due to the effects of scarring on the subsequent growth of these tissues. McComb described a technique that has become popular, consisting of dissecting the lower lateral cartilages free from the alar base and the surrounding attachments through an alar crease incision.^{93,95-97} This allows the nose to be bolstered and/or stented from within the nostril to improve symmetry.

Bilateral Lip Repair

Bilateral cleft lip repair can be one of the most challenging technical procedures performed in children with clefts. The lack of quality tissue present and the widely displaced segments are major challenges to achieving exceptional results, but superior technique and adequate mobilization of the tissue flaps usually yields excellent esthetic results (Figures 42-7–42-10). Additionally the columella may be quite short in length, and the premaxillary segment may be significantly rotated. Adequate mobilization of the segments and attention to the details of only using appropriately developed tissue will yield excellent results even in the face of significant asymmetry.

Some surgeons have used aggressive techniques to surgically lengthen the columella and preserve hypoplastic tissue using banked fork flaps.^{98,99} Early and aggressive tissue flaps in the nostril and columella areas do not look natural after significant growth has occurred and result in abnormal tissue contours. While surgical attempts at lengthening the columella may look good initially, they frequently look abnormally long and excessively angular later in life (Figure 42-11). Revision of these iatrogenic deformities is difficult

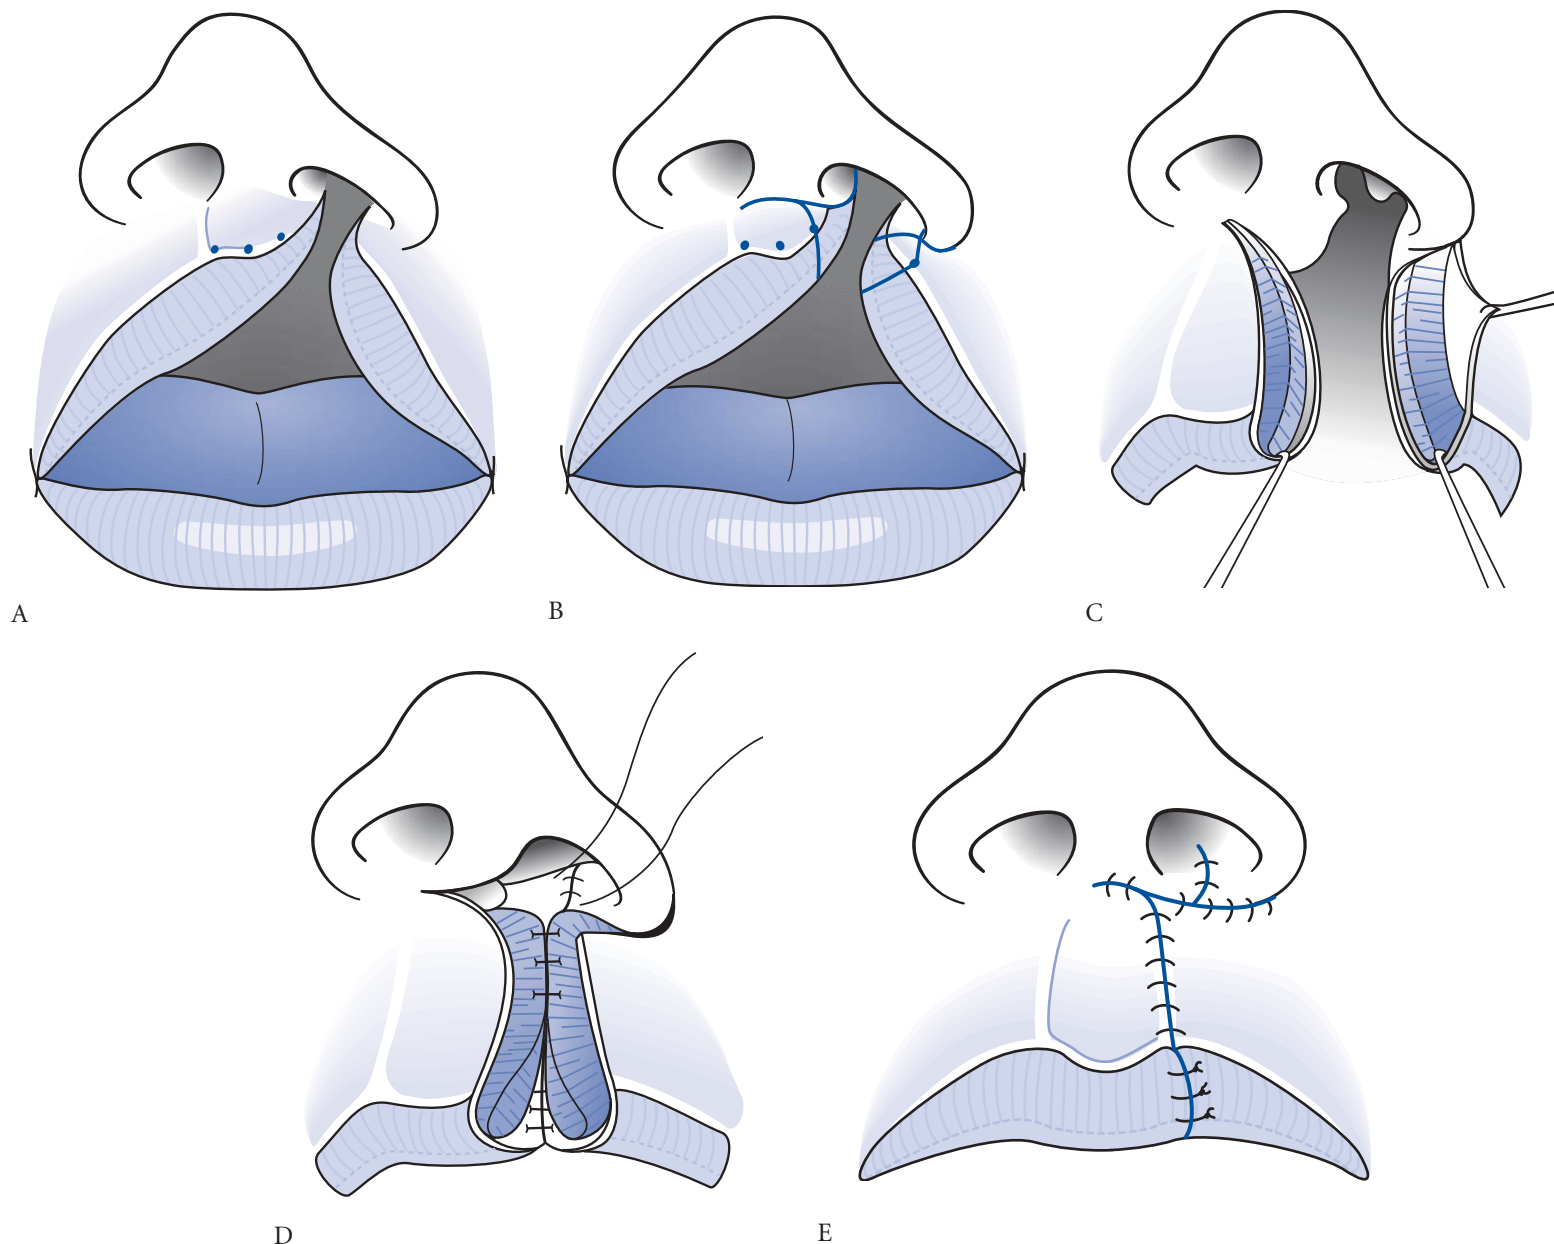

FIGURE 42-4 A, A complete unilateral cleft of the lip is shown highlighting the hypoplastic tissue in the cleft site that is not used in the reconstruction. Note the nasal deformities that are typical in the unilateral cleft, including displaced lower lateral nasal cartilages, deviated anterior septum, and nasal floor clefting. B, The typical markings for the authors' preferred repair are shown highlighting the need to excise the hypoplastic tissue and approximate good vermilion and white roll tissue for the repair. C, Once the hypoplastic tissue has been excised, the three layers of tissue are dissected (skin, muscle, and mucosa). It is important to completely free the orbicularis oris from its abnormal insertions on the anterior nasal spine area and lateral alar base. Nasal flaps are also incorporated into the dissection to repair the nasal floor (not shown). D, The orbicularis oris muscle is approximated with multiple interrupted sutures, and the vermilion border/white roll complex is reconstructed. The nasal floor and mucosal flaps are approximated. E, The lateral flap is advanced and the medial segment is rotated downward to create a healing scarline that will resemble the natural philtral column on the opposite side. The incision lines are hidden in natural contours and folds of the nose and lip.

and some of the contour irregularities will not be able to be revised adequately. Usually if the hypoplastic tissue is excised and incisions within the medial nasal base and columella are avoided, the long-term esthetic results are excellent.

The authors prefer a primary nasal reconstruction that can be performed in a similar fashion to the unilateral technique described by McComb.¹⁰⁰ This allows for release and repositioning of the lower lateral cartilages and alar base on both sides

without aggressive degloving of the entire nasal complex. Other open rhinoplasty techniques have been suggested using either direct incision on the nasal tip or through prolabial unwinding techniques.^{100–103} As with most early maneuvers

FIGURE 42-5 A, Three-month-old child with a right-sided incomplete unilateral cleft lip. Note the short philtrum near the midline that must be rotated downward to avoid notching and to improve symmetry. B, Nine-month-old boy after the rotation-advancement repair of his cleft lip and nasal deformities. C, The same child in B 2½ years after his cleft lip and nasal repairs.

aggressive rhinoplasty at this time may incur early scarring that affects the growth potential of the surrounding tissues, making revision more difficult and long-term esthetics less than ideal.

Cleft Palate Repair

The term *primary palate* is used to describe the anatomic structures anterior to the incisive foramen (eg, the alveolar ridge, maxilla, piriform rim). The term *secondary palate* refers to those structures posterior to the incisive foramen. Therefore, when surgeons refer to the initial or “primary” cleft palate repair, they are actually describing the closure of the secondary palate structures that include the hard palate, soft palate, and uvula. The structures of the embryologic primary palate are reconstructed later in childhood during the cleft maxillary/alveolar bone graft procedure.

There are two main goals of cleft palate repair during infancy: (1) the water-tight closure of the entire oronasal communication involving the hard and soft palate; and

(2) the anatomic repair of the musculature within the soft palate that is critical for normal creation of speech. The soft palate, or velum, is part of the complex coupling and decoupling of the oral and nasal cavities involved in the production of speech. When a cleft of the soft palate is present there are abnormal muscle insertions located at the posterior edge of the hard palate. Surgery must not simply be aimed at closing the palatal defect but rather at the release of abnormal muscle insertions. Muscle continuity with correct orientation should be established so that the velum may serve as a dynamic structure.

The exact timing of repair of a palate cleft is controversial. Generally the velum must be closed prior to the development of speech sounds that require an intact palate. On average this level of speech production is observed by about 18 months of age in the normally developing child. If the repair is completed after this time, compensatory speech articulations may result. Repair completed prior to this time allows

for the intact velum to close effectively, appropriately separating the nasopharynx from the oropharynx during certain speech sounds.^{104–107}

FIGURE 42-6 A typical scar that may result from a Z-type lengthening repair. Although the length and symmetry of the lip is good, an unnatural contour can occur due to the Z shape of the closure.

FIGURE 42-7 A, The bilateral cleft of the lip and maxilla shown here is complete and highlights the hypoplastic tissue along the cleft edges. The importance of the nasal deformity is evident in the shorter columella and disrupted nasal complexes. B, Markings of the authors' preferred repair are shown with an emphasis on excision of hypoplastic tissue and approximating more normal tissue with the advancement flaps. C, A new philtrum is created by excising the lateral hypoplastic tissue and elevating the philtrum superiorly. Additionally the lateral advancement flaps are dissected into three distinct layers (skin, muscle, and mucosa). Nasal floor reconstruction is also performed. D, The orbicularis oris musculature is approximated in the midline with multiple interrupted and/or mattress sutures. This is a critical step in the total reconstruction of the functional lip. There is no musculature present in the pre-maxillary segment, and this must be brought to the midline from each lateral advancement flap. The nasal floor flaps are sutured at this time as well. The new vermillion border is reconstructed in the midline with good white-roll tissue advanced from the lateral flaps. E, The final approximation of the skin and mucosal tissues is performed leaving the healing incision lines in natural contours of the lip and nose.

In patients with cleft palate, concerns for normal speech development are frequently balanced with the known biologic consequences of surgery during infancy; namely, the problem of surgery during the growth

phase resulting in maxillary growth restriction.^{33,72,73,108} When repair of the palate is performed between 9 and 18 months of age, the incidence of associated growth restriction affecting the maxillary development is

approximately 25%.^{31,33,109-111} If repair is carried out earlier than 9 months of age, then severe growth restriction requiring future orthognathic surgery is seen with greater frequency.^{22,26,31,33,109,112-114} At the

FIGURE 42-8 A, Presurgical appearance of the incomplete bilateral cleft lip of a 3-month-old boy. B, Surgical markings for excision of the hypoplastic tissue and the planned creation of a new philtrum. Advancement flaps from the lateral lip segments bring good white-roll to the midline via small cut-backs. C, The same child at 1 year of age after the repair of his bilateral cleft lip.

same time proceeding with palatoplasty prior to 9 months of age is not associated with any increased benefit in terms of speech development so the result is an increase in growth-related problems with an absence of any functional benefit.^{115,116} Using only the chronologic age it seems that carrying out the operation during the 9 to 18 months timeline best balances the need to address functional concerns such as speech development with the potential negative impact on growth. To date no case-controlled rigorous clinical trial has examined what is likely the most critical factor in dictating the exact timing of cleft repair—the individual child's true language age. In cases where significant developmental delay is present surgery should be delayed since speech formation is not yet an issue and there is a likely benefit in terms of growth of the maxilla. Delaying palatal closure is relevant in situations where the cleft palate is associated with other complex medical conditions, neurodevelopmental delay, complex craniofacial anomalies, and/or the presence of a tracheotomy.

Another approach used to balance speech issues with growth-related concerns is to stage the closure of the secondary palate with two operations. Generally this involves the repair of the soft palate early in life as an initial step, fol-

lowed by closure of the hard palate later in infancy. The idea is that timely repair of the soft palate, which is critical for speech, is accomplished while hard palate repair with mucoperiosteal stripping is delayed until growth is further along.^{117,118} Although this technique is not advocated by the majority of surgeons, some surgeons may feel that repairing the hard palate portion later may offer the advantages of less growth restriction, easier repair of larger clefts, and less chance for fistula formation. No convincing data exist to favor this approach over a single-stage repair, but the practice is continued by some centers where anecdotal evidence suggests that there may be some benefit. In contrast most North American speech and language pathologists prefer closure of the palate as a single operation.¹¹⁷

Cleft palate reconstruction requires the mobilization of multilayered flaps to reconstruct the defect due to the failure of fusion of the palatal shelves. Generally when the initial palate closure is performed, this refers to closure of the tissues posterior to the incisive foramen. This is done in a layered fashion by first closing the nasal mucosa and then the oral mucosa. Since the main function of the palate is to close the

FIGURE 42-9 A, Presurgical appearance of a bilateral cleft lip and palate with impressive asymmetry and rotation of the premaxillary segment. Note the significant nasal asymmetry and bunching of the orbicularis oris laterally. B, The same child at 14 months of age.

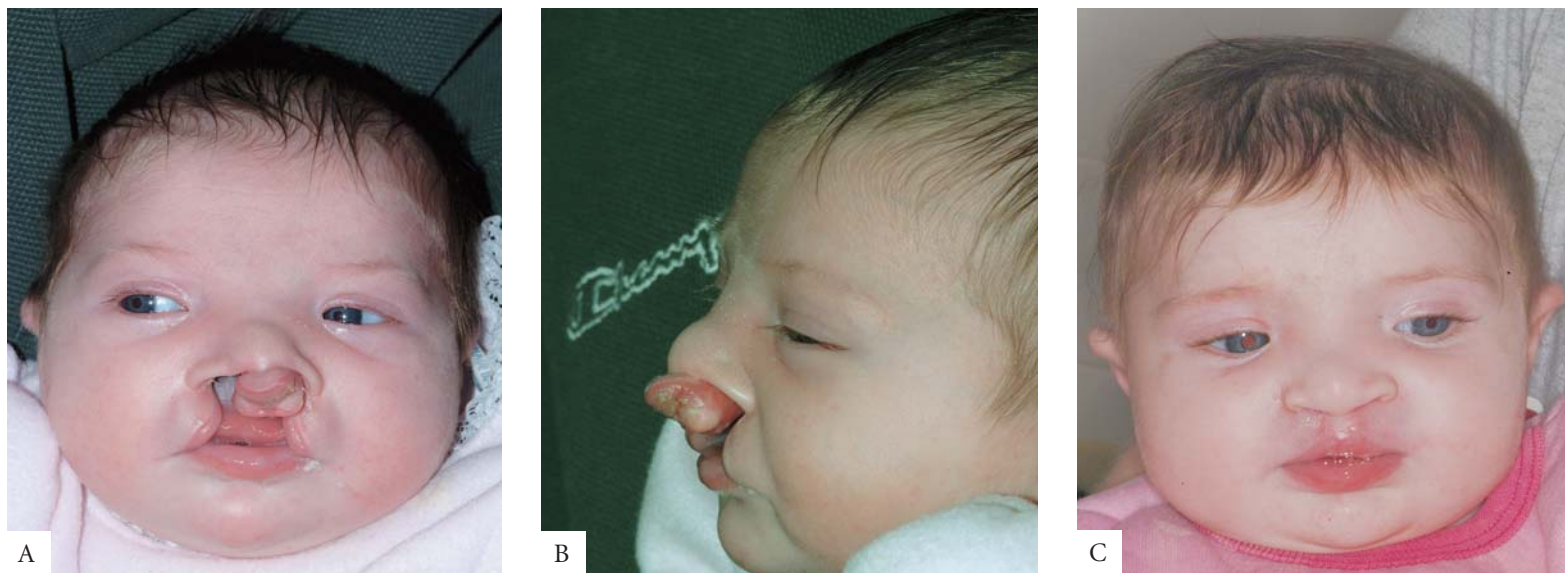

FIGURE 42-10 A, Presurgical frontal view of a wide bilateral cleft lip and palate with significant asymmetry and lack of columella length. B, Presurgical left lateral view of a wide bilateral cleft lip and palate with a protrusive premaxillary segment. Note the short columella length. C, The same child at 10 months of age after repair of her bilateral cleft lip and palate. No presurgical taping or orthopedic appliances were used.

space between the nasopharynx and oropharynx during certain speech sounds, the surgeon must also reconstruct the musculature of the velopharyngeal mechanism. The musculature of the levator palatini is abnormally inserted on the posterior aspect of the hard palate and therefore must be disinserted and reconstructed in the midline.^{26,119} Therefore, the soft palate is closed

in three layers by approximating the nasal mucosa, levator musculature, and the oral mucosa. The hard palate portion is closed in two layers using nasal mucosa flaps and then oral mucosa flaps. Both the hard and soft palate repairs must be done in a tension-free manner to avoid wound breakdown and fistula formation. Adequate mobilization of the flaps during the dissec-

tion is essential to achieve tension-free closure. At times some surgeons may elect to incorporate vomer flaps into the repair if there is difficulty in mobilizing the lateral flaps to the midline.

Many techniques have been described for repair of the palate.¹²⁰⁻¹²⁷ The Bardach two-flap palatoplasty uses two large full-thickness flaps that are mobilized with

FIGURE 42-11 A, Frontal view of a teenage girl who had undergone columella lengthening and banked fork flaps during her initial repair and multiple attempts at secondary rhinoplasty by another surgeon prior to orthognathic surgery. B, Frontal view of a patient who underwent columella lengthening and banked fork flaps during her initial repair. C, Lateral view of the patient from B with a columella that is curved upwards and abnormally angular.

layered dissection and brought to the midline for closure (Figure 42-12).^{26,120} This technique preserves the palatal neurovascular bundle as well as a lateral pedicle for adequate blood supply. The von Langenbeck technique is similar to the Bardach palatoplasty but preserves an anterior pedicle for increased blood supply to the flaps.^{26,121} This technique is also successful in achieving a layered closure but may be more diffi-

cult when suturing the nasal mucosa near the anteriorly based pedicle attachments. The authors do not favor push-back techniques as they may incur more palatal scarring, restrict growth, and do not show a measurable benefit in speech.

Another common technique is the Furlow double-opposing Z-plasty, which attempts to lengthen the palate by taking advantage of a Z-plasty technique on both

the nasal mucosa and the oral mucosa (Figure 42-13).^{26,124-127} This technique can be effective at closing the palate but has been reported by some to have a higher rate of fistula formation at the junction of the soft and hard palates where theoretical lengthening of the soft palate may compromise the closure.^{26,128-133} No benefit has been convincingly demonstrated with any particular repair technique when one looks at dental arch form, speech outcome, feeding, or any other functional variable. At this point in our understanding surgeons often consider their own experiences and training when repairing clefts, since definitive data suggesting that one repair is preferable over another are lacking.

In very wide clefts some surgeons will advocate the consideration of a pharyngeal flap at the primary palatoplasty procedure to assist in closure since revision palatoplasty is sometimes unsuccessful in eradicating fistulas. Those who use this technique usually perform it in extremely wide clefts and do so very selectively. This allows the central portion of the closure to be filled with posterior pharyngeal wall tissue making the closure of the nasal and palatal mucosa easier. Patients with Pierre Robin syndrome or Treacher Collins syndrome may have exceptionally wide clefts that are difficult to close with no tension, and this technique may be considered. The drawbacks of using a pharyngeal flap during the repair of the palate include a significantly increased risk for complications such as bleeding, snoring, obstructive sleep apnea, or hyponasality. The details of pharyngeal flap surgery and revision palatoplasty techniques are discussed in Chapter 44, "Reconstruction of Cleft Lip and Palate: Secondary Procedures."

Complex Facial Clefting

Clefting of the facial structures other than the typical nasolabial region is rare and often presents difficult challenges to the reconstructive cleft surgeon. Therefore it is important to consider referring patients

FIGURE 42-12 A, A unilateral cleft of the primary and secondary palates is shown with the typical involvement from the anterior vestibule to the uvula. B, The Bardach palatoplasty technique requires two large full-thickness mucoperiosteal flaps to be elevated from each palate shelf. The anterior portion (anterior to the incisive foramen) of the cleft is not reconstructed until the mixed dentition stage. C, A layered closure is performed in the Bardach palatoplasty by reapproximating the nasal mucosa. The muscle bellies of the levator palatini are elevated off of their abnormal insertions on the posterior palate. They are then reapproximated in the midline to create a dynamic functional sling for speech purposes. D, Once the nasal mucosa and musculature of the soft palate are approximated, the oral mucosa is closed in the midline. The lateral releasing incisions are quite easily closed primarily due to the length gained from the depth of the palate. In rare cases, in very wide clefts a portion of the lateral incisions may remain open and granulate by secondary intention.

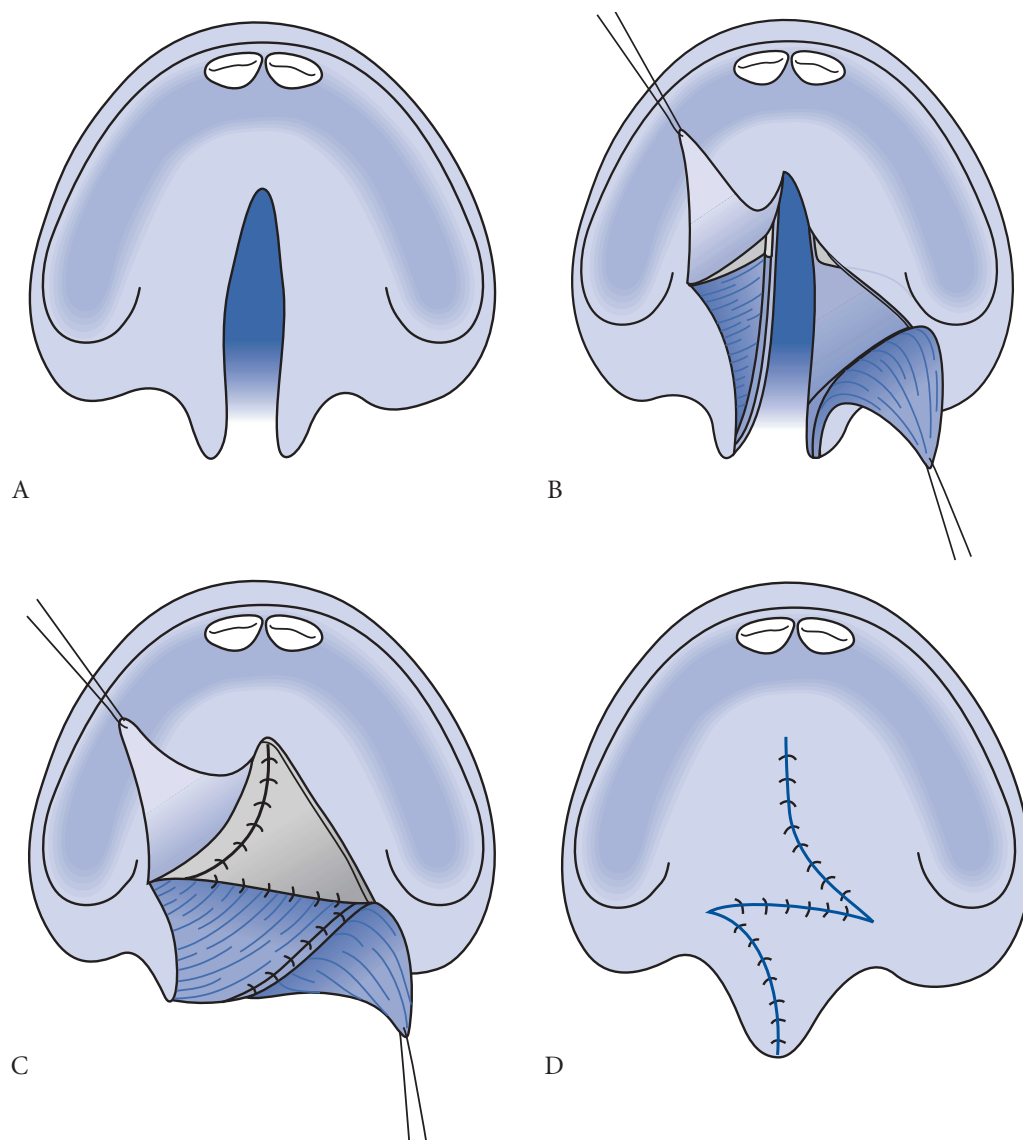

FIGURE 42-13 A, A complete cleft of the secondary palate (both hard and soft) is shown from the incisive foramen to the uvula. B, The Furlow double-opposing Z-plasty technique requires that separate Z-plasty flaps be developed on the oral and then nasal side. Note the cutbacks creating the nasal side flaps highlighted in blue. C, The flaps are then transposed to theoretically lengthen the soft palate. A nasal side closure is completed in the standard fashion anterior to the junction of the hard and soft palate. Generally this junction is the highest area of tension and can be difficult to close. This contributes to the higher fistula rate in this type of repair. D, The oral side flaps are then transposed and closed in a similar fashion completing the palate closure.

with complex facial clefting to surgeons with experience in this particular area. Comprehensive interdisciplinary care is mandatory to achieve the best results including involvement of neurosurgery, ophthalmology, orthodontics, speech pathology, and other members of the craniofacial team. Some interventions such as eye lubrication may be necessary within hours after birth, and accurate pre-

natal diagnosis of severe facial clefting is helpful in planning for early care.

The etiology of the various facial clefts may be related to failure of embryologic fusion, physical obstruction in fetal life, association with an encephalocele or tumor, amniotic bands, or other anatomic disruptions during fetal life.⁵⁵ The vast majority of complex facial clefts are sporadic events and not related to a single

gene disease. Many complex facial clefts involve the orbit, and the classification system most often used is orbitocentric in design (see Figure 42-2). Paul Tessier described a numbering system for facial clefting phenomena to make description and surgical planning more easily discussed.⁵⁶ Other systems exist but have a more cumbersome nomenclature.⁵⁷

Primary repair of severe facial clefts is often more difficult than even the most difficult standard bilateral clefts.¹³⁴⁻¹³⁶ While mobilization of the lip and nose structures is rather straightforward, the closure of clefts in the orbital region can be challenging due to the lack of eyelid and adjacent tissue for advancement and/or rotation. Revision surgery is the norm in this group and should include a skilled ophthalmologic surgeon early in the process for the best results.

The staged reconstruction of these types of severe facial clefts is similar to the more common cleft lip and palate protocols. However, several functional issues are present in patients with complex facial clefting that require more immediate attention. For example, patients with large Tessier no. 7 clefts may have problems with retaining foodstuffs in their oral cavities due to the discontinuity of the orbicularis oris (Figure 42-14). This may prompt early repair and reestablishment of the orbicularis oris musculature for functional concerns.

For those patients with orbital clefts a skilled pediatric ophthalmologist should evaluate the child early to avoid severe corneal abrasion and desiccation. Immediate lubrication of the globes is necessary to prevent severe irreversible corneal damage until eyelid structures can be mobilized to cover the globe adequately. Early after birth tarsorrhaphy stitches can be used to gain adequate closure of the lids for corneal protection. Ignoring the need for eye protection may result in severe corneal scarring that may cause blindness and prompt consideration for corneal transplantation. Corneal transplants in infants

FIGURE 42-14 A, A 2-month-old boy with a Tessier no. 7 left facial cleft associated with craniofacial microsomia (Kaban type IIb), congenital ear anomalies, a lateral tongue cleft, and a left-sided epibulbar dermoid. B, The same child at 8 months after the primary repair.

are often not successful but are possible in patients with severe orbitofacial clefts. Another concern is the support of the globes at the orbit floor that may be involved in some facial clefts. The timing of orbital reconstruction is dependent on the functional needs of the cleft area in each patient. These are just some of the concerns present in complex facial clefting, and a customized treatment plan must be formulated for each patient.

Outcome Assessment

Decision-making in cleft care should be based on evidenced-based research and a critical look at outcomes. Unfortunately there is little evidenced-based research available to guide clinicians through the many treatment protocols for cleft care.¹¹³ Although the clinical experience of the surgeon certainly has value, this must be integrated with a constant review of evidence-based research. Typically enthusiasm by a surgeon or a particular group of surgeons regarding a specific intervention because of personal experiences may help popularize that intervention but with little outcome data to support its use. Too frequently the long-term results are not forthcoming, and

the treatment regimen may still persist. Unfortunately some of the treatment regimens used today are based on the poor outcomes and mishaps of previous surgeons rather than regimens chosen as a consequence of published evidence of the actual success of a particular treatment.

Additionally the pressures of a costly health care system have made treatment decision questions even harder to investigate.⁸⁸ A need to understand the outcome differences between treatment philosophies will be critical to help determine which protocols will be most beneficial to the patient without extending valuable health care resources on unproven or ineffective methods. For this reason among many others, the need to discard unproven and unnecessary interventions has never been greater. Outcomes studies based on functional results such as appearance, facial growth, occlusion, patient satisfaction, and psychosocial development are all critical in this process. Surgeons involved in the care of patients with clefts must critically review the literature on a regular basis and not be tempted by poorly evaluated techniques popularized by clinical reports.

Conclusions

The comprehensive care of patients with clefts requires an interdisciplinary approach that demands precise surgical execution of the various procedures necessary to correct cleft deformities, as well as frequent long-term follow-up. Clinicians experienced in the comprehensive interdisciplinary care of patients with clefts are best equipped to deal with these concerns. The treatment of patients with cleft and craniofacial deformities should be free of bias and should demand team care that is patient, family, and community oriented. Only in this fashion can the overall treatment be optimally successful. This type of care maximizes the patient's ability to grow into adulthood and succeed in life without focusing on their deformity.

Reconstruction of the Alveolar Cleft

Peter E. Larsen, DDS

In the management of patients with cleft lip and cleft palate, the decision regarding alveolar cleft grafting is one of the most controversial. Is grafting of the residual alveolar defect indicated? If so, at what age is it most appropriate, what material is most ideal, and should adjunctive procedures such as orthodontic expansion be used before or after grafting? Lastly, what are appropriate measures of success? This chapter reviews what is known, discusses these controversies, and provides a rationale for the approach to the residual alveolar cleft defect.

Rationale for Grafting

Although some authors have advocated nongrafting techniques¹ or prosthodontic approaches, the general consensus is that achieving continuity between the cleft alveolar segments has significant advantages, regardless of how and when this is accomplished. Potential advantages include the following²:

1. Grafting achieves stability of the arch and prevents collapse of the alveolar segments. This provides improved orthodontic stability
2. Grafting preserves the health of the dentition. Grafting provides room for the canine and lateral incisors to erupt into the arch into stable alveolar bone and maintains bony support of teeth adjacent to the cleft^{3,4}
3. Grafting restores continuity not only of the alveolus, but also of the maxilla at the piriform rim. This supports the ala and provides improved stability and support for the nose. This may have a direct esthetic benefit and may also prove to be of long-term benefit when formal rhinoplasty procedures are performed³
4. Palatal and nasolabial fistulas are often present even following palatoplasty. Grafting of the alveolar defect provides an opportunity for the surgeon to address the residual oronasal fistula. This may have potential benefit for both hygiene and speech. Many cleft patients present with chronic upper respiratory and sinus disease, which may be related to reflux into the nasal cavity and sinus. There is some evidence that the residual fistula, whether labial or palatal can have an effect on speech articulation and nasality. There is evidence that closure of the fistula and grafting the cleft defect can improve nasal emission and nasality⁵

Measuring Outcomes

Prior to discussing the controversies associated with reconstruction of the residual alveolar cleft, it is important to accept some consistent measure of successful outcome. Most reports rely on descriptive data. This makes comparison

of different approaches difficult. To evaluate bone graft success, Bergland and colleagues described a semiquantitative approach that divided grafts into four types based on alveolar crest height.⁶ While this is effective, it has been suggested that occlusal alveolar bone height does not adequately measure success.⁷ Support of the ala and opportunity for successful tooth movement into the site or placement of an endosseous implant also requires apical bone formation. A modification of the Bergland scale that measures both occlusal and basal bone height may be a better tool for evaluating graft success. Although the Bergland scale and modifications of it rely on a two-dimensional radiograph to evaluate bone fill within a three-dimensional cleft, studies show good correlation between bone volume as predicted by these two-dimensional radiographs and that shown on three-dimensional computed tomography scans.⁸

Timing of the Graft

Perhaps the most controversial topic in managing the alveolar cleft is when grafting should be performed. In the traditional literature, terminology is not consistent. Outcome measures for various approaches are also defined inconsistently, which makes comparison difficult. Here, alveolar grafting will be grouped according to timing as defined below (Table 43-1).

Table 43-1 Timing of Alveolar Bone Grafting

<i>< 2 Years of Age: Primary Grafting</i>	
After lip repair	Before palate repair
<i>≥ 2 Years of Age: Secondary Grafting</i>	
Age in years	
2–5: Early secondary	
6–12: Mixed dentition secondary (after central incisor eruption and before the canine erupts)	
6–8: Early mixed dentition	
9–12: Late mixed dentition	
> 12: Late secondary grafting	

Primary Grafting

Some define primary alveolar bone grafting as that which is performed simultaneously with lip repair.⁹ Others have stated that any grafting that is performed at less than 2 years of age is considered primary grafting. Still others have defined primary grafting as grafting that is performed before the palate is repaired.^{10,11}

Primary grafting performed at the time of lip repair has failed to result in acceptable outcome. Long-term studies show abnormal maxillary development with maxillary retrognathia, concave profile, and increased frequency of crossbite compared with patients without grafts.^{12,13}

Primary grafting performed after the closure of the lip and before the closure of the palate has proven successful in a limited number of centers when a very specific protocol is followed.^{10,11} A prosthesis is placed before the lip is closed to mold the alveolar segments into close proximity. The lip is then closed, and this further aids in molding the segments. The segments must be in close proximity with good arch form before an onlay rib graft is placed across the labial surface of the cleft in a subperiosteal tunnel that is developed by limited dissection.

Advocates of this approach have not experienced problems with altered facial growth and malocclusion, most likely the

result of the limited dissection used in these cases. They have reported improved occlusion and graft success in these patients, compared with patients grafted at other ages.¹⁴ It is still difficult to wholeheartedly endorse this approach. Several additional anesthetics and surgeries are needed at a young age. This technique may not be possible in all patients, such as those with isolated alveolar clefts without palatal clefting or those patients in whom segments cannot be orthopedically aligned. In one center, because of these limitations, nearly one-half of patients could not be treated with primary grafting.¹⁰ Outcomes may also not be as good as with other approaches. In one study,¹⁵ there was an increased incidence of malformation of permanent lateral incisors in the primary graft group and decreased success of the graft, with only 41% of primary grafts (54% if pregrafting orthopedics was included) resulting in adequate bone height when measured with a Bergland scale. This was compared with 73% success of those sites grafted in the mixed dentition stage (after eruption of the permanent central incisors and before eruption of the maxillary canine).

Early Secondary Grafting

Grafting after the child reaches 2 years of age and before 6 years is considered early secondary grafting. The literature does not support early secondary grafting.

Secondary Grafting During the Mixed Dentition (after Eruption of the Maxillary Central Incisors and before Eruption of the Canine)

Alveolar reconstruction with grafting during the eruption of the permanent dentition may be best for various reasons. Rationale for grafting and for timing of grafting during this time period include the following:

1. There is minimal maxillary growth after age 6 to 7 years, and the effect of

grafting at this time will result in minimal to no alteration of facial growth^{16,17}

2. Cooperation with orthodontic and perioperative care is predictable. General anesthesia is not required for routine orthodontic procedures such as expansion
3. The donor site for graft harvest is of acceptable volume for predictable grafting with autogenous bone
4. Bone volume may be improved by eruption of the tooth into the newly grafted bone¹⁸
5. Grafting during this phase allows placement of the graft before eruption of permanent teeth into the cleft site, which achieves one of the primary goals of grafting — to enhance the health of teeth in and adjacent to the alveolar cleft

The landmark papers by Boyne and Sands established that grafting in the mixed dentition achieves many of the goals of reconstruction of the cleft alveolus.^{19,20} The ideal patient is between the ages of 8 and 12 years with a maxillary canine root that is one-half to two-thirds developed. This timing is supported by several well-documented studies.^{6,21–25} However, some authors have suggested that earlier grafting should be considered as a means of preserving the lateral incisor as well.^{12,26,27} These authors have suggested that grafting be considered as early as 6 years of age. There is some evidence that grafting between the ages of 6 and 8 years, in addition to achieving the expected goal of preserving the canine, can preserve the lateral incisor as well, but this remains controversial. Despite clear indications that grafting in the mixed dentition is preferable to either primary, early secondary, or late secondary grafting, it is not entirely clear whether this grafting should be performed early (age 6–8 years) or late (age 8–12 years). Various individual factors should be evaluated when determining the ideal time for grafting during the mixed dentition (Table 43-2).

Table 43-2 Factors Contributing to Timing of Grafting During the Mixed Dentition

Dental age vs chronologic age
Presence of the lateral incisor
Position of the lateral incisor
Degree of rotation/angulation of the central incisor
Trauma/mobility of premaxillary segment (bilateral clefts)
Social issues
Size of the patient and of the cleft
Occlusion
Need for adjunctive procedures
Dynamic of the team

Dental Versus Chronologic Age Many outcomes of grafting are related to preserving health of the dentition adjacent to and erupting into the cleft site. It makes sense that the timing of the graft be determined on the basis of dental rather than chronologic age. When the maxillary central incisors begin to erupt, regardless of chronologic age, the patient should be evaluated for grafting, taking into consideration the other factors discussed below. In some patients this may be much earlier than the traditionally recommended age for evaluation.

Presence of the Lateral Incisor Many proponents of earlier mixed dentition grafting advocate this timing because of the opportunity to salvage the lateral incisor.^{12,24,26} During the evaluation, attention should be directed to the presence of the lateral incisor and to whether this tooth appears to be normally formed. The incidence of congenitally missing permanent lateral incisors within the alveolar cleft is between 35 and 60%.^{15,28} If a lateral incisor is present and appears to be well formed, earlier grafting may be beneficial. Even if the tooth is not perfectly formed, it may still be beneficial to attempt to preserve it. The grafted alveolus will often thin to the point that alveolar width is not adequate for definitive reconstruction

with an endosseous implant without additional grafting.²⁹ Retaining the lateral incisor will maintain bone width and perhaps eliminate the need for yet another graft at the time of implant placement.

Position of the Lateral Incisor If the lateral incisor is mesial to the cleft it often has adequate space for eruption. However, if the lateral incisor is located in the posterior segment, earlier grafting may be necessary to preserve the lateral incisor.⁹ In one review, 36% of patients with cleft lip and alveolus had missing lateral incisors. Of the 64% who had lateral incisors, 90% of the lateral incisors were located distal to the cleft. In the same series of patients, 57% of those with cleft lip and palate had missing lateral incisors, and of the remaining 43%, 86% of the lateral incisors were located distal to the cleft.²⁸ Therefore, a significant number of patients may benefit from earlier grafting to preserve the lateral incisor (Figure 43-1).

Rotation of the Central Incisor The maxillary permanent central incisor will often erupt in a rotated and angled position (Figure 43-2). This reflects the morphology of the underlying bone. In extreme cases, the crowding of the two incisors can preclude normal oral hygiene methods, and this can lead to decay of the central incisor. The patient or parent may also be concerned with the position of the incisors for social reasons. If a decision is made to rotate these teeth into alignment, it may be necessary to graft the alveolar defect prior to this orthodontic tooth movement.³⁰ Failure to consider the morphology of the bone on the distal surface of the erupted central incisor can result in bone loss and periodontal defects as a result of orthodontic tooth movement. Since the incisor teeth erupt around age 6 years, the surgeon may choose to graft at an earlier age so that orthodontic movement of the incisors can be accomplished.

FIGURE 43-1 A, Occlusal radiograph shows lateral incisor distal to the cleft. B, Grafting which was done at age 7 years to facilitate eruption of the lateral incisor.

Social Issues The window for mixed dentition grafting is large (age 6–12 years). This is also during a period of tremendous social development for the patient. If a graft is necessary, the timing of surgery should respect the social and educational development of the child. Slightly earlier grafting, when it may cause less interference with education or other important opportunities for social development, may be preferable to grafting at an exact stage of dental development.

Size of the Patient and of the Cleft Petite patients with large cleft defects are challenging. Adequate closure of the defect may be difficult, and harvesting an adequate amount of graft material may be challenging as well. This is particularly true for large bilateral cleft defects. In these patients, the lateral incisor is often absent, the oronasal communication is often quite

FIGURE 43-2 A, Photograph of a typical unilateral cleft. There is rotation of the central incisor and angulation of the crown toward the cleft. This maintains bone support for the root of the tooth. B, Occlusal radiograph shows that the cleft defect is larger than it appears clinically and support for the incisor root is provided by only a thin margin of bone.

large, and the premaxilla is frequently in less than ideal position. In these large defects, later grafting is often better, to wait for growth of the patient and orthodontic alignment of the cleft segments.

Need for Other Procedures Patients are often evaluated for velopharyngeal incompetence, minor esthetic revision of the nose or the lip, and pressure-equalizing tubes for otitis media. It is reasonable to coordinate the timing of surgery for the alveolar cleft with other procedures that may be necessary. If velopharyngeal flap surgery is planned during the mixed dentition phase, it should take precedence over the alveolar graft. Improved speech is more important to the child's development than achieving continuity of the alveolus. Alveolar grafting would be compromised if performed simultaneously with velopharyngeal flap surgery, and in these patients, it is appropriate to delay the graft until the velopharyngeal flap surgery is accomplished and speech therapy re-instituted. Minor soft tissue, nasal, and lip revision are often desired by the patient and parents. These can be accomplished with alveolar grafting. The grafting process can distort the nose and soft tissue; these soft tissue procedures should be performed first with alveolar grafting undertaken in the same setting and with care not to disrupt the esthetic procedures already done.

Dynamic of the Team Cleft management should always involve a multidisciplinary team, with the wide expertise to develop a proper treatment plan. Difficulties may arise when the priorities of one specialty compete with those of another. If the surgical team is faced with an orthodontic provider who feels strongly that it is appropriate to align the maxillary central incisors as soon as they erupt, it will be necessary for the alveolar defect to be grafted earlier to prevent compromise of osseous support for the central incisors. Some orthodontists and surgeons believe that palatal expansion is necessary prior to grafting. These teams may find that it is more appropriate to graft patients at a later age, as it may take months to achieve the desired expansion prior to the graft.

Secondary Grafting after Eruption of the Permanent Canine (Late Secondary Grafting)

Late secondary grafting has received some support; however, data show that when all the goals of alveolar reconstruction are considered it has a less than acceptable outcome. Patients older than 12 years of age who undergo grafting have been reported to have decreased success when evaluated using the Bergland scale,^{6,15,25,27,31,32} loss of osseous support of teeth adjacent to the cleft,¹⁸ and increased morbidity.²⁷ There is less

opportunity to salvage the lateral incisor, and there is a delay in correction of the orthodontic condition. This delayed grafting does allow for increased options with regard to donor site for graft material, as harvest of the mandibular symphysis becomes possible. Such grafts are difficult in the mixed dentition stage, where it is difficult to obtain adequate bone without damaging unerupted teeth.

Source of Bone Graft

The selection of the ideal grafting material is somewhat dependent on the timing of the graft. In primary bone grafting, the rib is the only site for adequate quantity of bone with acceptable morbidity. In the mixed dentition stage, the rib is not as appropriate as other sites such as the calvaria or iliac crest. These options would also be possible sources for bone for late secondary grafting, as well as grafts from the mandibular symphysis and possibly the tibia.

As the data suggest that grafting during the mixed dentition is ideal, discussion will focus on comparing various sources of graft material for this group of patients. The advantages and disadvantages of various potential sources of bone are outlined in Table 43-3.

Iliac Crest

Potential advantages of the iliac crest bone graft include low morbidity and high volume of viable osteoblastic cells (cancellous bone); two teams may work simultaneously, and this procedure is well accepted by the patient.

Bone can be harvested from the iliac crest through various approaches. Some have suggested that a lateral approach is appropriate in the growing patient.³³ This procedure disrupts the iliotibial tract and has a higher incidence of gait disturbance and postoperative pain.³⁴ In theory it may be appropriate to avoid the anterior crest, which does not complete its growth until after age 20 years.³⁴ However, the carti-

Table 43-3 Comparison of Graft Sources

Site	Advantage	Disadvantage	Considerations
Ilium	Large quantity cancellous bone, two teams	Mild transient gait disturbance	All clefts, particularly large and bilateral clefts
Calvaria	Minimal postoperative discomfort, incision hidden, low morbidity	Limited cancellous/diploic bone, increased operative time	Unilateral clefts, lower success
Mandibular symphysis	Same operative field, rapid procurement, minimal pain	Limited bone	Older children with small defects
Rib	Two teams	Poor source cancellous bone, postoperative pain, visible scar, risk of pneumothorax	Not recommend except for primary grafting
Proximal tibia	Abundant cancellous bone, easy procedure, mild postoperative pain, two teams	—	Not recommend in patients that have not completed growth

Adapted from Ochs MW.⁴⁹

lagnous cap overlying the crest is reduced in thickness to about 1cm by age 9 years. Damage to the crest at this time could lead to disturbance in growth and cosmetic deformity of the crest; however, splitting the crest longitudinally, which allows access to the underlying cancellous marrow, has been used for harvest of bone in this age-group with no reported growth alteration and less postoperative gait disturbance than with the lateral subcrestal approach.^{35,36}

Calvarial Bone

Calvarial bone has been recommended by some as an alternative to iliac crest grafting.^{37,38} Some authors have concerns about the potential for success when calvaria is used as a graft source.^{39,40} This may be related to the technique of harvest. Bone grafts consisting of diploic bone have been shown to be more successful than those grafts harvested using a high-speed rotary device to shave off primarily cortical bone from the surface of the calvaria.⁴⁰ However, even when harvesting calvarial bone in such a way as to maximize diploic bone, results may not be as good as with iliac crest bone. In one study where primarily diploic bone was carefully harvested from the calvaria, the results were still less successful (80% graft success) than with tra-

ditional iliac crest bone (93% graft success).⁴¹ It is likely that either source is effective as long as primarily diploic bone is used. This limitation may render calvaria as a less useful source for large clefts and bilateral clefts.

Calvarial grafts may have decreased morbidity compared with iliac crest harvest. There is less postoperative pain and no gait disturbance. Other potential advantages include decreased surgery time. Cranial bone grafts can be harvested more quickly than iliac crest grafts. If a single team is performing surgery, this may be significant. However, it is not possible to harvest the cranial graft simultaneously with the alveolar cleft repair; grafting from the iliac crest if two teams are used can decrease overall operating time compared with calvarial grafting. Lastly, the incision for graft harvest is hidden in the hairline, which may have a cosmetic advantage.

Grafting from the calvaria has potential disadvantages. There is a perceived increased risk by patients and their families, although several studies show that the morbidity of bone harvest from the calvaria is minimal.³⁴ As mentioned previously, the volume of diploic bone is limited, making this less predictable for large or bilateral clefts.

Allogeneic Bone and Bone Substitutes

In an effort to eliminate the morbidity and time necessary to harvest bone from any autogenous site, some authors have evaluated allogeneic bone as a potential source of graft material. Studies have shown that allogeneic bone can be used successfully to graft secondary alveolar cleft defects and that results can be compared favorably with those achieved with autogenous bone.⁴² However, the demands of bone healing in the alveolar defect where there is potential communication between the graft and the nasal and oral cavity may make this less predictable in large cleft defects or bilateral clefts. In general, bone healing with autogenous bone is biologically different than with allogeneic bone. Autogenous bone grafts initiate an angioblastic response early in the healing process, and some of the transplanted cells remain viable, resulting in a more rapid formation of new bone. In contrast, allogeneic bone grafts demonstrate slower revascularization, as there are no viable cells transferred with the graft.^{42,43} There is also a theoretical risk of disease transmission from allogeneic sources of bone. Mathematically the risk is quite small but may be of concern to patients and families.

Preliminary work suggests that bone morphogenic proteins and other tissue-derived growth factors could be useful in eliminating the need for autogenous bone harvest in this patient population; however, there are insufficient outcome data and availability of these products commercially to make them the material of choice.

In summary, autogenous bone harvested from either the iliac crest or calvaria remains the most predictable technique for cleft reconstruction. The iliac crest has some potential advantage over the calvarial graft; however, this certainly depends on technique and surgeon preference.

Pre- versus Postsurgical Orthodontics

Controversy exists regarding the use of orthopedic expansion of the cleft segments and the relationship between expansion and grafting. This issue has not been entirely settled. Most authors prefer presurgical expansion, citing easier expansion because of less resistance, improved access to the cleft for closure of the nasal floor, better postoperative hygiene, and less chance of reopening the oronasal fistula.^{23,24} Presurgical expansion may also allow orthopedic movement of the premaxillary segment in the bilateral cleft patient, which can eliminate traumatic occlusion that can negatively impact graft success. Proponents of

expansion following grafting cite advantages of improved bone consolidation when the graft is placed under a dynamic load during healing, a smaller soft tissue defect to close, less difficulty procuring an adequate volume of bone, and a narrower defect, which will regenerate bone more quickly.²⁶ Both approaches have been used in conjunction with autogenous grafting in the mixed dentition stage with success.⁹

In practice, both approaches are valid, and the decision should be based on individual clinical presentation.³¹ Small unilateral clefts with collapse of the arch may be easier to graft with some presurgical expansion. In these cases, such expansion may not increase the size of the defect appreciably, and better alignment of the segments can improve hygiene of the teeth adjacent to the cleft and improve access (Figure 43-3). In these cases, the end point of presurgical expansion is improved arch form, not necessarily resolution of crossbite. Bilateral clefts with collapse of the lateral segments may also benefit from presurgical expansion. Expanding the lateral segments may allow the premaxilla, which is often anteriorly positioned, to be brought back into better relation with the arch, improving arch form, and, in some cases, eliminating traumatic occlusion (Figure 43-4). If this is not done prior to grafting, it may be difficult to

obtain ideal arch continuity, and positioning of the segments after grafting may be difficult. In patients with reasonable arch form, good alignment of the segments, and dental development corresponding to ideal timing for grafting, it makes little sense to delay grafting in order to expand preoperatively, even in the presence of a buccal crossbite. These crossbites may be related only to the anterior-posterior discrepancy, and even if they are truly representative of transverse deficiency, they can be treated easily with expansion following the graft. These clefts can be expanded without opening the oronasal fistula or having a negative effect on the graft.

Not only is there controversy regarding pre- versus postsurgical expansion, there are also two schools of thought regarding orthodontic movement of the erupted teeth adjacent to the cleft. Some authors suggest that aligning the teeth adjacent to the cleft produces better hygiene and an improved result.²³ However, orthodontic movement of teeth adjacent to the cleft is not typically desired.⁴⁴ Orthodontic movement of teeth adjacent to the cleft prior to grafting increases the risk of moving these teeth into the cleft site, compromising osseous support. Studies have directly correlated the success of grafting with the presence of adequate bone on the distal surface of the central incisor preoperatively.⁴⁵ These defects cannot subsequently be

FIGURE 43-3 A, Occlusal photograph of a typical unilateral cleft. There is rotation of the central incisors and collapse of the lesser segment. Expansion of the lesser segment will bring the arch into better form and facilitate grafting without widening the cleft. B, Similar cleft that has been expanded. C, This cleft is already wide without any expansion. It would not be appropriate to expand this cleft before grafting even if a crossbite is present.

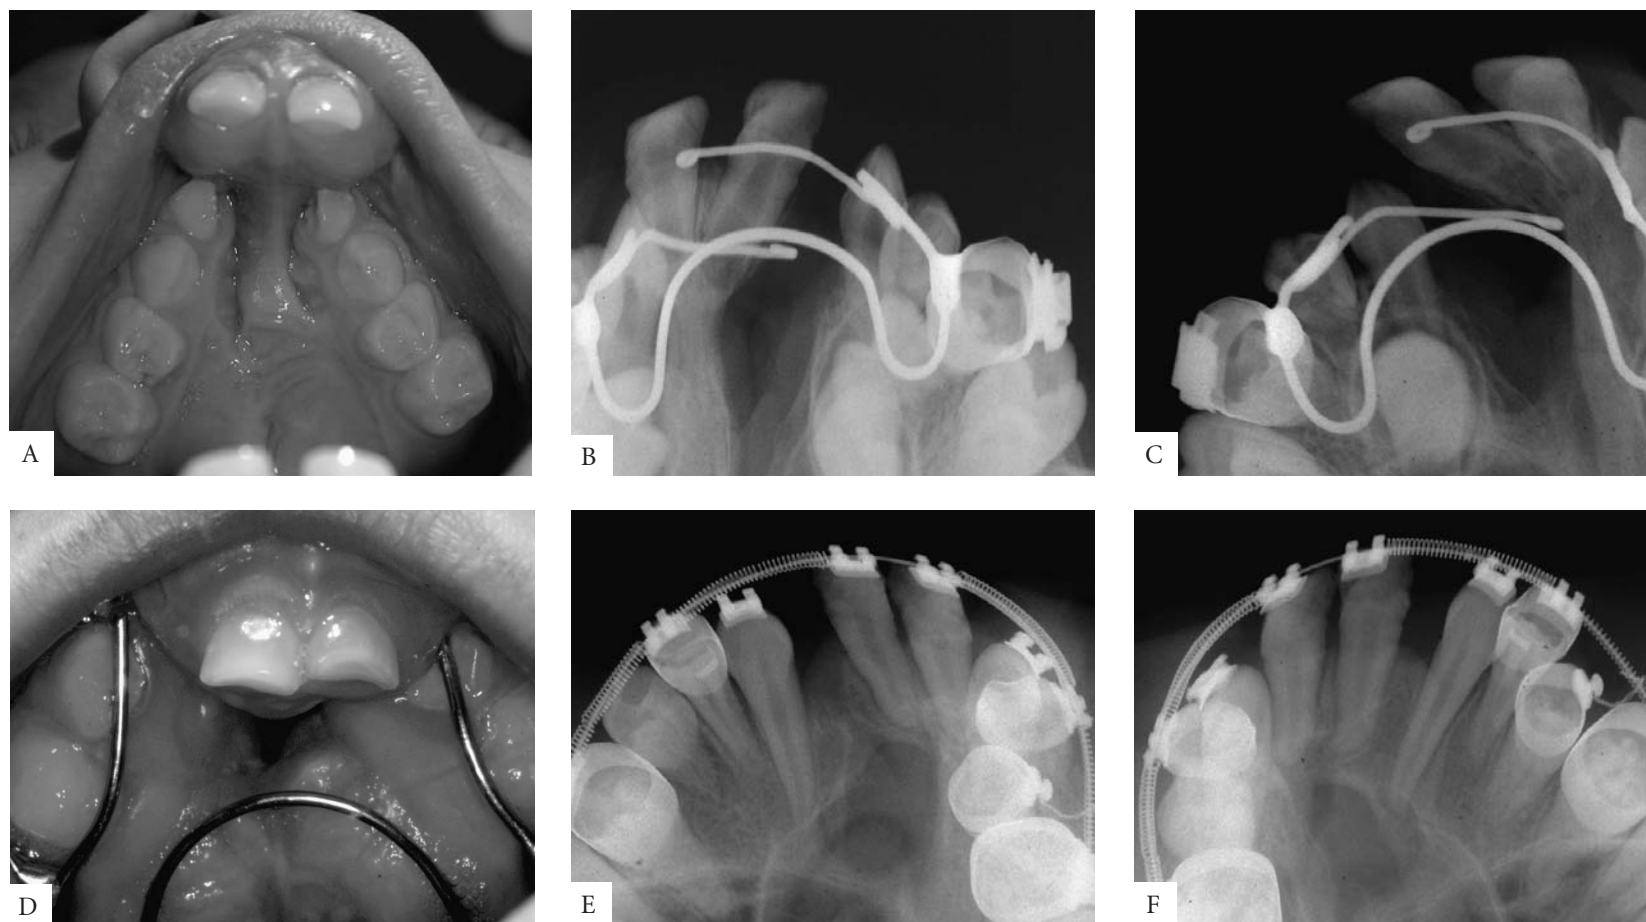

FIGURE 43-4 A, Occlusal photograph of bilateral cleft with collapse of the lateral segments and protrusion of the premaxilla. B and C, Right and left oblique occlusal radiographs show the cleft defect. D, Expansion of the bilateral cleft allows the premaxilla to move posteriorly and improves arch form and alignment of the segments. E and F, Occlusal radiographs of the same patient following grafting with eruption of the canine.

grafted as the bone graft will not adhere to the tooth surface. The central incisor adjacent to the cleft site is usually rotated and angled with the crown tipped toward the cleft. This rotation and angulation decreases the mesial-distal dimension of the tooth and allows for the best bony support of the tooth (see Figure 43-2). Orthodontic forces of rotation and tipping will have the undesirable effect of increasing the mesial-distal dimension, encroaching on the bony support at the cemento-enamel junction of the tooth. Orthodontic root torque to correct the angulation of the tooth will have the undesired effect of pushing the apical portion of the root toward the cleft site. The underlying osseous cleft is frequently much larger than the overlying soft tissue defect may indicate, giving a false sense of securi-

ty to the orthodontist who may want to move these teeth in the absence of a graft (Figure 43-5).

Surgical Technique for Grafting the Cleft Alveolus

The ideal technique will meet the following criteria:

1. Predictable closure of the nasal floor produces a watertight barrier between the graft and the nasal cavity
2. There is access to closure of residual palatal and labial fistula
3. Keratinized attached tissue is maintained around the teeth adjacent to the cleft and in the site where the yet unerupted lateral incisor and canine will erupt

4. Mobilization of tissue is adequate to close large defects without tension, when such defects are present

FIGURE 43-5 Occlusal radiograph of a patient that had orthodontic rotation of the maxillary central incisor adjacent to the cleft prior to grafting the defect. There is loss of bone on the distal surface of the root to the apex. The tooth required removal.

5. The vestibule is not shortened, and scarring is not excessive

Given these requirements, the technique most often used employs advancing buccal gingival and palatal flaps. This approach has some disadvantages, including the following:

1. Difficulty obtaining closure in large bilateral clefts, which heal by secondary intention of full-thickness wounds created by the advancement
2. A four-corner suture line that approximates the flaps directly overlying the graft, which may lead to dehiscence
3. The possibility that elevating large full thickness mucoperiosteal flaps leads to growth alteration in young patients. However, when compared with finger flaps and trapezoidal flaps, which can shorten the vestibule and place nonkeratinized tissue around the dentition, this approach remains the best

The procedure can be broken down as follows. The first step requires development

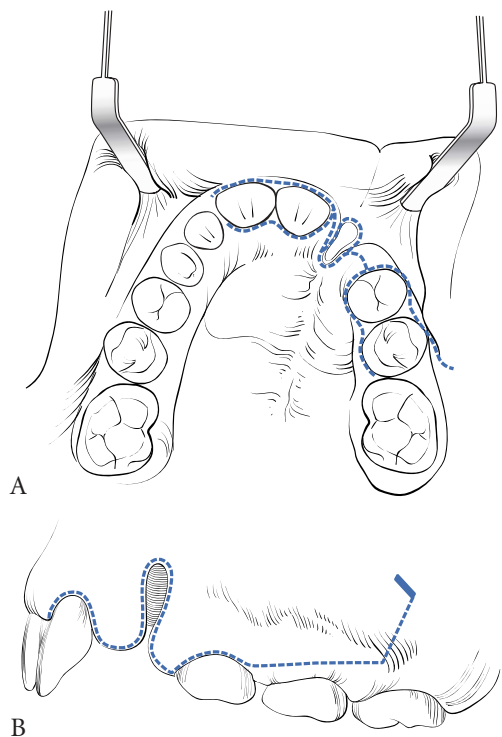

FIGURE 43-6 A and B, Sulcular incision used to develop sliding flaps for closure over the graft. Adapted from Hall HD and Posnick JC.²³

of full-thickness mucoperiosteal buccal flaps (Figure 43-6). Some authors may recommend papilla preservation. When grafting is done in the mixed dentition, especially if early, this is not necessary as the papilla will regenerate. Palatal flaps are then developed, incorporating whatever residual palatal defect may be present to allow for closure of the residual palatal fistula. Some diagrams show this incision being made from a palatal approach. This may be possible in wide clefts but in practice is more easily accomplished by starting reflection of the palatal flaps from a sulcular incision that is placed on the palatal side of the dentition followed by reflection of full-thickness palatal flaps toward the palatal defect. The palatal flaps can then be separated from the nasal tissue along the cleft margin by sharp dissection with scissors from the anterior extending posteriorly as the flaps are elevated (Figure 43-7A). In this manner, the maximum palatal soft tissue is preserved for closure, while assuring adequate nasal mucosa to obtain a watertight nasal closure. Once the buccal and palatal flaps have been developed, access is readily obtained to the nasal mucosa, which is then reflected and sutured, burying the knots to obtain a watertight nasal closure (Figure 43-7B and C). Most schematic diagrams of cleft closure show this portion of the procedure being performed from the palatal aspect. However, it is generally most readily accomplished in narrow clefts from the anterior through the cleft defect. Once the nasal mucosa is closed, the palatal defect is closed by first closing the palatal flaps, converting the cleft palate into a single flap (Figure 43-7D). The graft material is then placed into the cleft from the anterior, making certain to fill all voids completely to the piriform rim. Graft material can be condensed using an orthodontic band pusher or periosteal elevator (Figure 43-7E). It is helpful to place a malleable retractor to protect the nasal floor as the bone is packed into place. Finally, the labial flaps can be advanced, and they are sutured to each other and then to the palatal flap producing the

classic four-corner closure over the crest of the ridge (Figure 43-7F and G). In most cases, the sliding flaps will be advanced one papilla on either side of the cleft, or, in some cases, only a single papilla advancement from the posterior segment is necessary. It may be necessary to perform a small back cut or to release or score the periosteum to obtain a tension-free closure. It is best to use a resorbable monofilament suture.

A palatal stent can be used to stabilize the cleft and protect the soft tissue closure. This may compromise hygiene and blood supply to the palatal flaps and, in most cases, is not required for success. In the bilateral cleft, if there is a traumatic occlusion to the anterior maxillary dentition, a mandibular bite plane is helpful to open the bite and prevent mobility of the premaxilla.

It is appropriate to use intraoperative antibiotics. Previous studies show that graft success and incidence of infection are not improved by the use of postoperative antibiotics.⁴⁶ Some surgeons feel more comfortable with a 1-week course of antibiotics, particularly when the soft tissue closure is questionable.

The postoperative diet should be limited to full liquids for approximately 5 days. This can be advanced to a soft mechanical diet. However, it is critical that the patient refrain from incising food with the anterior dentition; rather the patient should cut food into small pieces and masticate primarily on the posterior teeth. In bilateral cases, this is particularly important as any trauma to the premaxilla will cause mobility of the segment leading to graft failure. Radiographic evidence of graft consolidation should be visible within 8 weeks. The surgeon should confirm successful consolidation of the graft prior to any orthodontic manipulation of the teeth adjacent to the cleft.

Overview

This chapter has outlined historic benefits of grafting, discussed many of the controversies, and provided data on the benefits and disadvantages of several approaches.

FIGURE 43-7 A, Palatal flaps are developed sharply with scissors. This also separates the nasal mucosa from the palatal tissue. B, Palatal closure. This can be done before or after the nasal mucosa is closed. C, Nasal mucosal flaps are reflected from the bony walls of the cleft. D, Nasal flaps are approximated with sutures burying the knots when possible. E, Bone is packed into the defect with a periosteal elevator or orthodontic band pusher. Digital pressure against the palatal flap facilitates packing and protects the palatal closure. F and G, The labial flaps are advanced toward each other and closed. This provides attached keratinized tissue. Exposed areas distally where the flaps have been advanced are left to granulate. Adapted from Hall HD and Posnick JC.²³

The following is a stepwise approach to managing the alveolar cleft from one perspective.

1. At age 5 to 6 years an orthodontic evaluation is performed. The ability of the patient to cooperate with ortho-

odontic treatment is assessed, the arch is evaluated for collapse, and erupted supernumerary teeth in the area of the cleft are identified. Radiographic examination should include a panoramic film as well as an intraoral view that allows detailed evaluation of

the cleft site. Periapical films can be used for this, but a lateral oblique occlusal film is best. An occlusal film is placed in the standard position while directing the beam obliquely to the midline along the long axis of the cleft (Figure 43-8)

FIGURE 43-8 A, Traditional maxillary occlusal radiograph. The cleft is identifiable, but overlap of the bone makes it difficult to determine the size of the defect and relationship of the teeth to the defect. B, Oblique occlusal radiograph is exposed by directing the beam obliquely to the midline, along the long axis of the cleft. Note that the morphology of the cleft is better identified, as is the relationship of unerupted teeth to the defect.

- If erupted supernumerary teeth are identified in the area of the cleft, these are extracted now or, at a minimum, 8 weeks before the graft (Figure 43-9A)
- Orthodontic expansion is performed if there are specific goals that can be met prior to grafting. These would include decreasing traumatic occlusion to the premaxillary segment in bilateral cleft patients and correcting arch collapse that will compromise grafting. No attempt is made to correct the crossbite at this stage, and there is no attempt to orthodontically correct rotation of the permanent central incisor (see Figure 43-9A)
- The alveolar cleft is grafted when the patient is between 6 and 8 years of age. Two teams perform the surgery with graft harvest from the iliac crest simultaneous with the cleft closure
- The graft is evaluated with a lateral oblique occlusal radiograph 3 months following surgery (Figure 43-9B)
- Final orthodontic expansion is performed if indicated, and permanent incisor teeth are then rotated into proper alignment
- Conventional orthodontic treatment is performed at a more traditional age, following eruption of the remaining permanent dentition. Patients are periodically monitored for eruption of the canine in the cleft. Some authors have indicated that in 30 to 73% of patients, eruption of the canine into the alveolar graft requires surgical uncovering of the tooth or uncovering and orthodontic assistance.^{12,47,48} Others have reported that nearly all of these teeth can be expected to erupt without surgical intervention²⁴ (Figure 43-9C).

FIGURE 43-9 A, The cleft has been expanded. The canine is in position to begin eruption. There is a supernumerary/malformed lateral incisor erupting horizontally into the cleft. B, The supernumerary tooth has been removed. The defect was grafted 2 months following extraction and the film shows good bone consolidation. C, The maxillary canine can be seen erupting into the graft.

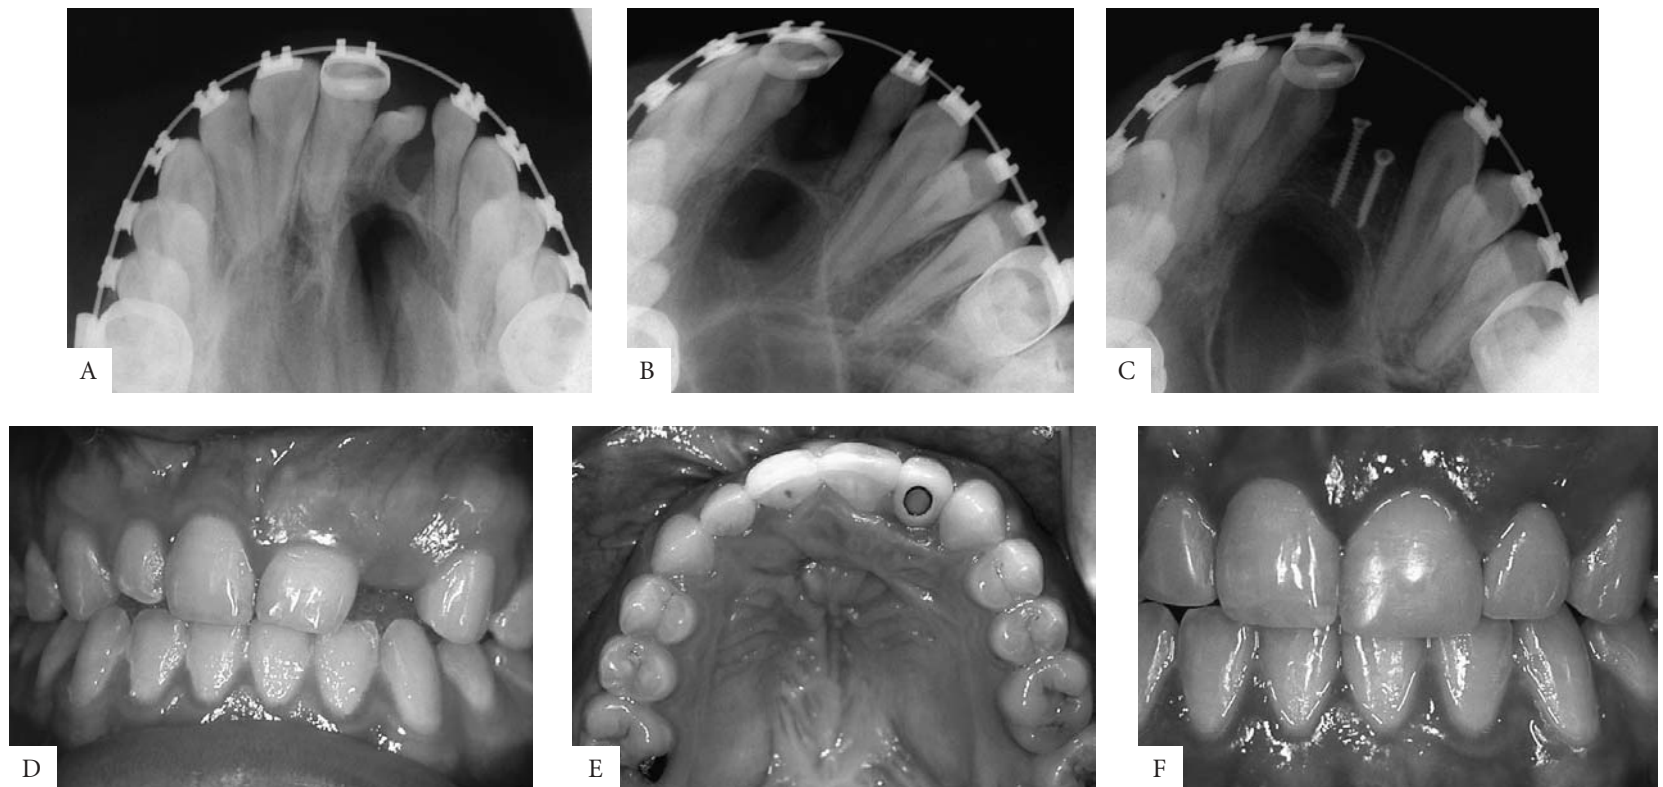

FIGURE 43-10 A, Occlusal radiograph shows thin bridge of bone with inadequate height. A malformed lateral incisor was maintained to preserve as much width as possible. B, The tooth was removed. C, After 2 months of healing, an onlay bone graft was placed. D, Clinical view after grafting. E and F, View following placement of the implant and reconstruction.

If uncovering is necessary, techniques to preserve attached tissue are used as would be appropriate for impacted canines in noncleft patients

8. Missing lateral incisors are managed with space development and implant placement, as opposed to canine substitution. This is accomplished following definitive orthodontic treatment and orthognathic surgery if indicated, after maxillary growth is complete. Even when bone height is adequate and teeth adjacent to the graft have good support, the graft undergoes resorption resulting in a narrow ridge. This is not unlike the bone resorption found with congenitally absent lateral incisors in noncleft patients. Successful implant restoration is possible, but further grafting is likely needed before adequate labial-palatal width is available for implant placement³⁰ (Figure 43-10). Attention to soft and hard tis-

sue is critical in these patients to achieve esthetic results

Conclusion

Restoration of the cleft alveolus and maxilla by grafting is a critical part of the overall management of the patient with cleft palate. A systematic approach can improve predictability. This is best accomplished during the mixed dentition stage. Adjunctive expansion may be accomplished before or after grafting, depending on the needs of the patient.

Reconstruction of Cleft Lip and Palate: Secondary Procedures

Ramon L. Ruiz, DMD, MD

Bernard J. Costello, DMD, MD

A congenital cleft of the lip and palate represents a complex malformation involving the hard and soft tissues of the face. Children born with cleft lip and palate face several unique functional and esthetic challenges requiring a combined (interdisciplinary) treatment approach in order to obtain an ideal outcome relative to speech, occlusion, facial appearance, and individual self-esteem. This successful reconstruction routinely requires multiple phases of surgical intervention. Because treatment is carried out during periods of growth, the benefit-risk ratio of any planned surgical procedure must be carefully considered in order to provide the maximum benefit to the patient.^{1,2} Surgeons caring for these children must maintain a firm cognitive understanding of the three-dimensional

anatomy of the cleft lip and palate malformation and the complex interplay that exists between the surgical procedures and ongoing facial growth.

The various surgical procedures involved in staged reconstruction of cleft lip and palate have been described extensively in the literature and are presented in Chapters 42, “Cleft Lip and Palate: Comprehensive Treatment Planning and Primary Repair,” Chapter 43, “Reconstruction of the Alveolar Cleft,” and Chapter 61, “Orthognathic Surgery in the Patient with Cleft Palate.”³⁻⁶ In addition, the American Cleft Palate–Craniofacial Association (ACPCA) has developed parameters of care in order to facilitate the coordinated interdisciplinary treatment of individuals affected with cleft lip and palate deformities.⁷ The ACPCA document summarizes a

management protocol that is centered around thoughtful timing of specific interventions based on the patient’s dental, skeletal, speech, and psychological development. The general staged approach to cleft lip and palate reconstruction from infancy through adolescence is presented in Table 44-1. Contemporary management protocols involve several phases of surgery during infancy (cleft lip repair and palate closure) and early childhood (bone graft reconstruction of the cleft maxilla and alveolus) that are considered required operations in all cases of complete unilateral or bilateral cleft lip and palate. In addition to those primary stages of repair, several children will go on to require additional procedures for correction of secondary problems. Secondary reconstruction of cleft lip and palate may involve

Table 44-1 Stages of Cleft Lip and Palate Reconstruction: Infancy through Adolescence

<i>Surgical Treatment</i>	<i>Age</i>	<i>Timing Considerations</i>
Cleft lip repair*	10 to 12 weeks	
Cleft palate repair*	9 to 18 months	Exact timing of repair is based on child’s speech/language age
Secondary palate surgery for VPI	3 to 5 years	
Bone graft reconstruction of cleft maxilla/alveolus*	6 to 9 years	Based on dental development
Orthognathic surgery	14 to 16 years for females, 16 to 18 years for males	
Dental implant placement	16 to 18 years	
Lip/nasal revision	After age 5 years	Varies widely depending on clinical findings and psychosocial concerns. Definitive nasal surgery usually delayed until adolescence.

*Reconstruction stage is required for all patients with complete cleft lip and palate. VPI = velopharyngeal insufficiency.

surgery for treatment of velopharyngeal dysfunction, bone graft reconstruction of bony clefts of the maxilla, correction of residual skeletal disproportion with malocclusion, closure of palatal fistulas, normalization of lip and nasal form, and prosthetic rehabilitation of the cleft dental gap. Although the indications for each of the primary and secondary surgical undertakings are different and the decision-making processes may vary, one cannot view each of these procedures as isolated events. This chapter reviews the different phases of secondary cleft lip and palate reconstruction that may be required after primary cleft lip and palate repair with the purpose of providing an organized description of the contemporary philosophy and rationale for surgical interventions and specific timing.

Fistula Closure

Background

When a child is born with a cleft palate, there is an abnormal communication between the oral and nasal cavities. One of the principles essential to successful surgical repair involves the separation of oral and nasal side soft tissues from each other and then reconstruction of those distinct tissue layers to establish separate nasal floor and oral mucosal linings. The result is closure of the hard palate in two layers (nasal mucosa and oral mucosa) and closure of the soft palate in three layers (nasal side, levator musculature, and oral side mucosa).

Residual abnormal oronasal communications, or “fistulas,” following the initial repair are relatively frequent problems that require subsequent surgical procedures in patients with cleft palate. Before addressing the specific management approach to residual fistulas, one must define the clinical situation based on the patient’s age, previous surgical history, and the exact location of the fistula. Another important consideration is the extent to which the cleft defect involves the primary and secondary palates. The primary palate comprises the anatom-

ic structures anterior to the incisive foramen (alveolus, maxilla, piriform, lip). The secondary palate comprises the anatomic structures between the incisive foramen and the uvula. Using this terminology, a complete cleft of the primary and secondary palates would involve the maxilla, alveolus, hard palate, and soft palate. An isolated cleft palate involving the hard and soft palate (without affecting the alveolar ridge) would be described as a complete cleft of the secondary palate while a cleft involving only the soft palate (and not the hard palate or alveolus) is described as an incomplete cleft of the secondary palate.

Even when a child is born with a complete cleft palate (ie, affecting the primary and secondary palate), the primary repair involves closure of the secondary palate only—those structures from the incisive foramen to the uvula. The goals of cleft palate repair during infancy are twofold: first, to establish complete watertight closure of the secondary palate for separation of the oral and nasal cavities and, second, to repair the levator musculature in order to allow for normal speech formation. Repair of the skeletal maxillary/alveolar cleft defect and its associated oronasal communication are not generally undertaken at this stage. Many surgeons consider this alveolar defect part of the original cleft deformity that has been purposely left unrepaired instead of a true “fistula.” Definitive repair of the anterior alveolar or nasolabial fistula is instead incorporated into the bone graft reconstruction performed during midchildhood based on the child’s dental development.^{5,6,8,9} Bone graft reconstruction of the cleft defect is presented in greater detail in Chapter 43, “Reconstruction of the Alveolar Cleft.”

Ideally, a child with a complete cleft palate will undergo palate repair during infancy with successful closure of the hard and soft (or secondary) palates and then bone graft reconstruction of the maxilla/alveolus (or primary palate) with closure of any residual nasolabial fistula

during childhood. Unfortunately, residual palatal fistulas are frequently encountered after the initial palate repair. The risk of fistula formation seems to be closely associated with the size of the original cleft defect.^{10,11} The type of repair used by the surgeon may also affect the fistula rate. Recent reports indicate that a two-flap palatoplasty technique is associated with the lowest rate (3.4%) of palatal fistula formation.¹² Another frequently employed technique, the Furlow double opposing Z-plasty, is associated with a higher incidence of oronasal fistula.⁵ This difference in the rate of fistula occurrence is probably more noticeable when the cleft defect being repaired is very wide. The most common location for development of a residual palatal fistula following cleft palate repair is the junction of the hard and soft palates followed by the anterior hard palate and incisive foramen region.^{5,6,11,13} The incidence of palatal fistula following single-stage palatoplasty varies greatly, with the reported rates as high as 50%.¹¹

Indications for Fistula Repair and Timing of Surgery

Most fistulas are noted early on in the post-surgical period following palate repair and are the direct result of local wound breakdown owing to tension or vascular compromise. Another time period when a palatal fistula may be encountered is during Phase I (pre-bone graft) orthodontic treatment, especially if maxillary expansion has been undertaken. There is disagreement about the causal relationship of orthodontic expansion and development of a palatal fistula. However, most experienced cleft surgeons believe that fistula defects discovered during maxillary expansion are preexisting oronasal communications and are not actually caused by the orthodontic treatment. Small fistulas present since infancy can be hidden within a narrow palate by collapsed maxillary segments and then uncovered as the maxillary arch form is expanded by orthodontic or orthopedic means.

The recommended timing of fistula closure may vary significantly and remains a controversial topic. Some surgeons and cleft teams may advocate relatively aggressive management with early closure of any fistula present after the initial palate repair. We prefer to take a more long-range view of these problems and delay surgery for several years whenever possible.

In infants, the closure of a small (1 to 4 mm), nonfunctional fistula can generally be deferred until later in childhood. In such cases, fistula repair may be incorporated into any future necessary procedures such as pharyngeal surgery for velopharyngeal insufficiency or bone graft reconstruction of the cleft maxilla and alveolus as long as there are no functional speech or feeding-related concerns. When a larger (> 5 mm) fistula is present, there is a greater likelihood that functional concerns will be encountered, such as nasal air escape which impacts speech, nasal reflux of food and liquids, and hygiene-related difficulties. In clinical situations where significant functional problems exist, earlier closure of the persistent fistula is indicated. As part of the decision-making process, surgeons must weigh the benefits of fistula repair against the negative effects of a second palatal surgery involving stripping of mucoperiosteum on subsequent maxillary growth. Another consideration in planning the exact timing of fistula closure is the type of repair technique being used for the repair. Attempts to close a fistula with local flaps or repeat palatoplasty may be undertaken during infancy and early childhood. On the other hand, in cases in which the use of a regional (eg, tongue) flap is required, the child must be old enough to cooperate with the perioperative regimen.

Operative Techniques for Closure of Palatal Fistulas

The repair of residual palatal fistulas following cleft palate repair has been described using several different techniques.^{5,10,14-16} Current operations used

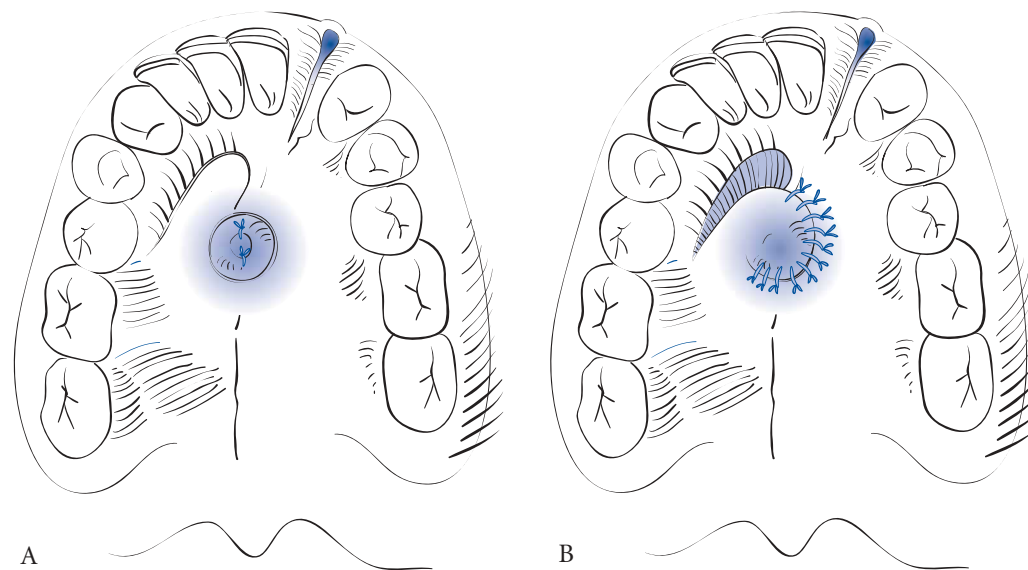

FIGURE 44-1 The use of a small, rotational flap for closure of a residual palatal fistula. This type of repair has a high failure rate. A, Turnover flaps are used to establish a nasal side closure and a palatal mucosal flap is outlined. B, Random pattern, full-thickness mucoperiosteal flap is elevated and mobilized for coverage of defect.

for fistula repair include local palatal flaps, modifications of the von Langenbeck and two-flap palatoplasty techniques, palatoplasty with incorporation of a pharyngeal flap, and the use of a tongue flap. Other regional flaps, including the tongue, buccal mucosa, buccinator myomucosal, temporalis muscle, and vascularized tissue transfer are less frequently used but have been described.^{14,17-21}

One of the most frequently described procedures for closure of residual fistulas is the use of local soft tissue flaps created within the palatal mucosa and rotated over the defect for closure (Figure 44-1). The components of this approach are the creation of turnover flaps around the defect for nasal side closure, elevation of a palatal finger flap, and rotation of the flap for coverage of the defect. A significant area of exposed bone is left at the donor site, and this is allowed to heal by secondary intention. Unfortunately, this type of repair is useful only for very small palatal defects and is associated with a relatively high failure rate.¹⁴ Small rotational flaps within palatal tissues that contain extensive scarring from prior surgical procedures are difficult to

mobilize without residual tension and may have diminished blood supply resulting in a less-than-ideal healing capacity and a greater chance of wound breakdown.

Our preferred approach to residual palatal fistulas involves the modification of one of the primary palate repair techniques, namely the Bardach or von Langenbeck procedures.^{5,22} These approaches allow adequate coverage of even large defects with the use of bulky soft tissue flaps, a layered repair of the nasal and oral sides, and a tension-free line of closure (Figures 44-2 and 44-3). In addition, the amount of bone that is left exposed after the repair is minimal to none. This is because the vertical depth of the palatal vault translates into soft tissue extension medially, and so the result is palatal soft tissue flaps that adequately cover the underlying bone with a layer of dead space between the palatal shelves and the oral mucosa lining. The Bardach (two-flap) palatoplasty is our preferred operation in cases where the fistula defect is 5 mm or larger. The primary advantage of this approach is the ability to raise large soft tissue flaps, which can be mobilized easily and allow for easy visualization and closure of

FIGURE 44-2 Modification of the two-flap palatoplasty technique for closure of a residual palatal fistula. A, Two large mucoperiosteal flaps are developed with dissection extended to a point posterior of the fistula defect. The nasal mucosa is repaired as a separate layer. B, Closure of the oral side. The midline is closed first using multiple interrupted sutures, and then the lateral incisions are reapproximated.

the nasal mucosa. By comparison, one of the theoretical advantages of the von Langenbeck procedure is the creation of bipediced flaps that maintain anterior and posterior blood supplies. While the anterior pedicles do provide additional perfusion, they also result in less freely movable flaps with limited access and visualization of the nasal side tissues. For this reason, we use the von Langenbeck technique only for relatively small defects within the hard palate.

In situations where there is a much larger (> 1.5 cm) defect, successful closure may dictate that the surgeon recruit additional soft tissue using a regional flap. Fistula defects within the posterior hard palate or soft palate may be addressed with the use of a modified palatoplasty procedure as described above in combination with a superiorly based pharyngeal flap. After the palatal flaps are developed and the nasal side dissection is complete, a pharyngeal flap is harvested. The pharyngeal flap soft tissue is then incorporated into the nasal side closure of the area where the fistula was present. Using this technique, a substantial amount of addi-

tional soft tissue can be recruited for tension-free repair of a large palatal defect. When the fistula is located within the anterior two-thirds of the hard palate, the

procedure of choice for recruitment of additional soft tissue is the anteriorly based dorsal tongue flap (Figure 44-4). First, nasal side closure of the palatal defect is performed using turnover flaps with multiple interrupted sutures. Next, this technique calls for development of an anteriorly based tongue flap that is approximately 5 cm in length by one- to two-thirds the width of the tongue. The tongue flap is elevated along the underlying musculature and then inset using multiple mattress sutures for closure of the oral side. The recipient bed within the tongue is closed primarily. After the initial surgery, the tongue flap is allowed to heal for approximately 2 weeks. At that time, the patient is returned to the operating room. Nasal fiber-optic intubation is indicated for the second procedure since the tongue is still sutured to the palate, restricting normal visualization of the airway. The flap is sectioned and the stump at the donor site is freshened and inset into the tongue. The use of laterally and posteriorly based tongue flaps has also been

FIGURE 44-3 Modification of the von Langenbeck technique for closure of a residual palatal fistula. A, Incisions are created at the fistula defect along the junction of oral and nasal mucosa, and laterally in order to develop palatal flaps. Care is taken to maintain anterior soft tissue attachment for improved blood supply. This may make flap mobilization and visualization of the defect difficult. B, The nasal side is closed first, and then oral side closure is accomplished with interrupted sutures.

presented in the cleft literature.^{23,24} In our opinion, however, an anteriorly based flap is better tolerated by most patients and allows for the greatest degree of tongue mobility with less risk of tearing the flap from its palatal insertion.

Secondary Cleft Palate Surgery for Management of Velopharyngeal Dysfunction

Background

The secondary palate is composed of a hard (bony) palate anteriorly and a soft palate or “velum” posteriorly. Within the soft palate, the levator veli palatini muscle forms a dynamic sling that elevates the velum toward the posterior pharyngeal wall during the production of certain sounds. Other muscle groups within the velum, the tonsillar pillar region,¹ and pharyngeal walls also impact resonance quality during speech formation (Table 44-2). The combination of the soft palate and pharyngeal wall musculature jointly form what is described as the velopharyngeal (VP) mechanism (Figure 44-5A). The VP mechanism functions as a sphincter valve in order to regulate airflow between the oral and nasal cavities and create a combination of orally based and nasally based sounds.

Children born with a cleft palate have, by definition, a malformation that dramatically impacts the anatomic components of the VP mechanism. Specifically, clefting of the secondary palate causes division of the musculature of the velum into separate muscle bellies with abnormal insertions along the posterior edge of the hard palate (Figure 44-5B). The initial palatoplasty is not carried out simply for closure of the palatal defect (oronasal communication) itself, but is aimed also at addressing these underlying anatomic discrepancies involving the musculature. During surgery for palatal closure, care must be taken to sharply separate the muscles off of the palatal shelves, realign them, and establish continuity in order to create

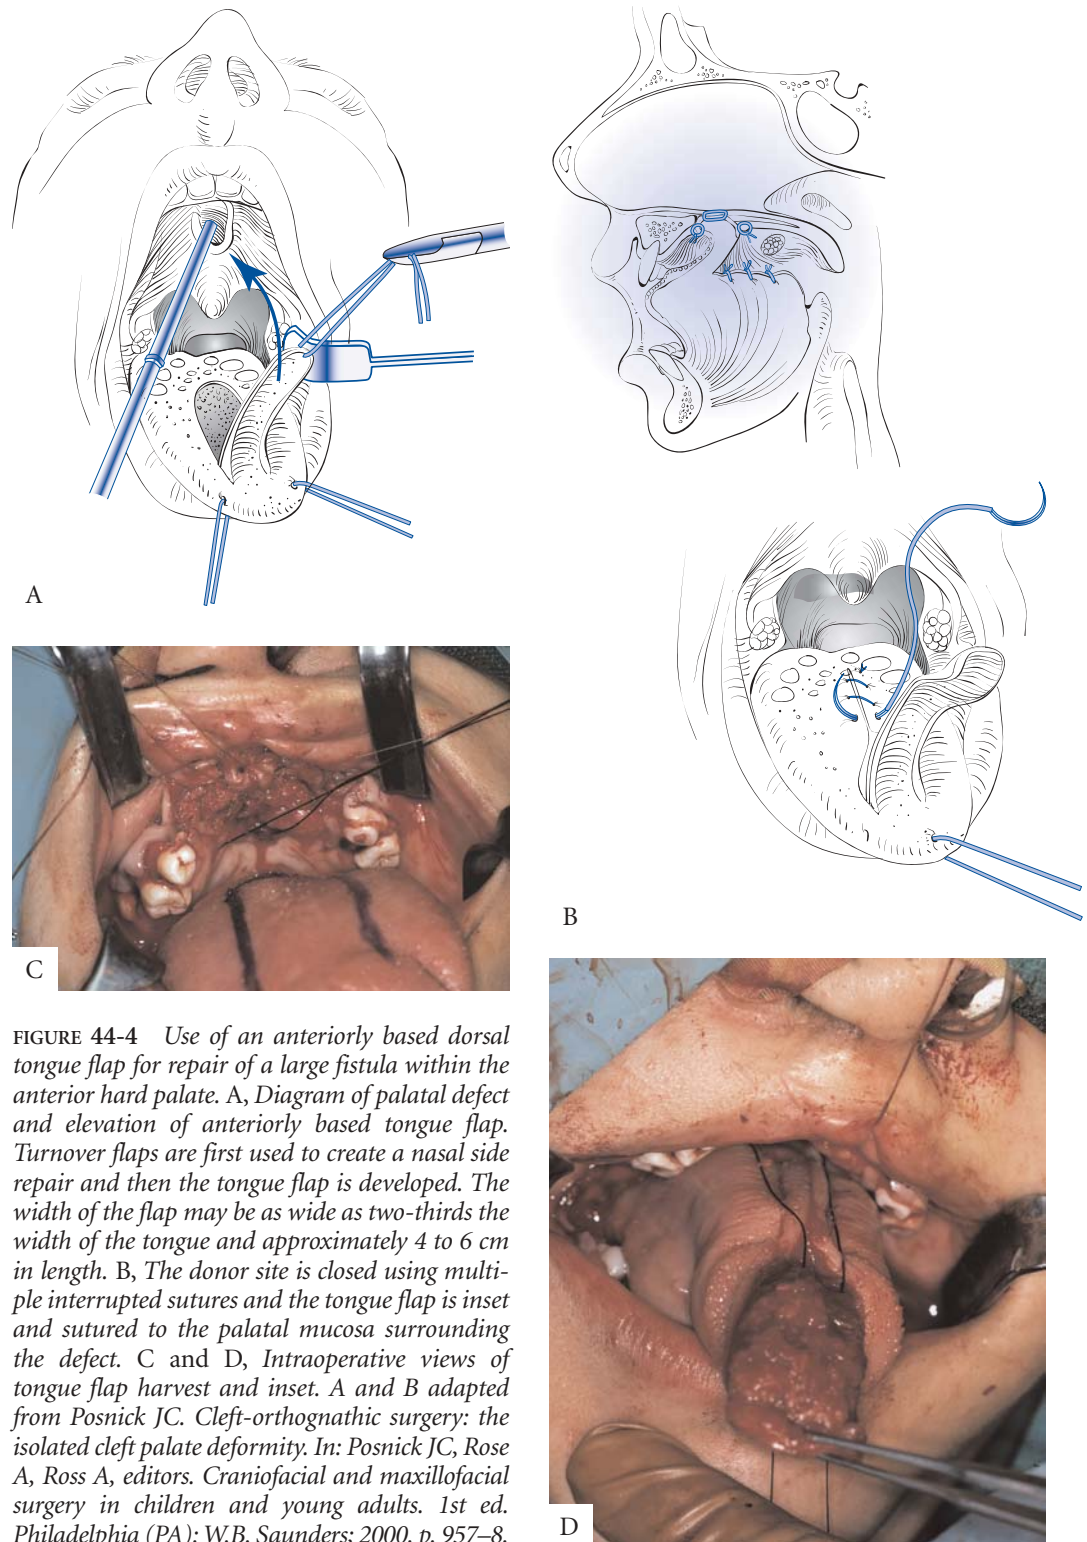

FIGURE 44-4 Use of an anteriorly based dorsal tongue flap for repair of a large fistula within the anterior hard palate. A, Diagram of palatal defect and elevation of anteriorly based tongue flap. Turnover flaps are first used to create a nasal side repair and then the tongue flap is developed. The width of the flap may be as wide as two-thirds the width of the tongue and approximately 4 to 6 cm in length. B, The donor site is closed using multiple interrupted sutures and the tongue flap is inset and sutured to the palatal mucosa surrounding the defect. C and D, Intraoperative views of tongue flap harvest and inset. A and B adapted from Posnick JC. Cleft-orthognathic surgery: the isolated cleft palate deformity. In: Posnick JC, Rose A, Ross A, editors. *Craniofacial and maxillofacial surgery in children and young adults*. 1st ed. Philadelphia (PA): W.B. Saunders; 2000. p. 957–8.

a functional palatal-levator muscle sling. Some describe this primary repair of the palatal musculature as “intravelar veloplasty,” a component of the cleft palate closure. Although this description helps to

articulate the importance of addressing the levator muscle, it may confuse some clinicians by suggesting that muscle repair or intravelar veloplasty is a separate procedure. Irrespective of the type of cleft palate

Table 44-2 Muscle Groups Contributing to the Velopharyngeal Mechanism

Muscle	Insertion	Origin	Function
Uvulus muscle	Mucous membrane of soft palate	Palatal aponeurosis	Velar extension
Tensor veli palatini	Soft and hard palates	Medial pterygoid plate	Opens auditory tube
Salpingopharyngeous	Palatopharyngeal aponeurosis	Torus tubarius	Motion of the lateral walls
Superior constrictor	Medial pharyngeal raphe	Velum; medial pterygoid plate	Posterior and lateral wall sphinctering
Levator veli palatini	Soft palate	Temporal bone	Elevation of the velum
Palatopharyngeous	Soft palate aponeurosis	Pharyngeal wall	Adduction of posterior pillars; sphinctering of velum
Palatoglossus	Tongue	Soft palate	Retracts tongue; antagonistic to the levator during speech

repair technique employed (von Langenbeck, Bardach, Furlow, etc), meticulous release of abnormal muscle insertions and velar muscle reconstruction must be incorporated as a critical element of the surgical procedure.

Most children who undergo successful cleft palate repair during infancy (9 to 18 months) will go on to develop speech that is normal or to demonstrate minor speech abnormalities that are amenable to treatment with speech therapy. In a smaller segment of this patient population, however, the velopharyngeal mechanism

will not demonstrate normal function despite surgical closure of the palate.²⁵ “Velopharyngeal insufficiency” (VPI) is defined as inadequate closure of the nasopharyngeal airway port during speech production. The exact etiology of VPI following successful cleft palate repair is a complex problem that remains difficult to completely define. Inadequate surgical repair of the musculature is one cause of VPI, but even muscles that have been appropriately realigned and reconstituted may fail to heal normally or function properly because of congenital defects with

their innervation. The role of postsurgical scarring and its impact on muscle function and palatal motion is poorly understood. When using a Furlow double opposing Z-plasty procedure for the initial palate repair, the theoretical advantages include better realignment of the palatal muscles and lengthening of the soft palate, but these benefits may be negatively balanced by a velum that demonstrates less motion or elevation owing to the additional scarring associated with two separate sets of Z-plasty incisions. In addition, it must be considered that the repaired cleft palate is

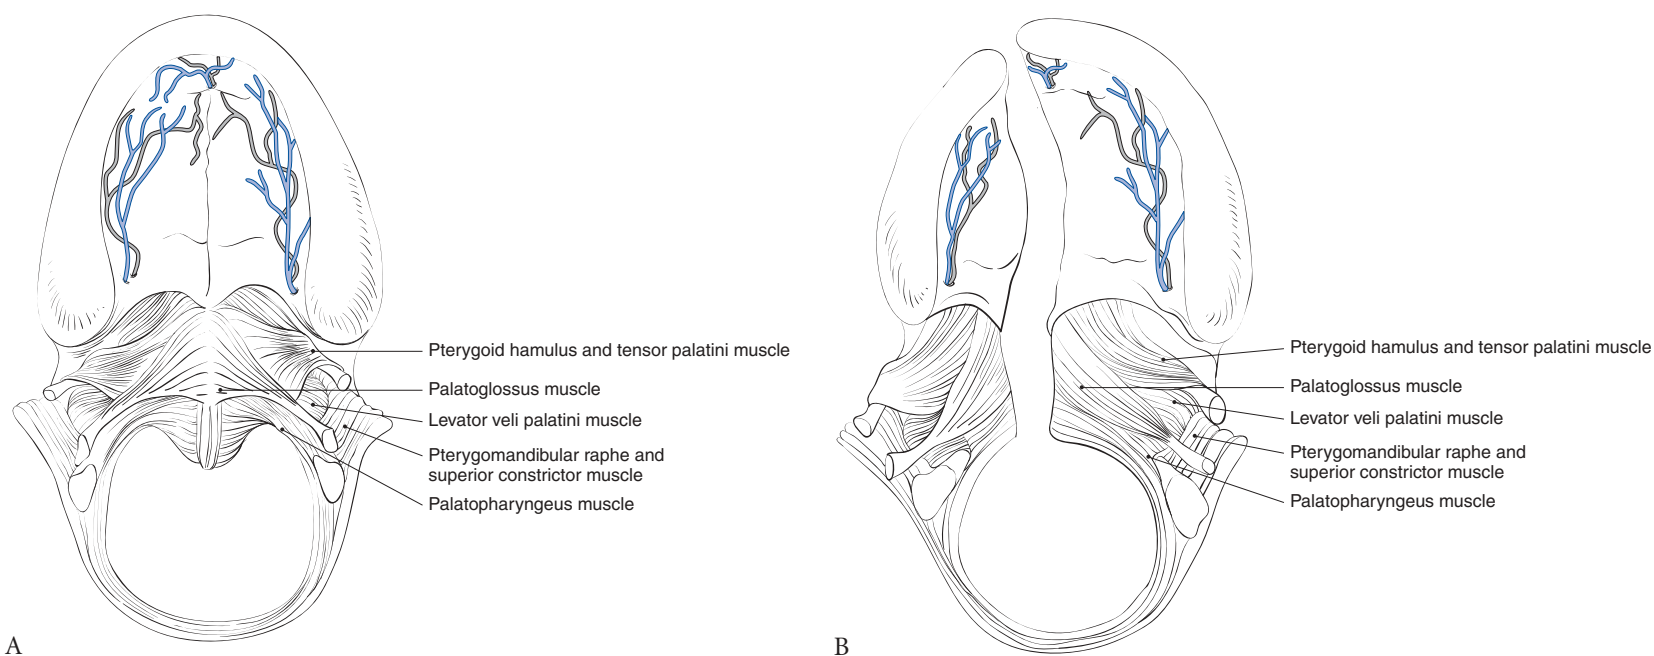

FIGURE 44-5 Anatomy of the velopharyngeal mechanism. A, Normal anatomy. B, Anatomic distortions associated with complete cleft of the primary and secondary palate. Note abnormal insertions of levator veli palatini muscle along the posterior edge of the hard palate.

only one factor contributing to VP function, and other abnormalities related to oropharyngeal morphology, lateral and posterior pharyngeal wall motion, and nasal airway dynamics may all contribute to VP dysfunction. Certainly, these other structures may also play a role in compensating for the palatal deformity. For example, a short, scarred soft palate that does not elevate very well may be compensated for by the recruitment and hypertrophy of muscular tissue within the posterior pharyngeal wall (“activation of Passavant’s ridge”).^{26–28}

The audible nasal air escape with resultant hypernasal speech that is associated with VPI is perhaps the most debilitating consequence of the cleft palate malformation. Approximately 20% of children with VPI following palatoplasty will go on to require management involving additional palatal surgery.²⁵ Left untreated, nasal air escape-related resonance problems will lead to other speech abnormalities, namely, abnormal compensatory articulations. Warren’s elegant aerodynamic demands theory provides the best explanation of what occurs with severe VPI.²⁹ His theory states that nasal air escape owing to inadequate VP closure will cause the patient to articulate pressure consonants at the level of the larynx or pharynx instead of within the oral cavity. These abnormal, compensatory, misarticulations further complicate problems with speech formation and decrease speech intelligibility in patients with cleft palate-related VPI.

Indications for Surgery and Timing

Following the initial cleft palate repair, periodic evaluations are critical in order to assess the speech and language development of each child. Typically, this involves a standardized screening examination performed by a speech and language pathologist as part of an annual visit to the cleft palate team. In patients with speech problems such as VPI, more detailed studies including the use of

videofluoroscopy and nasopharyngoscopy may be indicated. Videofluoroscopy studies are used to radiographically examine the upper airway with the aid of an oral contrast material. These techniques allow dynamic testing of the VP mechanism with views of the musculature in action. In addition, details of the upper airway anatomy including residual palatal fistulas can be visualized and their contribution to speech dysfunction evaluated during the study. For a videofluoroscopy study to be of diagnostic value, it must include multiple views of the VP mechanism and a speech pathologist must be present in order to administer verbal testing in the radiology suite. Nasopharyngoscopy using a small, flexible, fiber-optic endoscope is routinely used for the evaluation of patients with VPI. Nasopharyngoscopy allows for direct visualization of the upper airway and specifically the VP mechanism from the nasopharynx. This technique avoids the radiation exposure associated with videofluoroscopy but requires preparation of the nose with a topical anesthetic, skillful maneuvering of the scope, and a compliant patient. Once the endoscope is inserted, observations of palatal function, airway morphology, and pharyngeal wall motion are made while the patient is verbally tested by the speech pathologist.⁵ The opportunity for direct visualization of the VP mechanism in action during speech formation provides information that is critical to clinical decision-making related to secondary palatal surgery in cases of confirmed or suspected VPI.

Secondary palatal surgery in young children is indicated when VPI causes hypernasal speech on a consistent basis and is related to the anatomical problem.^{30–32} The exact timing of surgery for VPI remains controversial, however, with recommendations ranging from 2.5 to 5 years of age. In children 2.5 to 4 years of age, obtaining enough diagnostic information to make a definitive decision regarding treatment is often difficult. In such a young age group, variables such as the

child’s language and articulation development and a lack of compliance during the speech evaluation compromise the diagnostic accuracy of preoperative assessments.^{33–35} By the time a child reaches 5 years of age, compliance with nasopharyngoscopy is better, and there is enough language development to allow for a more thorough perceptual speech evaluation. These factors allow for more definitive conclusions regarding the status of VP function or dysfunction in the child with a repaired cleft palate. One final salient point is that decisions regarding the advisability of surgery for VPI must be made only through close collaboration with an experienced speech and language pathologist. The decision to go forward with additional surgery for VPI simply is not an isolated surgical judgment.

The problem of VPI with hypernasal speech may also be encountered later in life in patients that require orthognathic surgery for correction of cleft-related maxillary deficiency. As discussed in Chapter 61, “Orthognathic Surgery in the Patient with Cleft Palate,” approximately 25% of patients who have undergone cleft palate repair during infancy will require additional surgery for correction of midfacial deficiency during adolescence when they are nearing skeletal maturity.³⁶ This usually involves midfacial advancement at the Le Fort I level with or without mandibular surgery in order to normalize skeletal position, correct malocclusion, and improve facial form. Large advancements of the maxilla in patients with a repaired cleft palate may worsen preexisting VPI or may be the cause of new-onset VPI.^{37–39} A minority of patients with borderline VP closure preoperatively will develop hypernasal speech even after relatively small degrees of maxillary forward displacement. Since predicting exactly how each patient will respond to maxillary advancement is difficult, formal speech assessment and detailed counseling of the patient and family regarding the possibility of developing postoperative VPI is recommended prior to

undertaking any cleft orthognathic surgery involving maxillary advancement. Fortunately, most patients who develop VPI following maxillary advancement will recover adequate VP closure without the need for additional palatal surgery. In a study by Turvey and Frost, pressure-flow studies were used to examine VP function after maxillary advancement in patients with repaired cleft palate.⁴⁰ In their study group of patients with adequate VP closure before surgery, the VP apparatus demonstrated three different responses following midfacial advancement: (1) adequate VP closure after surgery, (2) deterioration with inadequate VP function after surgery followed by a gradual improvement and recovery of normal closure over a 6-month period, and (3) inadequate VP closure after surgery without improvement necessitating pharyngeal flap surgery. When maxillary advancement does result in clinically significant VPI, additional corrective surgery should be delayed at least 6 months. In most cases, postoperative neuromuscular adaptation allows the VP mechanism to recover, and the patient returns to a baseline level of function with resolution of hypernasal speech without the need for additional operative intervention.

Operative Techniques

Contemporary surgical management of VPI generally involves the use of either of two types of procedures: (1) the superiorly based pharyngeal flap, and (2) the sphincter pharyngoplasty. The use of autogenous and alloplastic implants for augmentation of the posterior pharyngeal wall has been described, but is not a commonly used procedure. More recently, some surgeons have advocated the use of a second palatoplasty operation as an attempt at palatal lengthening in the patient with VPI; however, limited data exist to support this as a preferred technique.

The superiorly based pharyngeal flap remains the standard approach for surgical management of VPI after palate repair.

The procedure was initially described by Schoenborn in 1876.⁴¹⁻⁴³ Surgical maneuvers are directed at recruiting tissue by developing a superiorly based soft tissue flap from the posterior pharyngeal wall (Figure 44-6). The soft palate is then divided along midsagittal plane from the junction of the hard and soft palate to the uvula and the flap from the posterior pharyngeal wall is inset within the nasal layer of the soft palate. As a result, a large nasopharyngeal opening which cannot be completely closed by the patient's VP mechanism is converted into two (right and left) lateral pharyngeal ports. Closure of these ports is easier for the patient to accomplish as long as adequate lateral pharyngeal wall motion is present. When randomly applied to patients with VPI, the superiorly based pharyngeal flap procedure is effective 80% of the time.⁴⁴ When the flap is applied using careful preoperative objective evaluations, success rates as high as 95 to 97% have been reported.^{45,46} Shprintzen and colleagues have advocated custom tailoring of the pharyngeal flap width and position based on the particular characteristics of each patient as seen on nasopharyngoscopy.^{44,47} The high overall success rate and the flexibility to design the dimensions and position of the flap itself are advantages of the superiorly based pharyngeal flap procedure. The disadvantages of the pharyngeal flap procedure are primarily related to the possibility of severe nasal obstruction resulting in mucous trapping and postoperative obstructive sleep apnea.

Inferiorly based pharyngeal flaps for management of VPI are rarely used. Previous reports have documented increased morbidity without better speech outcomes associated with inferiorly based flaps.⁴⁸ In addition, inferiorly based flaps tend to cause downward pull on the soft palate following healing and contracture of the flap. The result may be a tethered palate with decreased ability to elevate during the formation of speech sounds.

The dynamic sphincter pharyngoplasty is another option for the surgical management of VPI. This procedure was described by Hynes in 1951 and modified by several other authors.⁴⁹⁻⁵⁴ The operative procedure involves the creation of two superiorly based myomucosal flaps created within each posterior tonsillar pillar (Figure 44-7). Each flap is elevated with care taken to include as much of the palatopharyngeal muscle as possible. The flaps are then attached and inset within a horizontal incision made high on the posterior pharyngeal wall. The goal of this procedure is the creation of a single nasopharyngeal port (instead of the two ports of the superiorly based pharyngeal flap) that has a contractile ridge posteriorly to improve VP valve function. The main advantage of the sphincter pharyngoplasty over the superiorly based flap is a lower rate of complications related to nasal airway obstruction as described above.⁵⁵⁻⁵⁷ Despite this advantage, there is no evidence that pharyngoplasty procedures achieve superior outcomes in the resolution of VPI. Also, the use of a sphincter pharyngoplasty technique may be associated with increased scarring along the tonsillar pillar region.

In the past, augmentation of the posterior pharyngeal wall has been attempted in order to facilitate closure of the nasal airway. Various autogenous and alloplastic materials have been used including local tissue, rib cartilage, injections of Teflon, silicon, Silastic, Proplast, and collagen.^{58,59} Improvement in speech after augmentation of the posterior pharyngeal wall is unpredictable. Problems with migration or extrusion of the implanted material and an increased rate of infection added to the problems with these techniques. For these reasons, pharyngeal wall implants are rarely used.

Some surgeons advocate the use of a revisional palatoplasty instead of a pharyngeal flap or pharyngoplasty procedure in the management of patients with VPI after

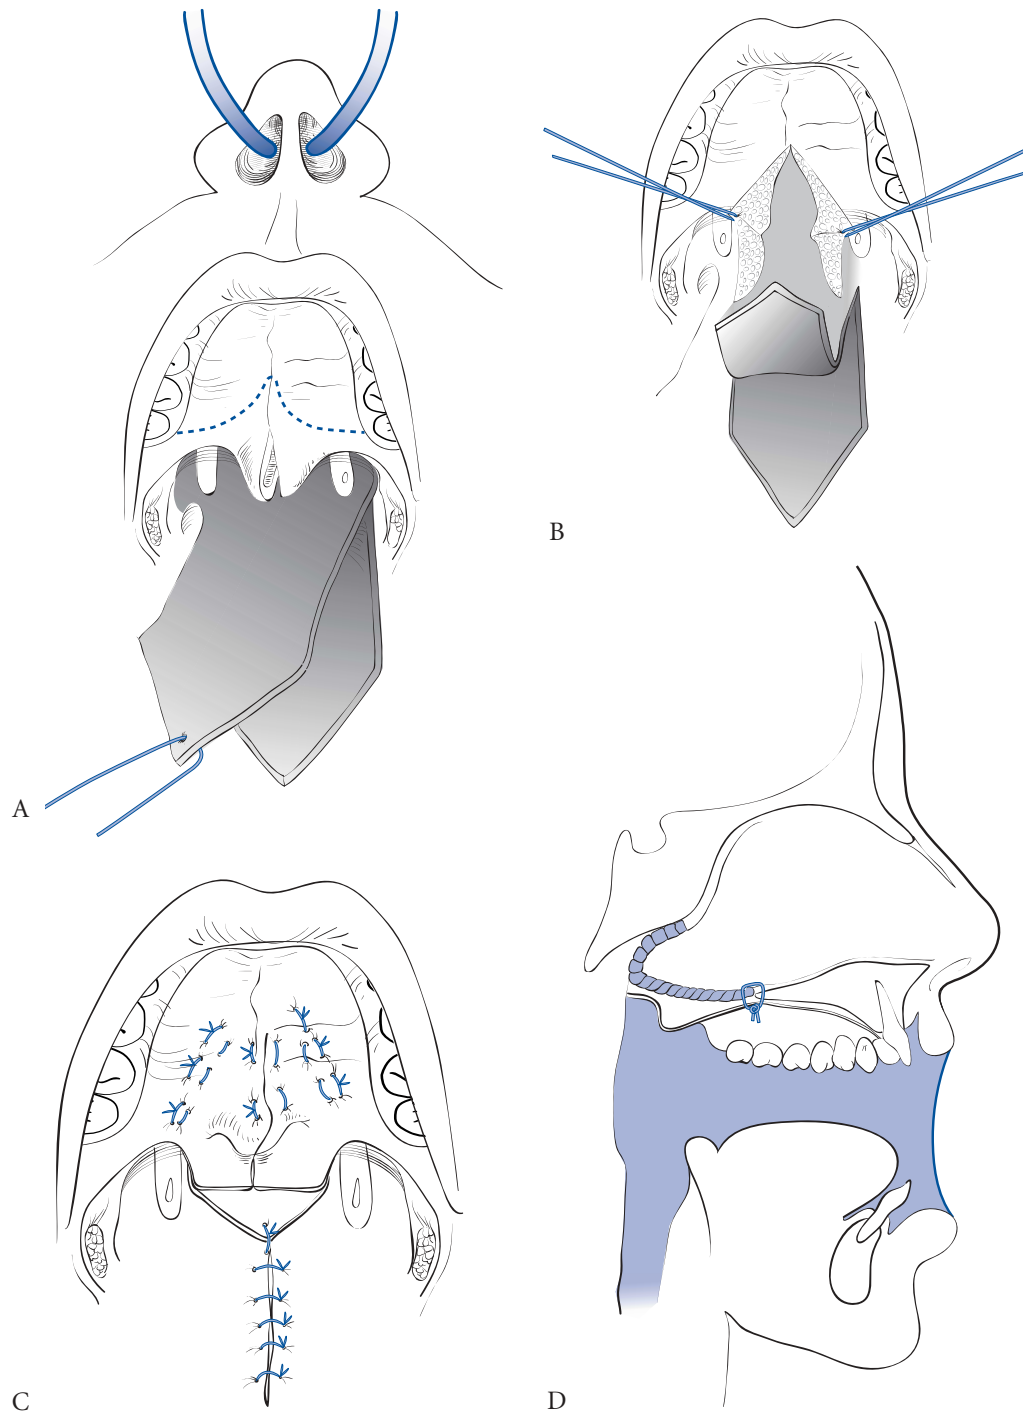

FIGURE 44-6 Illustration of superiorly based pharyngeal flap operative procedure. A, Creation of superiorly based flap of posterior pharyngeal wall soft tissues. The pharyngeal flap is developed and elevated off of the prevertebral fascia. Soft palate is divided with a midline incision from the uvula to the junction of the hard and soft palates. B, Soft palate oral, nasal, and muscle layer dissection in preparation for flap inset. Nasopharyngeal airways are placed in order to help size each lateral pharyngeal port. C, The flap is sutured into the nasal side of the soft palate before the nasal side is repaired and the oral mucosa and underlying musculature are repaired. D, Sagittal view demonstrating appropriate vertical level of flap inset.

cleft palate repair in infancy.⁶⁰ Specifically, a Furlow double opposing Z-plasty palatoplasty is carried out in order to lengthen

the soft palate and facilitate VP closure. Unfortunately, the anticipated benefits of these second palatoplasties have never been

established. The clinician also must consider the disadvantages of this type of surgical procedure and weigh them against potential benefits. The double opposing Z-plasty procedure requires a more aggressive dismantling of the palate than what is required during a conventional pharyngeal flap procedure. The result may be a slightly longer palate, but one with more extensive scarring and less physiologic movement. Another consideration is the significantly higher rate of fistula formation associated with this type of repair.

Complications Related to Surgical Procedures for VPI

Surgery involving airway structures is always associated with the potential for complications related to postoperative hemorrhage and edema. As a result, patients who undergo attachment of a pharyngeal flap require admission to the surgical intensive care unit with continuous airway monitoring during the first 24 hours following surgery. This type of setting permits the rapid recognition and prompt management of complications that may result in airway compromise. Of all the procedures related to cleft care, the pharyngeal flap and sphincteroplasty operations carry the greatest risk for early airway compromise. Airway loss and compromise are not common but require immediate management when they are encountered in order to avoid life-threatening consequences.

Long-term postoperative complications related to the superiorly based pharyngeal flap are frequently associated with problems related to increased airway resistance. Insertion of a pharyngeal flap will decrease the size of the nasopharyngeal airway, facilitate VP closure, decrease nasal air escape, and make speech more intelligible. At the same time, however, the procedure may create a pathologic level of upper airway obstruction that leads to new problems. In several cases, patients who have undergone pharyngeal flap surgery

FIGURE 44-7 Sphincteroplasty procedure. A, Incision of the posterior pharyngeal wall and the posterior tonsillar pillars. B, Elevation of bilateral myomucosal flaps within the tonsillar pillars. Care is taken to include palatopharyngeous muscle. C, The mobilized flaps are then sutured to each other at the midline. D, Closure is then achieved by inseting the joined flaps within the posterior pharyngeal wall incision. The donor site of each flap is also closed with interrupted sutures.

start snoring. Snoring itself does not represent any significant pathophysiology but may concern parents or significant others who observe the patient during sleep. When the degree of upper airway resistance is more severe, the result may be postoperative obstructive sleep apnea (OSA). OSA is a cessation of breathing during sleep secondary to upper airway

obstruction that disrupts the sleep cycle, compromises effective oxygenation, and may cause behavioral changes and daytime somnolence in affected individuals. Left untreated, OSA is associated with severe cardiac and pulmonary consequences. When OSA is suspected in a child who has previously undergone a pharyngeal flap procedure, a formal work-up

including nasopharyngoscopy and sleep study (polysomnography) is indicated. Care should be taken to evaluate the entire airway in order to determine the level of the obstruction. Surgeons may initially assume that the airway obstruction is related to the flap only to discover that a more severe problem exists somewhere else in the upper airway tract. Often, a thorough clinical evaluation yields abnormal findings that contribute to the problem of OSA at multiple levels of the upper airway. Because of the complexity of these clinical problems, the decision to modify or take down a pharyngeal flap in a child with OSA must be made only after discussions between the surgeon, airway expert (eg, pediatric otolaryngologist or pediatric pulmonologist), and speech and language pathologist. Interestingly, many patients who have had pharyngeal flap placement during their childhood will tolerate surgical division of the flap without a recurrence of severe VPI or hypernasal speech. On the rare occasion when VPI does recur following flap take-down, interval treatment with a prosthetic device such as a palatal lift appliance for at least 6 months should be considered prior to embarking on any further airway surgery.

Management of the Submucous Cleft Palate

A submucous cleft palate is another form of the congenital cleft palate malformation in which the overlying mucosal layer is intact, but the underlying soft palate musculature is divided. As described by Calnan, the classic clinical findings with a submucous cleft palate are a triad of bifid uvula, hard palate bony notch, and separation along the median raphe of the soft palate especially during elevation of the velum.⁶¹

When a submucous cleft palate is present, the levator muscle is clefted and abnormally inserts into the posterior edge of the hard palate. The primary functional concern related to submucous cleft palate is

the possibility that the patient will develop VPI and resultant hypernasal speech as encountered in other cleft palate patients. Despite this concern, the majority of patients with a submucous cleft palate will not require surgical intervention. In fact, 44% of patients will actually remain completely asymptomatic until childhood.⁶²

As described above, the bifid uvula is often the most easily detected feature of the submucous cleft palate triad of clinical findings. However, a bifid uvula may also be observed in the absence of any other features of submucous clefting (eg, notched hard palate, velar separation, hypernasality). In fact, the incidence of bifid uvula is approximately 1:80 while the incidence of submucous cleft palate is 1:280.⁶³ Previous investigation has suggested a connection between the isolated finding of a bifid uvula and VP dysfunction when otherwise asymptomatic patients were evaluated using a nasopharyngoscopic protocol.⁶⁴ As a result, the clinical finding of an isolated bifid uvula may be considered an indicator of increased risk for VPI in a patient who is to undergo adenoidectomy. This underscores the value of a thorough clinical examination before any of these surgical procedures are undertaken and the importance of presurgical speech evaluation and family counseling regarding the potential risks of postsurgical VPI.

A certain proportion of children will present with an occult submucous cleft palate. The occult submucous cleft palate does not have any of the classic triad of physical findings. In most cases, the reason for consultation is VPI-related speech difficulties that have been noted during childhood speech development or that have arisen following a surgical intervention (eg, adenoidectomy). In our experience, the proportion of children with occult submucous cleft palate approaches 10% and preoperative diagnosis is often difficult. Prior reports have attempted to describe characteristic facial features, cephalometric findings, and voice studies

that can assist in the presumptive diagnosis of submucous cleft palate.⁶⁵

The vast majority of patients with a submucous cleft palate will require either no treatment or speech therapy only. Surgical intervention is not undertaken simply because the diagnosis of submucous cleft palate has been made. The speech of these individuals is closely monitored during childhood with interval speech evaluations, and surgery is reserved for only those cases where VPI is diagnosed and not amenable to speech therapy. The type of specific surgical procedure used to manage submucous cleft-related VPI varies depending on the preference of the surgeon and speech pathologist. Several early procedures emphasized exploration of the soft palate through a limited midline incision with repair of the levator muscle. Contemporary methods primarily involve the use of a standard palatoplasty (two-flap, push-back, or Furlow) and repair of the velar musculature, with or without a simultaneous pharyngeal flap procedure.

Bone Graft Reconstruction of the Cleft Maxilla and Palate

Approximately 75% of all orofacial clefts will involve the maxilla.⁵ Despite successful lip repair and closure of the hard and soft palate during infancy, a residual nasolabial fistula and bony cleft defect that involves the alveolar ridge, maxilla, and piriform rim will remain. These residual deformities are addressed by secondary bone grafting performed during middle childhood (6 to 9 years of age). The objectives of bone graft reconstruction of the cleft maxilla are to establish adequate bony matrix for eruption of the permanent cuspid tooth, close any residual alveolar fistula communication, establish bony continuity of the maxillary ridge, and improve the underlying bony support of the nasal base. In the case of bilateral cleft lip and palate, an added benefit of bone graft reconstruction is the stabilization of the previously mobile premaxilla segment.

The details of bone graft reconstruction of the cleft maxilla are discussed in greater detail in Chapter 43, "Reconstruction of the Alveolar Cleft."

Orthognathic Surgery for Correction of Midfacial Deficiency

Patients who have undergone cleft palate repair during infancy will often exhibit some degree of maxillary growth restriction. This disproportionate jaw growth is the biological consequence of prior surgical intervention and is not related to the congenital cleft deformity. Previous authors have reported a 25% incidence of maxillary hypoplasia that is severe enough to produce a clinically significant dentofacial deformity with negative effects on speech and occlusion.^{5,6,17,36} The successful correction of these secondary skeletal deformities frequently requires treatment protocols that include orthognathic surgery in conjunction with the final phase of orthodontic treatment. Simultaneous bone grafting is used for contouring the dysmorphic skeletal structures. The use of orthognathic techniques to correct residual skeletal problems in the patient with cleft lip and palate is discussed in greater detail in Chapter 61, "Orthognathic Surgery in the Patient with Cleft Palate."

Revisional Surgery for Cleft Lip and Nasal Deformities

Reconstruction of the Cleft Nasal Deformity

Congenital clefts that involve the lip, nose, and underlying skeletal structure will cause a complex three-dimensional deformity of the nasal complex that affects both form and function.^{66,67} In the case of a complete unilateral cleft, the typical nasal deformity is characterized by splaying of the alar base, inferior displacement of the alar rim, deviation of the nasal tip, and irregularity of the caudal nasal septum. Abnormal fibrous insertions exist between the lateral crus of the lower lateral cartilage and the lateral

piriform rim on the cleft side. At the time of the initial lip repair procedure, maneuvers for primary nasal reconstruction include dissection along the lower lateral cartilage in order to separate the overlying skin from the cartilage and sharp release of the fibrous insertions along the piriform rim so that the nostril can be repositioned appropriately. Despite effective primary cleft lip and nasal repair during infancy, most patients will demonstrate enough residual nasal dysmorphology that secondary nasal surgery for correction of the cleft-associated malformation or improvement in nasal airflow will be required later in life.

The timing of cleft nasal revisional surgery also remains controversial. Some surgeons take a more aggressive approach and undertake extensive nasal reconstruction during early childhood. Our philosophy is to delay the definitive cleft rhinoplasty until the nasal complex is close to mature size. If the patient's reconstructive treatment plan also requires maxillary advancement, then nasal surgery should be delayed until approximately 6 months following the orthognathic procedure. This allows for a more predictable outcome and long-lasting improvement in nasal function and facial esthetics. Early surgery is reserved for individuals with severe airway or nasal airflow problems or children that have the potential to experience psychosocial consequences such as teasing at school. When possible, early nasal surgery should be timed after the bone graft reconstruction of the maxilla so that a stable bony foundation along the piriform rim and nasal base exists first.

Secondary cleft-nasal reconstruction will often require dorsal reduction, lower lateral cartilage sculpting, cartilage grafting, and nasal osteotomies. Cartilage grafting is a critical component of the final nasal reconstruction and is used for augmentation of the dysmorphic lower lateral cartilage and improvement of nasal tip projection^{5,68,69} (T.J. Tejera, DMD, MD,

personal communication, November 2003). Several different donor sites may be used including auricular cartilage, nasal septum, and rib cartilage. Ear cartilage is most useful in situations where augmentation of hypoplastic cleft-side lower lateral cartilage is required. Septal cartilage is most easily accessible and provides an excellent scaffold for repositioning of the lower lateral cartilages and improvement of nasal tip symmetry and projection. Unfortunately, patients may present for definitive nasal reconstruction having undergone previous septal cartilage harvest and not have sufficient quantity for a second septal cartilage graft. In these cases, the use of costochondral cartilage is another excellent option. Rib cartilage provides adequate amounts of graft material, but requires a distant donor surgical site. We have found this type of cartilage graft to provide excellent strength for straightening the nasal tip and alar complex. These techniques are best carried out through an open rhinoplasty approach.⁵ A transcolumellar splitting incision is combined with marginal incisions in order to provide wide access and direct visualization of the nasal dorsum, upper and lower lateral cartilages, and nasal septum.

A similar rationale is applied when considering the timing of secondary nasal reconstruction in the bilateral cleft lip patient, but the specific dysmorphology addressed is somewhat different. Generally, nasal asymmetry is less problematic, and the dysmorphology is characterized by deficient columellar length. Previous literature has focused on the secondary lengthening of the columella through the use of banked forked flaps or columellar lengthening using soft tissue flaps from the floor of the nose and alar flaps.^{70,71} Unfortunately, these types of surgical procedures often result in a distorted columellar-labial angle, excessive "railroad" scars that extend onto the nasal tip, and additional distortion of the broad nasal tip. We find that the approach described by Posnick

using septal cartilage strut grafts attached to the caudal nasal septum and lower lateral cartilages yields the most natural-looking results.^{5,6} The objective is correction of the underlying cartilaginous anatomy with stretching of the overlying soft tissue envelope, instead of direct surgical manipulation of the columellar skin.

Secondary Surgery for Cleft Lip Scar Revision

Even when the initial cleft lip repair procedure is considered to be successful, the vast majority of children will go on to require an additional operation for lip revision at some point in their lifetime.^{4,72} Although revisional procedures are often viewed as optional phases of cleft lip reconstruction, surgeons must advise families of this likelihood.

As a child grows, the hard and soft tissues of the maxillofacial complex grow and change, and the repaired lip is affected. Ongoing growth often makes it difficult to predict which children will need additional lip surgery. A child's lip may initially look satisfactory and over time demonstrate unfavorable changes necessitating revision. On the other hand, favorable changes may occur during the healing process that actually improve the appearance of the repaired cleft lip. At approximately 8 to 10 weeks following surgery, significant lip contracture may be seen during the fibroblastic phase of healing. The result is vertical shortening of the repaired cleft side that will seemingly require further surgery. If the same child is reevaluated 6 months later, after additional wound maturation, they may demonstrate perfectly acceptable lip esthetics and not be considered a candidate for revision.

Ideally, only one lip scar revision is undertaken, when the child is between the ages of 5 and 15 years. The procedure is staged for as late in childhood as possible. When a severe deformity persists or psychosocial concerns exist, lip revision may be carried out earlier in life before the child becomes school aged.

The surgical objectives of cleft lip revision include excision of residual scar, reapproximation of key anatomic landmarks such as the vermilion-cutaneous junction and vermilion-mucosal junction, and leveling of vertical lip lengths (philtral columns). Critical to an acceptable outcome is the meticulous repair of the orbicularis oris muscle as a distinct layer. The cleft surgeon must dissect and repair all layers (skin or vermilion, muscle, oral mucosa) in order to establish improved lip form and normalize lip function and animation (Figure 44-8). Often this requires complete take-down of the lip and recreation of a full-thickness defect.

Comprehensive Dental and Prosthetic Rehabilitation

In patients with a cleft of the primary palate (maxilla and alveolus), three possibilities exist with regard to the status of the permanent lateral incisor: (1) the lateral is present and erupts normally, (2) the lateral is congenitally missing, or (3) the lateral is present, but is dysmorphic and not a restorable tooth. When the lateral incisor is this dysmorphic, extraction is usually

required prior to or at the time of bone graft reconstruction.

In those cases where a lateral incisor is not present, management of the residual dental gap will eventually be required. Treatment options include the placement of a three-unit fixed prosthesis, replacement of the missing tooth with an endosseous dental implant, or orthodontic substitution of the ipsilateral cuspid tooth for the lateral incisor.

In contemporary practice, the use of a three-unit bridge for replacement of a congenitally missing incisor is generally avoided, especially in young patients. This prosthetic option has several disadvantages: it usually requires preparation of two otherwise perfectly healthy teeth (central and cuspid), hygiene is more difficult around the pontic, and even in the best of circumstances the prosthetic restoration will require replacement several times during the patient's lifetime.

Over the course of the past two decades, the use of titanium dental implants has revolutionized the prosthetic rehabilitation of patients with missing teeth. This technology has also been

applied to patients born with cleft lip and palate (Figure 44-9).⁷³⁻⁷⁵ The use of an implant-supported crown provides a natural-looking restoration with excellent long-term viability and obviates the need for instrumentation of the surrounding teeth. When a dental implant is being considered, pertinent treatment-planning concerns include the maintenance of adequate space for the implant and restoration and the quantity of alveolar bone available for placement of the titanium fixture. Our preferred approach involves the preservation of approximately 7 mm of interdental space in order to allow for placement of a 3.5 mm dental implant. In most patients who have undergone previous successful bone grafting, the vertical dimension of the alveolar ridge seems to be well maintained until the time of implant placement. Facial-palatal width of the ridge, however, may be more problematic, and a significant number of cleft patients may require some additional minor bone grafting approximately 3 to 4 months prior to implant surgery. In most cases, the width of the alveolus can be nicely augmented with bone harvested from the mandibular symphysis or ramus region. Implant placement requires that the patient be at or near skeletal maturity.

Another option for management of the cleft dental gap when the lateral incisor is not present is the use of orthodontic therapy in order to substitute the missing lateral incisor with the ipsilateral cuspid tooth. Interestingly, this maneuver frequently results in very acceptable dental esthetics even if prosthetic modification of the cuspid is not undertaken. Like the use of a dental implant, this treatment option also obviates the need for preparation of the adjacent healthy tooth structure. In most cases, the substitution option also eliminates the need for any prosthetic component at all. Another advantage of this treatment option is that it may be undertaken at a younger age than the other prosthetic options. Limiting factors

FIGURE 44-8 A to C, Unilateral cleft lip revision. Pre- and immediate postoperative photographs of a patient undergoing revision of a unilateral cleft lip. The full-thickness cleft defect is recreated with care taken to reconstitute the orbicularis oris muscle. The hypertrophic scar was excised and anatomic landmarks including the vermilion border, white roll, wet-dry line, and nasal sill are reapproximated.

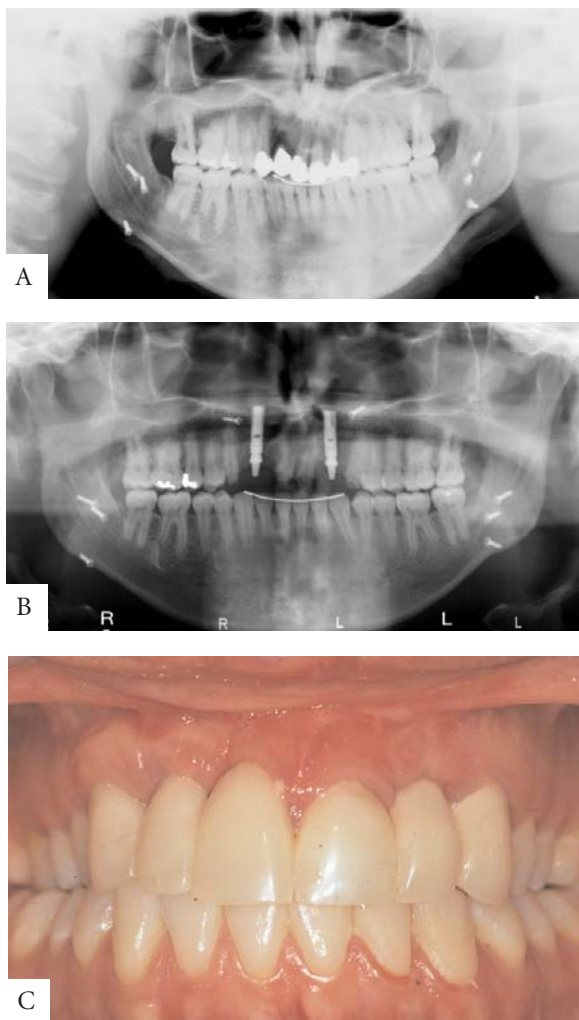

FIGURE 44-9 Prosthetic rehabilitation of a 27-year-old patient with previously unrepaired bilateral maxillary alveolar clefts. She had undergone primary lip and palate repair during infancy but never underwent bone graft reconstruction. Treatment consisted of bone graft reconstruction of the bony clefts using autogenous corticocancellous bone graft obtained from the anterior iliac crest followed by dental implant placement 6 months later. A, Preoperative panoramic radiograph reveals large bilateral bony cleft defects. B, Panoramic radiograph following bone graft reconstruction and implant placement. C, Temporary prosthetic restoration. Implant placement was performed as a single-stage procedure with construction of temporary bilateral three-unit bridges.

related to this option are primarily related to issues of orthodontic anchorage.

Summary

Orofacial clefts are complex malformations that affect the three-dimensional anatomy of the maxillofacial hard and soft tissues and have profound functional and

esthetic consequences. Successful reconstruction of these defects involves multiple stages of surgical intervention. Primary surgery is centered on initial closure of the lip and palatal defects. Secondary surgical procedures are then carried out in order to close residual oronasal communication, address VPI, reconstruct the bony maxillary cleft, normalize maxillary skeletal position and occlusion, improve lip and nasal esthetics and function, and facilitate the dental prosthetic rehabilitation of the patient. Because multiple, separate surgical interventions are carried out during active growth, thoughtful timing of each stage of reconstruction is critical in order to maximize the benefit for the patient and mitigate the potentially negative biologic consequences related to growth. Surgeons must maintain a thorough understanding of the anatomy, the intricacies of the cleft malformation, and the underlying patterns of growth and development of the craniomaxillofacial region.

Nonsyndromic Craniosynostosis

G. E. Ghali, DDS, MD

Douglas P. Sinn, DDS

In its basic form craniosynostosis represents premature suture fusion. It occurs in approximately 1 per 1,000 live births in the United States. Craniosynostosis may be classified as nonsyndromic or syndromic. Most forms of craniosynostosis are isolated and not associated with any other conditions and are therefore nonsyndromic. Syndromic craniosynostosis will be covered in another chapter. The pathogenesis of craniosynostosis is complex and probably multifactorial. Moss theorized that craniosynostosis such as seen in Apert and Crouzon syndromes results from abnormal tensile forces transmitted to the dura from an anomalous cranial base through key ligamentous attachments.¹ This hypothesis fails to explain craniosynostosis in patients with a normal cranial base configuration. The cause of craniosynostosis may be postulated to be the result of either primary suture abnormalities, sufficient extremes of forces that overcome the underlying expansive forces of the brain, inadequate intrinsic growth forces of the brain, or various genetic and environmental factors.² Cranial vault growth achieves approximately 80% of the adult size at birth and definitive size by 2.5 to 3 years of age.³ The existence of the six major sutural regions allows for head expansion as well as transvaginal head deformation.⁴ Recall that posterior fontanelle closure (3–6 mo) generally precedes anterior fontanelle closure (9–12 mo).

Functional Considerations

The major functional problems associated with craniosynostosis are intracranial hypertension, visual impairment, limitation of brain growth, and neuropsychiatric disorders.⁵ In general the functional problems increase as the number of sutures involved increases.⁵ These functional abnormalities are gradual in their development, difficult to detect, and often irreversible in nature.

Intracranial Hypertension

Intracranial hypertension is defined as a pressure of greater than 15 mm Hg. Studies by Marchac and Renier have demonstrated a 13% incidence of intracranial hypertension with single suture stenosis and up to a 42% incidence in multisuture-stenosed children.⁶ The clinical symptoms of intracranial hypertension include headaches, irritability, and difficulty sleeping. The radiographic signs may include cortical thinning or a lückenschädel (hammered metal) appearance of the inner table of the skull; these clinical and radiographic signs are relatively late developments. If intracranial hypertension goes untreated, it affects brain function; if persistent this may necessitate early operative intervention during the first few months of life. Intracranial hypertension most likely affects those with the greatest disparity between brain growth and intracra-

nial capacity and may occur in as many as 42% of untreated children with more than one suture affected. Currently intracranial volume is measured using computed tomography (CT) scans, a noninvasive method appropriate for use in children with craniosynostosis. It might be possible to identify individuals who are at a greater risk for developing intracranial hypertension and would benefit the most from early surgery.

Visual Impairment

Intracranial hypertension, if left untreated, may lead to papilledema, typically acute. After chronic intracranial hypertension, eventually optic atrophy develops, which results in complete or partial blindness. Some forms of craniosynostosis may involve orbital hypertelorism and may lead to compromised visual acuity and restricted binocular vision.

Limitation of Brain Growth

Brain volume in the normal child almost triples during the first year of life. By 2 years of age the cranial capacity is four times that at birth. If brain growth is to proceed unhindered, open sutures at the level of the cranial vault and base must spread during phases of rapid growth for marginal ossification.

In craniosynostosis, premature suture fusion is combined with continuing brain growth. Depending on the number and

location of prematurely fused sutures and the timing of closure, the growth potential of the brain may be limited. Surgical intervention can provide suture release and reshaping to restore a more normal intracranial volume. In general this does not completely reverse craniosynostosis, and diminished volume is often the end result.

Neuropsychiatric Disorders

Neuropsychiatric disorders are believed to be secondary to cerebral compression. Disorders range from mild behavioral disturbances to overt mental retardation. Several studies have shown that children with craniosynostosis and associated neuropsychiatric disorders often improve after cranial vault reconstruction.

Diagnosis

One should suspect craniosynostosis in any infant with an abnormal head shape. Definitive diagnosis is based on clinical and radiographic evaluations. The clinical evaluation involves the palpation of the skull for any movement, ridging, and presence of the anterior and posterior fontanelles. Quantitative measurements of the superior orbital rims, relative to the most anterior aspect of the cornea, also may help in planning treatment for superior orbital rim advancements.

The radiographic evaluation of craniosynostosis is used to define quantitatively aberrant anatomy, plan surgical procedures, and, most importantly, provide a means to demonstrate to the parents the difference between stenosed and nonstenosed sutures. Conventional skull radiographs, such as plain skull films and lateral cephalograms, are inexpensive and widely available. The preoperative assessment of patients with suspected or known craniosynostosis is based on these conventional radiographs. Most cases of synostosis can be demonstrated on plain skull films. Normal or patent cranial sutures manifest as a line. The absence of a radiolucent line in the normal anatomic position of a suture may suggest craniosynostosis.

Currently, CT scans provide improved hard tissue imaging. The definition of these elements of the bony facial structures on high-resolution CT images with or without three-dimensional reconstruction is unmatched by other imaging techniques (Figure 45-1). The development of CT scanning, particularly three-dimensional reformatting, and the maturation of readily available means of craniofacial surgery have led to a close dependence on CT scanning for preoperative surgical planning. CT scanning also has been used to document surgical changes in vivo and to follow developments longitudinally.⁷⁻¹⁸

Classification

The classification of craniosynostosis is based on the shape of the skull, which usually reflects the underlying prematurely fused suture or sutures.^{19,20} The major cranial vault sutures that may be involved include the left and right coronal, metopic, sagittal, and lambdoid sutures.

FIGURE 45-1 Computed tomography scan with three-dimensional reconstruction. Patency of metopic and coronal sutures as well as anterior fontanelle; premature fusion of sagittal suture. Reproduced with permission from Ghali GE et al.⁴⁶ p. 3.

Unilateral Coronal Synostosis

Unilateral coronal synostosis results in flatness on the ipsilateral side of the forehead and supraorbital ridge region. The head is inherently asymmetric in shape with a flattened or repositioned forehead on the ipsilateral side, especially when viewed from the top (Figure 45-2). The term for this deformity is “anterior plagiocephaly.” One should rule out infant molding or positional plagiocephaly and congenital torticollis as other possible diagnoses. Premature fusion of the unilateral

FIGURE 45-2 Frontal and superior views. Characteristic right anterior plagiocephaly. Adapted from Ghali GE et al.⁴⁶ p. 4.

coronal suture represents 20% of the isolated or nonsyndromic cases of synostosis in the United States. Characteristic morphologic features occur on the ipsilateral side. The frontal bone is flat, and the supraorbital ridge and lateral orbital rim are recessed (Figure 45-3). The orbit is shallow, and the anterior cranial base is short in the anteroposterior dimension. The root of the nose may be constricted and deviated to the affected side (Figure 45-4). The ipsilateral zygoma and infraorbital rim also may be flat and recessed.

FIGURE 45-3 Superior view. Recessed frontal bone, supraorbital ridge, and lateral orbital rim on patient's right side. Reproduced with permission from Ghali GE et al.⁴⁶ p. 5.

FIGURE 45-4 Frontal view. Nasal bridge and root deviation to the affected (right) side characteristic in plagiocephaly. Reproduced with permission from Ghali GE et al.⁴⁶ p. 5.

Bilateral Coronal Synostosis

Bilateral coronal synostosis is the most common cranial vault suture synostosis pattern associated with Apert and Crouzon syndromes. Bilateral coronal synostosis results in recession of the supraorbital ridges, which causes the overlying eyebrows to sit posterior to the corneas. In addition to the recessed supraorbital bone, the forehead appears to be lower and there is sagittal shortening of the skull (Figure 45-5). The term for this cranial vault deformity is "brachycephaly." The anterior cranial base is short in the anteroposterior dimension and wide transversely. The

FIGURE 45-5 Frontal and superior views. Characteristic brachycephaly. Adapted from Ghali GE et al.⁴⁶ p. 4.

overlying cranial vault is high in the superior-inferior dimension, with anterior bulging of the upper forehead that results from compensatory growth of the patent metopic suture (Figure 45-6). The orbits are also shallow (exorbitism), with the eyes bulging (exophthalmus) and abnormally separated (orbital hypertelorism). Brachycephaly represents 20% of the isolated craniosynostosis cases in the United States and is the most common syndrome-associated synostosis.

Metopic Synostosis

Metopic synostosis usually occurs in isolation and results in a triangular shape to the skull (Figure 45-7). The term for this cranial vault deformity is "trigonocephaly." The associated cranial vault deformity consists of relative hypotelorism, an elevated supraorbital ridge medially, and posterior-inferior recession of the lateral orbital rims and lateral aspect of the supraorbital ridges. Palpation often reveals a prominent midline keel in the region of the metopic suture. (Figure 45-8). The bitemporal width is decreased, which results in an

FIGURE 45-6 Frontal view. High cranial vault and transverse widening characteristic of brachycephaly. Note visible ridging in the bicoronal suture region. Reproduced with permission from Ghali GE et al.⁴⁶ p. 7.

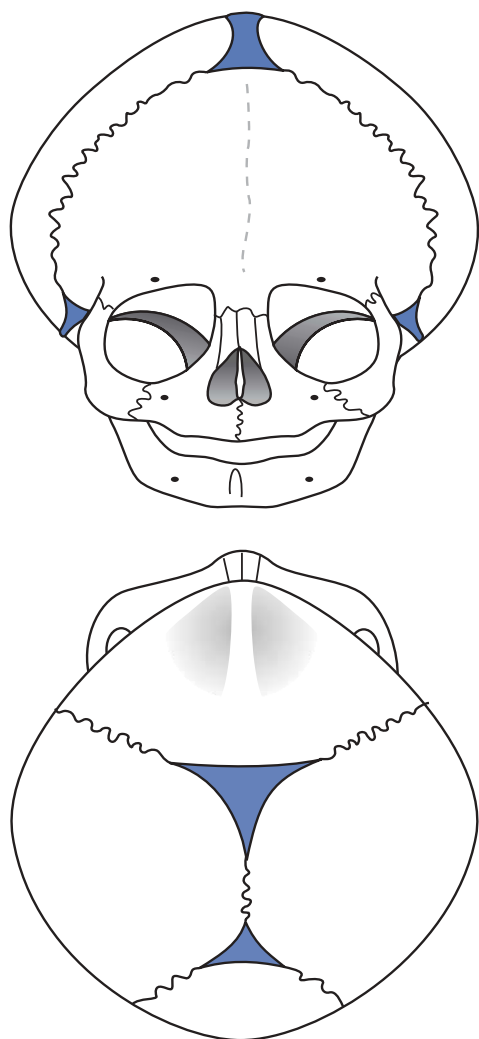

FIGURE 45-7 Frontal and superior views. Characteristic trigonocephaly. Adapted from Ghali GE et al.⁴⁶ p. 8.

FIGURE 45-8 Intraoperative view following shaving of the head demonstrates prominent midline ridging. Reproduced with permission from Ghali GE et al.⁴⁶ p. 9.

abnormal anterior cranial vault shape and decreased anterior cranial vault volume. The overlying forehead is sloped posteriorly to approximately the level of the coronal sutures. Trigonocephaly represents 10% of the nonsyndromic craniosynostosis cases in the United States.

Sagittal Synostosis

Sagittal synostosis, the most common form, is rarely associated with increased intracranial pressure. The skull typically has anteroposterior elongation with a compensatory transverse narrowing (Figure 45-9). The term for this cranial vault deformity is “scaphocephaly.” The deformity consists of an elongated anteroposterior dimension and a narrow transverse dimension to the cranial vault (Figure 45-10). Usually, the midface and anterior cranial vault sutures are not affected. Scaphocephaly represents 50% of all single-suture craniosynostosis cases in the United States.

Unilateral Lambdoid Synostosis

Unilateral lambdoid synostosis results in flatness of the affected ipsilateral parieto-occipital region. The location of the ear canal and external ear are more posterior and inferior on the ipsilateral side compared with the contralateral side. This configuration is more noticeable when the patient is examined from the superior view and is relatively inconspicuous from the frontal or profile views. The term for this cranial vault deformity is “posterior plagiocephaly.” One should rule out infant molding and congenital torticollis (Figure 45-11). With positional (or deformational) plagiocephaly, the ipsilateral ear and forehead are positioned anteriorly, and the ear is not inferiorly displaced as it is with true unilateral lambdoid fusion. The use of head-molding helmet therapy has received renewed interest in the past decade as the preferred treatment of children with positional head shape abnormalities.²¹ The overall incidence of true unilateral lambdoid synostosis is less than 3% of all isolated synostosis cases in the United States.

FIGURE 45-10 Intraoperative view following shaving of the head demonstrates prominent sagittal suture ridging associated with scaphocephaly. Reproduced with permission from Ghali GE et al.⁴⁶ p. 11.

Principles of Management

Multidisciplinary Team Approach

The multidisciplinary team approach was developed in response to the failures that commonly occurred when various aspects of care were not coordinated and when the relationships among coexisting problems were not known.^{3,22} The objectives of this approach are diagnosis, formulation, and execution of treatment plans and longitudinal follow-up for patients with craniofacial deformities; the team should meet at least monthly for regular outpatient evaluations. Transcripts of these evaluations are forwarded with recommendations to primary care providers and appropriate agencies. Children under the age of 5 years are usually evaluated annually, whereas children over 5 years of age are seen every other year. The frequency of evaluation varies with the stability of the deformity and its consequences.

The craniofacial team should consist of a pediatric anesthesiologist, a pediatric ophthalmologist, a surgeon, an audiologist, a maxillofacial prosthodontist, an orthodontist, a psychologist, a geneticist, an otolaryngologist, a pediatrician, social workers, a speech pathologist, and a nurse.^{23–27} All these team members have integral roles at various times in the child's development.^{28,29}

Current Surgical Approach

The goals of craniosynostosis suture release are twofold. The first goal is to allow the brain to grow and expand without restriction. The second goal is to establish a more normal contour to the forehead, supraorbital ridges, and skull.^{30–32} In most cases, an intracranial approach is used for cranial vault and orbital osteotomies, with reshaping and advancement of bony segments for ideal age-appropriate bony morphology. When planning the time and type of surgical

FIGURE 45-11 Frontal (A) and superior (B) views of a child with positional plagiocephaly. Radiographic and clinical examination demonstrated no evidence of craniosynostosis; note asymmetry of external ear position.

intervention, one must consider the functions, future growth, and the development of the craniofacial skeleton and the maintenance of normal body image. Simple craniosynostosis can be managed successfully with frontocranial remodeling.

Although the timing of craniosynostosis repair remains controversial and individualized, we prefer early surgical repair between the ages of 4 and 8 months.^{33–35} Early surgical repair allows for rapid frontal lobe growth, which supports the forehead and supraorbital ridge advancement. At this age, the cranium is highly malleable and therefore easier to contour; a positive effect on facial growth may be achieved and future deformities may be lessened. Also during this period of rapid growth, residual bony defects heal more rapidly. In severe forms of craniosynostosis, additional revision of the cranial vault and orbit is necessary during infancy or early childhood to increase intracranial volume further, which allows for continued brain growth and avoids or reduces the likelihood of intracranial hypertension.

A craniotomy is performed by a pediatric neurosurgeon to remove the deformed section of cranium and provide

access for osteotomies to be performed in the cranial base. The skeletal segments are reshaped and replaced into a new position. Although many of the following examples of surgical repair depict transosseous wiring and titanium plating, the current trend includes the use of resorbable plates and screws. These plates, which are composed of polylactic and polyglycolic acid, are completely resorbed by hydrolysis within 9 to 14 months while maintaining tensile strength for initial stabilization.^{36–38} As a result, growth restrictions are minimized, as is the potential for transcranial migration.

Surgical Considerations

Unilateral Coronal Synostosis

Multiple surgical approaches for the correction of unilateral coronal synostosis (Figures 45-12 and 45-13) have been described.^{39–41} Good long-term results are obtained when treatment of coronal synostosis includes suture release along with cranial vault and orbital osteotomies for reshaping and advancement in infancy. At the Louisiana State University Health Sciences Center in Shreveport, unilateral orbital rim advancement and

FIGURE 45-12 A child with unilateral coronal synostosis resulting in left-sided anterior plagiocephaly. A, Asymmetric forehead and orbit viewed from above. Note marked left supraorbital retrusion and right forehead and cranial vault bulging. B, Bur holes prepared for bifrontal craniotomy at the level of the supraorbital region, allowing a 1 cm fronto-orbital unit (bandeau), which extends into the temporal fossa via tongue-in-groove (tenon) extensions. Note that the degree of extension into the lateral and inferior orbital rims is variable based on esthetics. C, The removed bandeau is contoured bilaterally via removal of wedges from the left orbital roof and scoring the right orbital roof. D, The bandeau is reshaped to achieve symmetry by bending the left side and straightening the right side. E and F, Stabilization of forehead and bandeau achieved via resorbable plates and screws. Adapted from Ghali GE et al.⁴⁶ p. 14–15.

frontal bone reshaping are ideally performed at 6 to 8 months of age. Other centers have reported good results when treatment is provided between the ages of 2.5 and 3 years. To achieve optimal symmetry, we prefer to use a bilateral surgical approach. Symmetry of the cranial vault and orbit must be achieved during surgery, because results generally do not improve over time. Stabilization is

achieved by using direct intraosseous wires or resorbable plates and screws.

Bilateral Coronal Synostosis

The treatment of bilateral coronal synostosis (Figures 45-14 and 45-15) requires suture release and simultaneous bilateral orbital rim and frontal bone advancements.^{42,43} Surgery is performed when the patient is between 6 and 8 months of age.

Other centers have reported good results with children treated between the ages of 2.5 and 3 years of age. The osteotomies for the bilateral orbital rim advancement are made superior to the nasofrontal and frontozygomatic sutures and extend to the squamous portion of the temporal bone. Stabilization is achieved with direct transosseous wires or resorbable plates and screws. The more normalized shape provides the needed increase

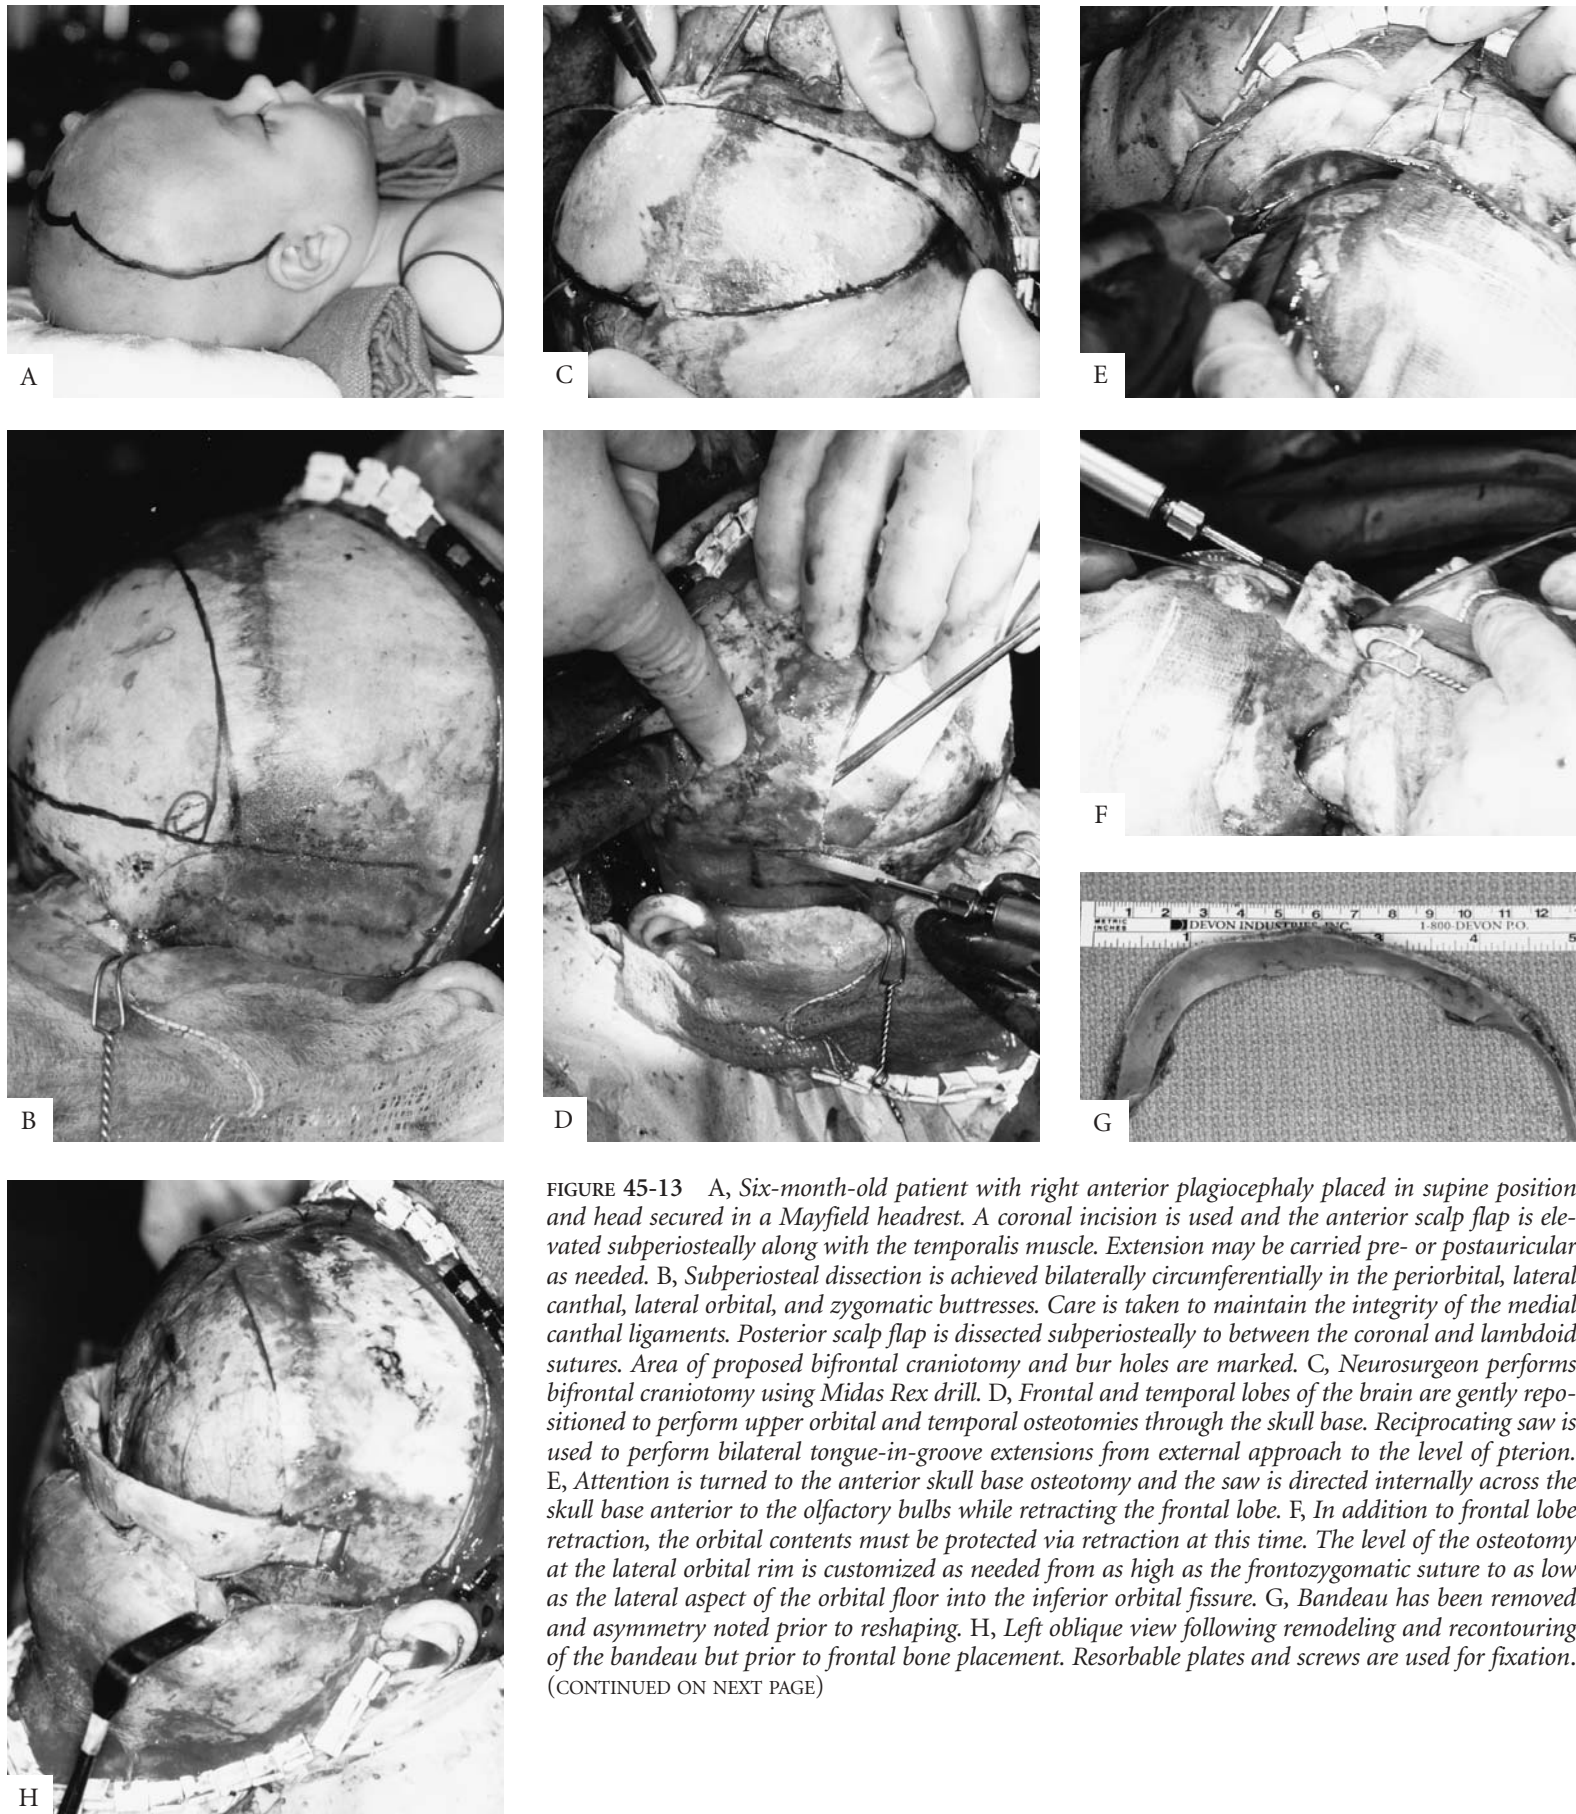

FIGURE 45-13 A, Six-month-old patient with right anterior plagiocephaly placed in supine position and head secured in a Mayfield headrest. A coronal incision is used and the anterior scalp flap is elevated subperiosteally along with the temporalis muscle. Extension may be carried pre- or postauricular as needed. B, Subperiosteal dissection is achieved bilaterally circumferentially in the periorbital, lateral canthal, lateral orbital, and zygomatic buttresses. Care is taken to maintain the integrity of the medial canthal ligaments. Posterior scalp flap is dissected subperiosteally to between the coronal and lambdoid sutures. Area of proposed bifrontal craniotomy and bur holes are marked. C, Neurosurgeon performs bifrontal craniotomy using Midas Rex drill. D, Frontal and temporal lobes of the brain are gently repositioned to perform upper orbital and temporal osteotomies through the skull base. Reciprocating saw is used to perform bilateral tongue-in-groove extensions from external approach to the level of pterion. E, Attention is turned to the anterior skull base osteotomy and the saw is directed internally across the skull base anterior to the olfactory bulbs while retracting the frontal lobe. F, In addition to frontal lobe retraction, the orbital contents must be protected via retraction at this time. The level of the osteotomy at the lateral orbital rim is customized as needed from as high as the frontozygomatic suture to as low as the lateral aspect of the orbital floor into the inferior orbital fissure. G, Bandeau has been removed and asymmetry noted prior to reshaping. H, Left oblique view following remodeling and recontouring of the bandeau but prior to frontal bone placement. Resorbable plates and screws are used for fixation. (CONTINUED ON NEXT PAGE)

in intracranial volume within the anterior cranial vault.

Metopic Synostosis

Surgical treatment of metopic synostosis (Figures 45-16 and 45-17) involves metopic suture release, simultaneous bilateral orbital rim advancements, and lateral widening via frontal bone

FIGURE 45-15 A female infant born with bilateral coronal synostosis and apparent normal growth of her midface. She underwent anterior cranial vault and bilateral superior orbital rim osteotomies with reshaping at 6 months of age as previously described. A, Frontal view soon after birth. B, Superior view preoperatively at 6 months of age. C, Intraoperative lateral view of anterior cranial vault and orbits after osteotomies, reshaping, and fixation of segments. advancement. These procedures are usually performed at 6 to 8 months of age. Orbital hypotelorism is corrected by splitting the supraorbital ridge unit vertically in the midline and placing autogenous cranial bone grafts to increase the intraorbital distance. Stabilization is achieved with direct transosseous wires or resorbable microplate fixation. The

microplate fixation is usually placed at the inner surface of the cranial bone. The abnormally shaped bone that has been removed is cut into sections of appropriate shape for the new forehead configuration. The anterior cranial base, anterior cranial vault, and orbit are given a more esthetic shape, and the volume of the anterior cranial vault is increased, which

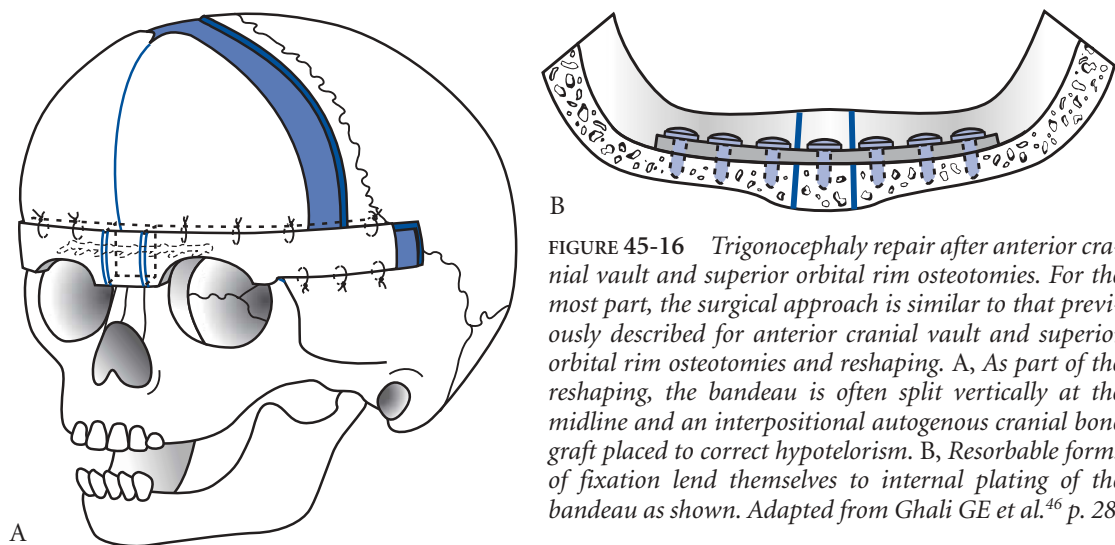

FIGURE 45-16 Trigenocephaly repair after anterior cranial vault and superior orbital rim osteotomies. For the most part, the surgical approach is similar to that previously described for anterior cranial vault and superior orbital rim osteotomies and reshaping. A, As part of the reshaping, the bandeau is often split vertically at the midline and an interpositional autogenous cranial bone graft placed to correct hypotelorism. B, Resorbable forms of fixation lend themselves to internal plating of the bandeau as shown. Adapted from Ghali GE et al.⁴⁶ p. 28.

allows the brain adequate space. Autogenous bone may be taken from the posterior cranium, when required, to enhance frontal reconstruction.

Sagittal Synostosis

Historically, when premature closure of a sagittal suture (Figures 45-18 and 45-19) was recognized in early infancy, most neurosur-

geons believed that simple release of the sagittal suture through a strip craniectomy without simultaneous skull reshaping was adequate treatment.^{4,36,44,45} Our results using this technique have been less than favorable, and a residual cranial vault deformity usually results. If improvements in cranial vault shape are to be achieved, most cases require a formal total cranial vault reshaping at the age of 4 to 8 months. Variations in the degree of the scaphocephalic deformity are common, depending on the extent of sagittal suture stenosis. When the posterior half is fused, the patient is treated in the prone position with the posterior two-thirds of the cranial vault reshaped. When the anterior half is fused, the patient is treated in the supine position with the anterior two-thirds of the cranial vault reshaped, with or without superior orbital rim reshaping. When the entire suture is fused, a combination of

both approaches may be necessary. Unless a significant concomitant supraorbital deformity exists, we prefer to treat full sagittal suture stenosis (anterior and posterior) at one operative setting in the prone position

via a total cranial vault reshaping. For older children (older than 1 year) or children with a need for upper orbital reconstruction, we prefer the supine position at one operative setting or, rarely, in two stages,

with posterior reconstruction preceding anterior and orbital reconstruction by 4 to 6 months. Other centers have reported good results when routinely staging full sagittal synostosis.

Unilateral Lambdoid Synostosis

Many surgeons consider simple strip craniectomy of the involved suture or partial craniectomy of the region to be adequate treatment. More extensive vault craniectomy and reshaping are generally necessary. If improvements in cranial vault shape are required after 10 to 12 months of age, formal posterior cranial vault reshaping is performed.

Summary

In approximately 1 in 1,000 live births in the United States, an infant has some variant of a craniofacial deformity. If cleft lip and palate deformities are included, the incidence is even greater. Surgical management of these patients has been advocated to occur from the first few weeks after birth until well into the second decade. Many of these patients require multiple, staged procedures that involve movements of the bone and soft tissue from both the intracranial and extracranial approaches. The surgical approach to most of these congenital deformities was radically changed by techniques introduced to the United States by Paul Tessier of France in 1967. From his imaginative intracranial and extracranial approaches, numerous advances have been made that facilitate the biodegradable plating systems, which have improved the management of these complex craniomaxillofacial deformities.

Craniofacial Dysostosis Syndromes: Staging of Reconstruction

Jeffrey C. Posnick, DMD, MD

Ramon L. Ruiz, DMD, MD

Paul S. Tiwana, DDS, MD, MS

Cranial sutures are a form of bone articulation in which the margins of the bones are connected by a thin layer of fibrous tissue. The cranial vault is composed of six major sutural areas and several minor sutures, which serve two critical functions during the postnatal period. Initially, the sutures allow head deformation during vaginal delivery as part of the birthing process. Later, during an infant's postnatal development, cranial vault sutures facilitate head expansion to accommodate propulsive brain growth.¹ Only small amounts of pressure (5 mm Hg) from the growing brain are required to stimulate bone deposition at the margins of a cranial bone.^{2,3} Under normal conditions, the brain volume will triple within the first year of life, and by age 2 years, the cranial capacity is four times that at birth.⁴ Under normal circumstances, closure of the cranial vault sutures occurs earlier than closure of the membranous facial bone sutures, which often remain patent until adulthood.

The term *craniosynostosis* is defined as a premature fusion of a cranial vault suture. With rare exception, this is an intrauterine event. A more accurate description of craniosynostosis may be a *congenital absence* of the cranial vault sutures. The result is

fusion of the bones adjacent to the suture and arrested sutural growth of the adjacent bones. The classic theory known as Virchow's law states that premature fusion of a cranial vault suture results in limited development of the skull perpendicular to the fused suture and a compensatory "overgrowth" through the sutures that remain open.⁵ The result is a dysmorphology with characteristics depending on the sutures affected, and potential neurologic consequences related to underlying brain compression. Most forms of craniosynostosis represent random, nonsyndromic malformations limited to the cranial vault and orbital regions. Management typically requires a combined neurosurgical and craniofacial approach for release of the involved suture and reshaping of the dysmorphic skeletal components. For additional discussion of the treatment of nonsyndromic craniosynostosis, see Chapter 45, "Nonsyndromic Craniosynostosis." Craniofacial dysostosis is the term applied to syndromal forms of craniosynostosis. These disorders are characterized by sutural involvement that not only includes the cranial vault but also extends into the skull base and midfacial skeletal structures. Craniofacial dysostosis syndromes have been

described by Carpenter, Apert, Crouzon, Saethre-Chotzen, and Pfeiffer.⁶ Although the cranial vault and cranial base are thought to be the regions of primary involvement, there is also significant impact on midfacial growth and development.^{7,8} In addition to cranial vault dysmorphology, patients with these inherited conditions exhibit a characteristic "total midface" deficiency that is syndrome specific and must be addressed as part of the staged reconstructive approach.

Functional Considerations

Brain Growth and Intracranial Pressure

If the rapid brain growth that normally occurs during infancy is to proceed unhindered, the cranial vault and base sutures must remain open and expand during phases of rapid growth, resulting in marginal ossification. In craniosynostosis, premature fusion of sutures causes limited and abnormal skeletal expansion in the presence of continued brain growth. Depending on the number and location of prematurely fused sutures, the growth of the brain may be restricted.^{2,9-11} In addition, abnormal cranial vault and midfacial morphology occurs as determined by

Virchow's law. If surgical release of the affected sutures and reshaping to restore a more normal intracranial volume and configuration are not performed, decreased cognitive and behavioral function is likely to be the end result.

Elevated intracranial pressure (ICP) is the most serious functional problem associated with premature suture fusion. A "beaten-copper" appearance along the inner table of the cranial vault seen on a plain radiograph or the loss of brain cisternae as observed on a computed tomography (CT) scan may suggest elevated ICP,¹² but these are considered soft radiographic findings.

Intracranial hypertension can be established invasively by means of a bur-hole craniotomy used to place either an epidural or intraparenchymal pressure sensor. Increased ICP is most likely to affect patients with great disparity between brain growth and intracranial capacity and may occur in as many as 42% of untreated children in whom more than one suture is affected.^{2,10,13} Unfortunately, there is no absolute agreement on what levels of ICP are normal at any given age in infancy and early childhood.

The clinical signs and symptoms related to elevated ICP may have a slow onset and be difficult to recognize in the pediatric population. Although standardized CT scans allow for indirect measurement of intracranial volume, it is not yet possible to use these studies to make judgments as to who requires craniotomy for decompression.^{14,15} Careful neurosurgical and pediatric ophthalmologic evaluation are critical components of the data gathering required to formulate a definitive treatment plan in a patient with craniosynostosis.

Vision

Untreated craniosynostosis with elevated ICP will cause papilledema and eventual optic nerve atrophy, resulting in partial or complete blindness. If the orbits are shallow (exorbitism) and the eyes are proptot-

ic (exophthalmos), as occurs in the craniofacial dysostosis syndromes, the cornea may be exposed and abrasions or ulcerations may occur. An eyeball extending outside of a shallow orbit is also at risk of trauma. If the orbits are extremely shallow, herniation of the globe itself may occur, necessitating emergency reduction followed by tarsorrhaphies or urgent orbital decompression.

Some forms of craniofacial dysostosis result in a marked degree of orbital hypertelorism, which may compromise visual acuity and restrict binocular vision. Divergent or convergent nonparalytic strabismus or exotropia occurs frequently and should be considered during the diagnostic evaluation. This may be the result of congenital anomalies of the extraocular muscles themselves. Paralytic or nonparalytic unilateral or bilateral upper eyelid ptosis also occurs with greater frequency with craniofacial dysostosis than in the general population.

Hydrocephalus

Hydrocephalus affects as many as 10% of patients with a craniofacial dysostosis syndrome.¹⁶⁻¹⁹ Although the etiology is often not clear, hydrocephalus may be secondary to a generalized cranial base stenosis with constriction of all the cranial base foramina, which impacts the patient's cerebral venous drainage and cerebrospinal fluid (CSF) flow dynamics. Hydrocephalus may be identified with the help of CT or magnetic resonance imaging (MRI) to document progressively enlarging ventricles. Difficulty exists in interpreting ventricular findings as seen on a CT scan especially when the skull and cranial base are brachycephalic. The skeletal dysmorphology seen in a child with severe cranial dysmorphology related to craniosynostosis may translate into an abnormal ventricular shape that is not necessarily related to abnormal CSF flow. Serial imaging and clinical correlation is indicated, and a great deal of clinical

judgment is often required in making these assessments.

Effects of Midface Deficiency on Airway

All newborn infants are obligate nasal breathers. Many infants born with a craniofacial dysostosis syndrome have moderate to severe hypoplasia of the midface as a component of their malformation. They will have diminished nasal and nasopharyngeal spaces with resulting increased nasal airway resistance (obstruction). The affected child is thus forced to breathe through the mouth. For a newborn infant to ingest food through the mouth requires sucking from a nipple to achieve negative pressure as well as an intact swallowing mechanism. The neonate with severe midface hypoplasia will experience diminished nasal airflow and be unable to accomplish this task and breathe through the nose at the same time.²⁰⁻²³ Complicating this clinical picture may be an elongated and ptotic palate and enlarged tonsils and adenoids. The compromised infant expends significant energy respiring, and this may push the child into a catabolic state (negative nitrogen balance). Failure to thrive results unless either nasogastric tube feeding is instituted or a feeding gastrostomy is placed. Evaluation by a pediatrician, pediatric otolaryngologist, and feeding specialist with craniofacial experience can help distinguish minor feeding difficulties from those requiring more aggressive treatment.

Sleep apnea of either central or obstructive origin may also be present. If the apnea is found to be secondary to upper airway obstruction based on a formal sleep study, a tracheostomy may be indicated. In rare situations, "early" midface advancement is useful to improve the airway and allow for tracheostomy decannulation. Central apnea may occur from poorly treated intracranial hypertension and other contributing factors. If this is the case, the condition may improve by reducing the intracranial

pressure to a normal range through cranio-orbital or posterior cranial vault decompression or expansion.

Dentition and Occlusion

The incidence of dental and oral anomalies is higher among children with craniofacial dysostosis syndromes than in the general population. In Apert syndrome in particular, the palate is high and constricted in width. The incidence of isolated cleft palate in patients with Apert syndrome approaches 30%.¹³ Clefting of the secondary palate may be submucous, incomplete, or complete. Confusion has arisen over whether the oral malformations and absence of teeth that are often characteristic of these conditions are a result of congenital or iatrogenic factors (eg, injury to dental follicles associated with early mid-face surgery). The midfacial hypoplasia seen in the craniofacial dysostosis syndromes often results in limited maxillary alveolar bone to house a full complement of teeth. The result is severe crowding, which often requires serial extractions in order to address the problem. An Angle Class III skeletal relationship in combination with anterior open bite deformity is typical.

Hearing

Hearing deficits are more common among patients with the craniofacial dysostosis syndromes than in the general population.²⁴ In Crouzon syndrome, conductive hearing deficits are common, and atresia of the external auditory canals may also occur. Otitis media is more common in Apert syndrome, although the exact incidence is unknown. Middle ear disease may be related to the presence of a cleft palate that results in eustachian tube dysfunction. Congenital fixation of the stapedial footplate is also believed to be frequent. The possibility of significant hearing loss is paramount in importance and should not be overlooked because of preoccupation with other more easily appreciated craniofacial findings.

Extremity Anomalies

Apert syndrome results in joint fusion and bony and soft tissue syndactyly of the digits of all four limbs.²⁴ These Apert-associated extremity deformities are often symmetric. Partial or complete fusion of the shoulder, elbow, or other joints is common. Broad thumbs, broad great toes, and partial soft tissue syndactyly of the hands may be seen in Pfeiffer syndrome, but these are variable features. Preaxial polysyndactyly of the feet may also be seen in Carpenter syndrome.

Morphologic Considerations

Examination of the patient's entire craniofacial region should be meticulous and systematic. The skeleton and soft tissues are assessed in a standard way to identify all normal and abnormal anatomy. Specific findings tend to occur in particular malformations, but each patient is unique. The achievement of symmetry and normal proportions and the reconstruction of specific esthetic units are essential to forming an unobtrusive face in a child born with a craniofacial dysostosis syndrome.

Frontoforehead Esthetic Unit

The frontoforehead region is dysmorphic in an infant with craniofacial dysostosis.^{25–30} Establishing normal position of the forehead is critical to overall facial symmetry and balance. The forehead may be considered as two separate esthetic components: the supraorbital ridge–lateral orbital rim region and the superior forehead (Figure 46-1A and B).^{31,32} The supraorbital ridge–lateral orbital rim region includes the glabella and supraorbital rim extending inferiorly down each frontozygomatic suture toward the infraorbital rim and posteriorly along each temporoparietal region. The morphology and position of the supraorbital ridge–lateral orbital rim region is a key element of upper facial esthetics. In a normal forehead, at the level of the frontonasal suture, an angle ranging from 90 to 110° is formed by the supraor-

bital ridge and the nasal bones when viewed in profile. Additionally, the eyebrows, overlying the supraorbital ridge, should be anterior to the cornea. When the supraorbital ridge is viewed from above, the rim should arc posteriorly to achieve a gentle 90° angle at the temporal fossa with a center point of the arc at the level of each frontozygomatic suture. The superior forehead component, about 1.0 to 1.5 cm up from the supraorbital rim, should have a gentle posterior curve of about 60°, leveling out at the coronal suture region when seen in profile.

Posterior Cranial Vault Esthetic Unit

Symmetry, form, and the appropriate intracranial volume of the posterior cranial vault are closely linked. Posterior cranial vault flattening may result from either a unilateral or bilateral lambdoidal synostosis, which is rare; previous craniectomy with reossification in a dysmorphic flat shape, which is frequent; or postural molding because of repetitive sleep positioning.³³ A short anterior–posterior cephalic length may be misinterpreted as an anterior cranial vault (forehead) problem when the occipitoparietal (posterior) skull represents the primary region of the deformity. Careful examination of the entire cranial vault is essential to defining the dysmorphic region so that appropriate therapy may be carried out.

Orbitonasozygomatic Esthetic Unit

In craniofacial dysostosis syndromes, the orbitonasozygomatic regional deformity is a reflection of the cranial base malformation. For example, in Crouzon syndrome when bilateral coronal suture synostosis is combined with skull base and midfacial deficiency, the orbitonasozygomatic region will be dysmorphic and consistent with a short (anterior–posterior) and wide (transverse) anterior cranial base.³⁴ In Apert syndrome, the nasal bones, orbits, and zygomas, like

FIGURE 46-1 The craniofacial skeleton of a child with bilateral coronal synostosis before and after anterior cranial vault and three-quarter orbital osteotomies with reshaping. A, Site of osteotomies as indicated. B, After osteotomies and reshaping and fixation of the cranio-orbital regions. Adapted from Posnick JC.⁷⁶

the anterior cranial base, are transversely wide and horizontally short (retruded), resulting in a shallow hyperteloritic upper midface (zygomas, orbits, and nose).³⁴ Advancing the midface without simultaneously addressing the increased transverse width will not adequately correct the dysmorphology.³⁵

Maxillary-Nasal Base Esthetic Unit

In the craniofacial dysostosis patient with midface deficiency, the upper anterior face (nasion to maxillary incisor) is vertically short, and there is a lack of horizontal anterior-posterior (A-P) projection of the midface.^{36,37} These findings may be confirmed with cephalometric analysis that indicates a sella-nasion angle (SNA) below the mean value and a short upper anterior facial height (nasion to anterior nasal spine). The width of the maxilla in the dentoalveolar region is generally constricted with a high arched palate. In order to normalize the maxillonasal base region, multidirectional surgical expansion and reshaping are generally required. The maxillary lip-to-tooth relationship and occlusion are normalized through Le Fort I osteotomy and orthodontic treatment as part of the staged reconstruction.

Quantitative Assessment

A quantitative analysis of measurements taken from CT scans, surface anthropometry, cephalometric analysis, and dental casts is critical to data gathering for evaluation of craniofacial deformities.³⁸⁻⁴³ This analysis will confirm or refute clinical impressions, aid in the treatment planning of intraoperative skeletal movements and reshaping, and provide a framework for objective assessment of immediate and long-term results. These methods of assessment rely on the measurement of linear distances, angles, and proportions based on accurate, reliable, and reproducible anatomic landmarks found to be useful for patient evaluation.

CT Scan Analysis

The use of CT scans has clarified our appreciation of the dysmorphology of a child born with a craniofacial malformation.^{44,45} Accurate standardized points of reference have been identified in the cranio-orbitozygomatic skeleton based on axial CT images.^{42,43} Knowledge of differential facial bone growth patterns and normal measurement values can now be used to improve diagnostic accuracy, assist in the staging of reconstruction by understanding growth vectors, and offer the option of making intraoperative measurements that correlate with the preoperative CT scan measurements and ideal dimensions. This information can effectively guide the surgeon in the reconstruction of an individual with a craniofacial malformation and also allows for accurate postoperative reassessment.

Anthropometric Surface Measurements

Cross-sectional studies of the patterns of postnatal facial growth based on anthropometric surface measurements have been carried out in growing Caucasian children.^{38–41,46} This published material has proven useful in the quantitative evaluation and recognition of discrepancies in postnatal development in the head and face of patients with specific craniofacial syndromes. This is particularly useful when evaluating basic distances, angles, and proportions of the head, face, and orbits in patients affected with craniofacial dysostosis syndromes.

Cephalometric Analysis

Cephalometric radiography, first introduced by Broadbent in 1931, has been traditionally used to study the morphology and patterns of growth of the maxillofacial skeleton.⁴⁷ The large collection of normative data developed allows clinicians to monitor an individual's facial growth. The interpretation of cephalometric radiographs remains useful in the analysis of

facial heights and maxillary, mandibular, and chin positions and their relationships to one another; the cranial base; and the dentition.^{30,36,48,49} The lateral cephalometric radiograph offers an accurate view from the midsagittal plane if the facial skeleton being analyzed is relatively symmetric. Unfortunately, the number of anatomic landmarks that can be identified accurately in the cranio-orbitozygomatic region is limited because of the overlap of structures, which makes predictably locating these anatomic landmarks more difficult.

Surgical Management

Historic Perspectives: The Pioneers

The first recorded surgical approach to craniosynostosis was performed by Lannelongue in 1890⁵⁰ and Lane in 1892,⁵¹ who completed strip craniectomies of the involved sutures. Their aim was to control the problem of brain compression (intracranial hypertension) within a congenitally small cranial vault.

The classic neurosurgical techniques were refined over the ensuing decades and were geared toward resecting the synostotic sutures in the hope that the “released” skull would reshape itself and continue to grow in a normal and symmetric fashion.⁵² Strip craniectomy procedures were supposed to allow for creation of new suture lines at the site of the previous synostosis. With the realization that this goal was not achieved, attempts were made to surgically disassemble the involved cranial vault and then replace the pieces of calvaria as free grafts to shape the cranial vault. Problems with these methods included uncontrolled postoperative skull molding, resulting in reossification in dysmorphic configurations. In some other children, when extensive craniectomies were carried out, permanent skull defects remained.

After World War II, Gillies and Harrison reported experience with an extracranial Le Fort III osteotomy to improve the

anterior projection of the midface in an adult with Crouzon syndrome.⁵³ The early enthusiasm for this technique later turned to discouragement when the patient's facial skeleton relapsed to its preoperative status.

In 1967, Tessier described a new (intracranial–cranial base) approach to the management of Crouzon syndrome.⁵⁴ His landmark presentation and publications were the beginning of modern craniofacial surgery.^{55–63} To overcome the earlier problems encountered by Gillies and Harrison, Tessier developed an innovative basic surgical approach that included new locations for the Le Fort III osteotomy, a combined intracranial–extracranial (cranial base) approach, use of a coronal (skin) incision to expose the upper facial bones, and use of an autogenous bone graft. He also applied an external fixation device to help maintain bony stability until healing had occurred.

The concept of simultaneous suture release for craniosynostosis combined with cranial vault reshaping in infants was initially discussed by Rougerie and colleagues⁶⁴ and later refined by Hoffman and Mohr in 1976.⁶⁵ Whitaker and others proposed a more formal anterior cranial vault and orbital reshaping procedure for unilateral coronal synostosis in 1987,⁶⁶ and then Marchac and colleagues published their experience with the “floating forehead” technique for simultaneous suture release and anterior cranial vault and orbital reshaping to manage bilateral coronal synostosis in infancy.³²

The widespread use of cranial bone as a graft option has virtually eliminated the need for rib and hip grafts when autogenous bone replacement is required in cranio-orbitozygomatic procedures. This represents another of Tessier's contributions to craniofacial surgery that has stood the test of time.

In 1968, Luhr introduced the use of small metal plates and screws to stabilize maxillofacial fractures and then osteotomies.⁶⁷ In current practice, the use of internal plate and screw fixation is the

preferred form of stabilization for the three-dimensional reconstruction of multiple osteotomized bone segments and grafts. The development of resorbable plates and screws as a form of stable fixation continues to evolve as a fixation alternative, especially for use in growing bones and for immobilization of onlay bone grafts.⁴⁷ The reliability of resorbable fixation to withstand the compressive (relapse) forces after total midfacial advancement procedures and the normal loading forces of occlusion during the active bone healing phase leave it a less desirable fixation option for the craniofacial dysostosis patient.

More recently, the intraoperative placement of a distraction device as a method of achieving advancement of the midface in patients with severe forms of craniofacial hypoplasia has been added to the surgeon's armamentarium.⁴⁷ If used, distraction osteogenesis is not applied until after successful completion of standard osteotomies and disimpaction in the operating room. The distraction apparatus is either anchored to the "stable" skeleton internally or externally (through a "halo" head frame) and then to the palatal (intraoral) and infraorbital rims or zygomatic buttresses. Advancement of the "total midface" can then proceed. Once adequate (midface) advancement has been accomplished (on an outpatient basis) over a period of several weeks, the patient is generally returned to the operating room for stabilization and final reconstruction. The final reconstruction may require additional segmental osteotomies, bone grafting, or placement of plate and screw fixation. The "distraction approach" to the midface deformity is a labor-intensive, technique-specific, and relatively crude method of accomplishing horizontal advancement with difficulty in controlling the vertical dimension of the midface and without the ability to alter the transverse deformity or deficiency. In our opinion, the current level of distraction technology leaves it an

adjunctive rather than primary technique. It is most useful when the midfacial hypoplasia is severe to the extent that conventional techniques cannot reliably allow the immediate (in the operating room) desired advancement and when complex vertical and transverse reconstruction is not required.

Philosophy Regarding Timing of Intervention

In considering the timing and type of intervention the experienced surgeon will take several biologic realities into account: the natural course of the malformation (ie, Is the dysmorphology associated with Crouzon syndrome progressively worsening or is it a nonprogressive craniofacial deformity?); the tendency toward growth restriction of an operated bone (esthetic unit) that has not yet reached maturity (ie, we know that operating on a palate of a child born with a cleft in infancy will cause scarring and later result in maxillary hypoplasia in a significant percentage of individuals); and the uncertain relationship between the underlying growing viscera (ie, brain or eyes) and the congenitally affected and surgically altered skeleton (ie, If the cranial vault is not surgically expanded by 1 year of life in a patient with multiple suture synostosis, will brain compression occur?).

In attempting to limit functional impairment and also achieve long-term ideal facial esthetics, an essential question the surgeon must ask is, "During the course of craniofacial development, does the operated-on facial skeletal of the child with craniofacial dysostosis tend to grow abnormally, resulting in further distortions and dysmorphology, or are the initial positive skeletal changes (achieved at operation) maintained during ongoing growth?" Unfortunately, the theory that craniofacial procedures carried out early in infancy will "unlock growth" has not been documented through the scientific method.⁶⁸⁻⁷⁰

Incision Placement

For exposure of the craniofacial skeleton above the Le Fort I level, the approach used is the coronal (skin) incision. This allows for a relatively camouflaged access to the anterior and posterior cranial vault, orbits, nasal dorsum, zygomas, upper maxilla, pterygoid fossa, and temporomandibular joints. For added cosmetic advantage, placement of the coronal incision more posteriorly on the scalp and with postauricular rather than preauricular extensions is useful. When exposure of the maxilla at the Le Fort I level is required, a circumvestibular maxillary intraoral incision is used. Unless complications occur that warrant unusual exposure, no other incisions are required for managing any aspect of the craniofacial dysostosis patient's reconstruction. These incisions (coronal [scalp] and maxillary [circumvestibular]) may be reopened as needed to further complete the patient's staged reconstruction.

Management of Cranial Vault Dead Space

The management of the dead space that results with cranial vault or cranial base expansion is critical to limiting complications. Dead space within the cranial vault after cranial expansion is managed by being gentle to the tissues, achieving good hemostasis, closure of tissue layers, placement of bone grafts, the stable fixation of osteotomy segments, and obliteration (of dead space) with soft tissue flaps or grafts when indicated.

Expansion of the cranial vault with forward advancement of the anterior cranial base, orbits, and midface results in both extradural (retrofrontal) dead space and a communication of the anterior fossa with the nasal cavity.⁷¹ Dead space within the anterior cranial vault and the communication of the frontal fossa with the nasal cavity across the anterior skull base may result in hematoma formation, CSF

leakage, infection, and fistula formation.^{72,73} Management of this expanded space in the anterior cranial fossa following frontofacial or forehead advancement remains controversial. Relatively rapid filling of the expanded intracranial space by the frontal lobes has been documented in infants and young children when the expansion remains in a physiologic range.^{71,74} This observation supports the conservative management of retrofrontal dead space in younger patients. More gradual and less complete filling is thought to occur in older children and adults. If so, this may be particularly troublesome when the anterior fossa dead space communicates directly with the nasal cavity. When possible, closing off the nasal cavity from the cranial fossa at the time of operation is preferred. Insertion of a pericranial flap can help to separate the cavities and at the same time obliterate dead space. The use of fibrin glue to seal the anterior cranial base also provides a temporary repair between the cavities, allowing time for the reepithelialization of the nasal mucosa.⁷⁵ When feasible, after midface advancement the anterior skull base is reconstructed (ie, bone grafts) to facilitate healing across the skull base to limit CSF leakage and prevent fistula formation. Until the torn nasopharyngeal mucosa heals, communication between the nasal cavity and cranial fossa is a potential for leakage (air, fluid, bacteria) and nasocranial fistula formation. To prevent this, postoperative endotracheal intubation may be extended for 3 to 5 days and bilateral nasopharyngeal airways may be placed after extubation. In addition, sinus precautions and restriction of nose blowing further limit reflux (nose to cranial fossa) of air and fluid during the postoperative period. All of these maneuvers are aimed at avoiding a pressure gradient and will facilitate sealing of the intracranial cavity from the upper aerodigestive tract. When anterior cranial vault reconstruction is performed and aerated frontal sinuses

are present, management of the sinus is by either cranialization or obliteration.

When a craniofacial dysostosis patient is to undergo intracranial volume expansion as part of the craniofacial procedure and they also require hydrocephalus management, the potential for problems increases. Complications may arise from excessive CSF drainage (“overshunting”). With overshunting there is decreased brain volume and dead space remains. Fronto-orbital advancement and cranial vault expansion procedures should be carefully staged with ventriculoperitoneal (VP) shunting procedures. Ultimately, the decision regarding the sequencing of shunting procedures is based on neurologic findings and the neurosurgeon’s judgement. In a patient with a VP shunt in place before the surgery, careful neurosurgical evaluation, including CT scanning of the ventricular system, is carried out to confirm that the shunt is functioning appropriately.

Soft Tissue Management

A layered closure of the coronal incision (galea and skin) optimizes healing and limits scar widening. Resuspension of the midface periosteum to the temporalis fascia in a superior and posterior direction facilitates redraping of the soft tissues. Each lateral canthus should be adequately suspended or reattached in a superior–posterior direction to the lateral orbital rim. The use of chromic gut for closure of the scalp skin in children may be used to obviate the need for postoperative suture or staple removal.

Crouzon Syndrome

Primary Cranio-orbital Decompression: Reshaping in Infancy

The initial treatment for Crouzon syndrome generally requires bilateral coronal suture release and simultaneous anterior cranial vault and upper orbital osteotomies with reshaping and advancement (see Figure 46-1).^{76–79} Our preference is to carry

this out when the child is 9 to 11 months of age unless clear signs of increased intracranial pressure are identified earlier in life (Figure 46-2). Reshaping of the upper three-quarters of the orbital rims and supraorbital ridges is geared toward decreasing the bitemporal and anterior cranial base width, with simultaneous horizontal advancement to increase the A-P dimension. This also increases the depth of the upper orbits, with some improvement of eye proptosis. The overlying forehead is then reconstructed according to morphologic needs. A degree of overcorrection is preferred at the level of the supraorbital ridge when the procedure is carried out in infancy. In our opinion, by allowing additional growth to occur (waiting until the child is 9 to 11 months old), the reconstructed cranial vault and upper orbital shape is better maintained with less need for repeat craniotomy procedures but without risking compression of the underlying brain.

The goals at this stage are to provide increased intracranial space in the anterior cranial vault for the brain; to increase the orbital volume, which allows the eyes to be positioned more normally for better protection from exposure; and to improve the morphology of the forehead and upper orbits.

A postauricular coronal (scalp) incision is made, and the anterior scalp flap is elevated along with the temporalis muscle in the subperiosteal plane. Bilateral circumferential periorbital dissection follows, with detachment of the lateral canthi, but with preservation of the medial canthi and nasolacrimal apparatus to the medial orbital walls. The subperiosteal dissection is continued down the lateral and infraorbital rims to include the anterior aspect of the maxilla and zygomatic buttress. The neurosurgeon then completes the craniotomy to remove the dysmorphic anterior cranial vault. With protection of the frontal and temporal lobes of the brain (remaining anterior to each olfactory bulb), safe direct

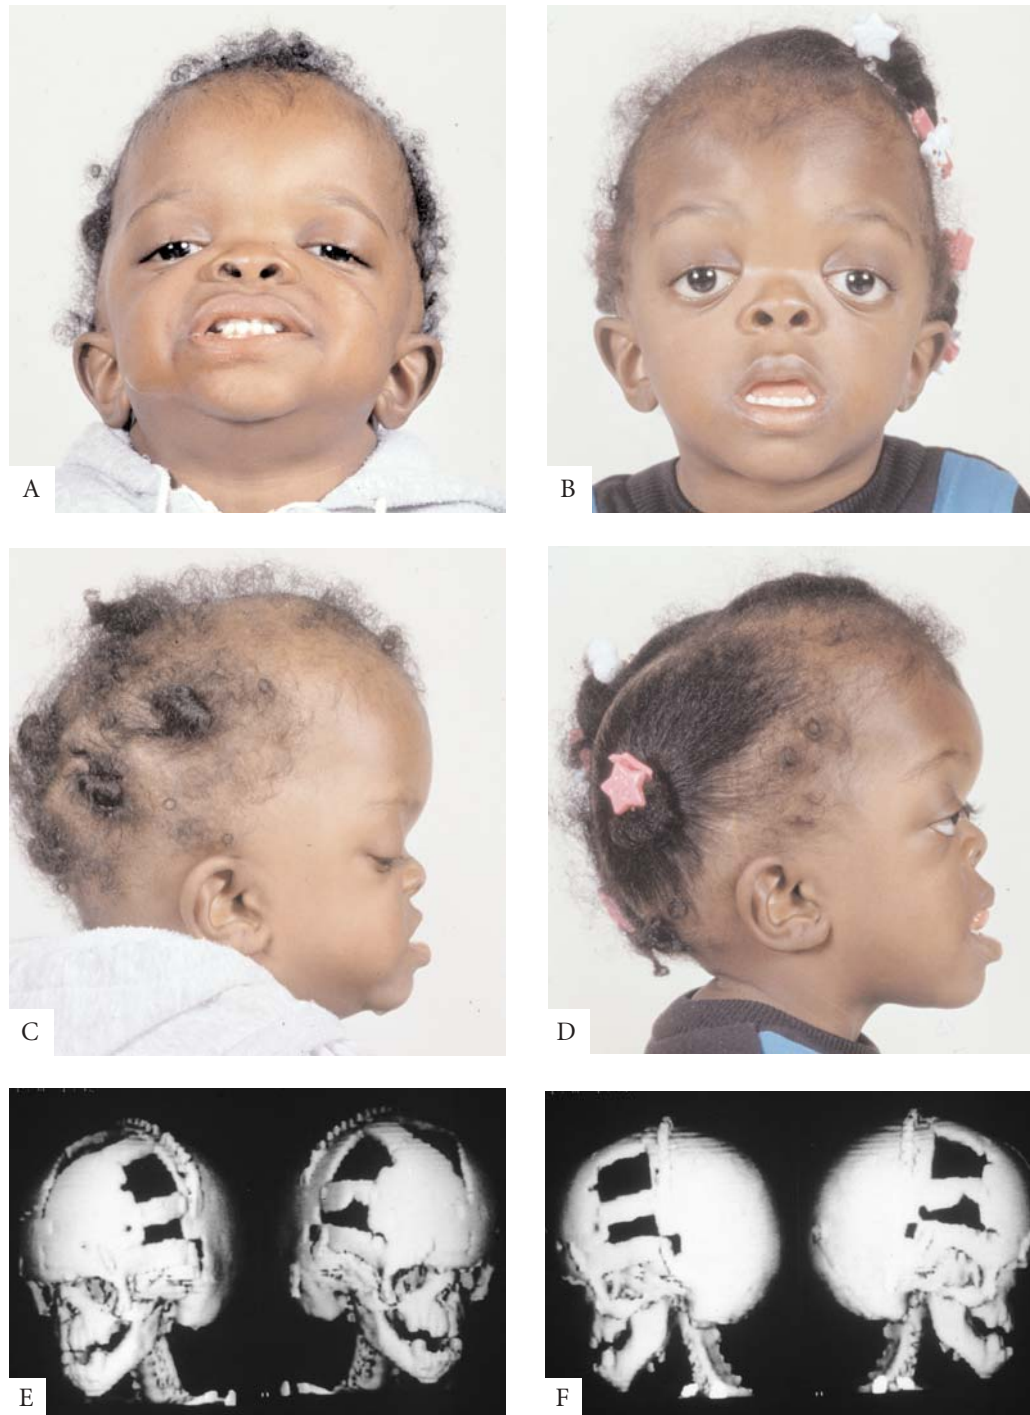

FIGURE 46-2 An 18-month-old girl with brachycephaly and midface deficiency with a mild degree of papilledema was referred for evaluation. She was found to have bilateral coronal synostosis and midface hypoplasia without extremity anomalies. The diagnosis of Crouzon syndrome was made. She underwent cranio-orbital reshaping (see Figure 46-1). Several months later, a ventriculoperitoneal shunt was placed for management of hydrocephalus. Further staged reconstruction will include a total midface advancement procedure later in childhood followed by orthodontic treatment and orthognathic surgery in the early teenage years. A, Frontal view before surgery. B, Frontal view at 3 years of age, 1.5 years after undergoing cranio-orbital decompression and reshaping. C, Profile view before surgery. D, Profile view at 3 years of age, 1.5 years after undergoing first-stage cranio-orbital decompression and reshaping. E and F, Three-dimensional CT scan views of craniofacial skeleton, just 1 week after cranio-orbital reshaping with advancement. Reproduced with permission from Posnick JC. Crouzon syndrome: evaluation and staging of reconstruction. In: Posnick JC, editor. *Craniofacial and maxillofacial surgery in children and young adults*. Philadelphia (PA): W.B. Saunders Co.; 2000. p. 275.

visualization of the anterior cranial base and orbits is possible at the time of orbital osteotomies.

The orbital osteotomies are then completed across the orbital roof and superior aspect of the medial orbital walls, laterally through the lateral orbital walls and inferiorly just into the inferior orbital fissures. The three-quarter orbital osteotomy units, with their tenon extensions, are removed from the field. The orbital units are reshaped and reinserted into a preferred position. Orbital depth is thereby increased, and global proptosis is reduced. Fixation is generally achieved with 28-gauge interosseous wires or suture at each infraorbital rim and with plates and titanium or resorbable screws at the tenon extensions and frontonasal regions.

The removed calvaria is cut into segments, which are placed individually to achieve a more normally configured anterior cranial vault. The goal of reshaping is to narrow the anterior cranial base and orbital width slightly and provide more forward projection and overall normal morphology.

Repeat Craniotomy for Additional Cranial Vault Expansion and Reshaping in Young Children

After the initial suture release, decompression, and reshaping are carried out during infancy, the child is observed clinically at intervals by the craniofacial surgeon, pediatric neurosurgeon, pediatric ophthalmologist, and developmental specialist and undergoes interval CT scanning. Should signs of increased ICP develop, urgent brain decompression with cranial vault expansion and reshaping is performed.⁴⁷ When increased ICP is suspected, the location of brain compression influences for which region of the skull further expansion and reshaping is planned.

If the brain compression is judged to be anterior, then further anterior cranial vault and upper orbital osteotomies with reshaping

FIGURE 46-3 A child with Crouzon syndrome is shown at 10 months of age. His deformities are characterized by mild bilateral coronal and marked bilateral lambdoid synostosis in combination with midface deficiency. He has diminished intracranial volume, resulting in brain compression. The orbits are shallow with resulting eye proptosis, and the midface is deficient with malocclusion. He is shown before and after undergoing posterior cranial vault decompression and reshaping to expand the intracranial volume. He later underwent placement of a ventriculoperitoneal shunt for management of hydrocephalus. He will require a total midface advancement (monobloc) with further anterior cranial vault reshaping after 5 years of age. This will be followed by orthognathic surgery in combination with orthodontic treatment in the teenage years. A, Profile view before surgery. B, Profile view after posterior cranial vault reconstruction. C, Intraoperative lateral view of cranial vault (patient in prone position) as seen with posterior scalp flap elevated. D, Same intraoperative view after posterior cranial vault decompression, reshaping, and fixation of bone segments with microplates and screws. E, Comparison of three-dimensional CT scan views before and after reconstruction. F, Comparison of three-dimensional CT scan views of cranial base before and after reconstruction. Reproduced with permission from Posnick JC. *The craniofacial dysostosis syndromes: secondary management of craniofacial disorders.* *Clin Plast Surg* 1997;24:429.

ing and advancement are carried out. The technique is similar to that described previously.^{47,78} If the problem is posterior compression, expansion of the posterior cranial vault, with the patient in the prone position, is required (Figure 46-3).

The “repeat” craniotomy carried out for further decompression and reshaping in the child with Crouzon syndrome is often complicated by brittle cortical bone (which lacks a diploic space and contains sharp spicules piercing the dura), the presence of previously placed fixation devices in the operative field (eg, Silastic sheeting, metal clips, stainless steel wires, plates, and screws), and convoluted thin dura compressed against (or herniated into) the inner table of the skull. All of these issues result in a greater potential for dural tears during the calvarectomy than would normally occur during the primary procedure. A greater potential for morbidity should be anticipated when re-elevating the scalp flap, dissecting the dura free of the inner table of the skull and cranial base, and then removing the cranial vault bone.

Management of “Total Midface” Deformity in Childhood

The type of osteotomies selected to manage the “total midface” deficiency or deformity and residual cranial vault dysplasia should depend on the extent and location of the presenting dysmorphology rather than on a fixed approach to the midface malformation.^{47,53–57,78–84} The selection of a monobloc (with or without additional orbital segmentation), facial bipartition (with or without additional orbital segmental osteotomies), or Le Fort III osteotomy to manage the basic horizontal, transverse, and vertical orbital, and upper midface deficiencies or deformities in a patient with Crouzon syndrome depends on the patient’s presenting midface and anterior cranial vault morphology. The observed dysmorphology is dependent on the original malformation, the previous procedures carried out, and the effects of ongoing growth (Figures 46-4 and 46-5).

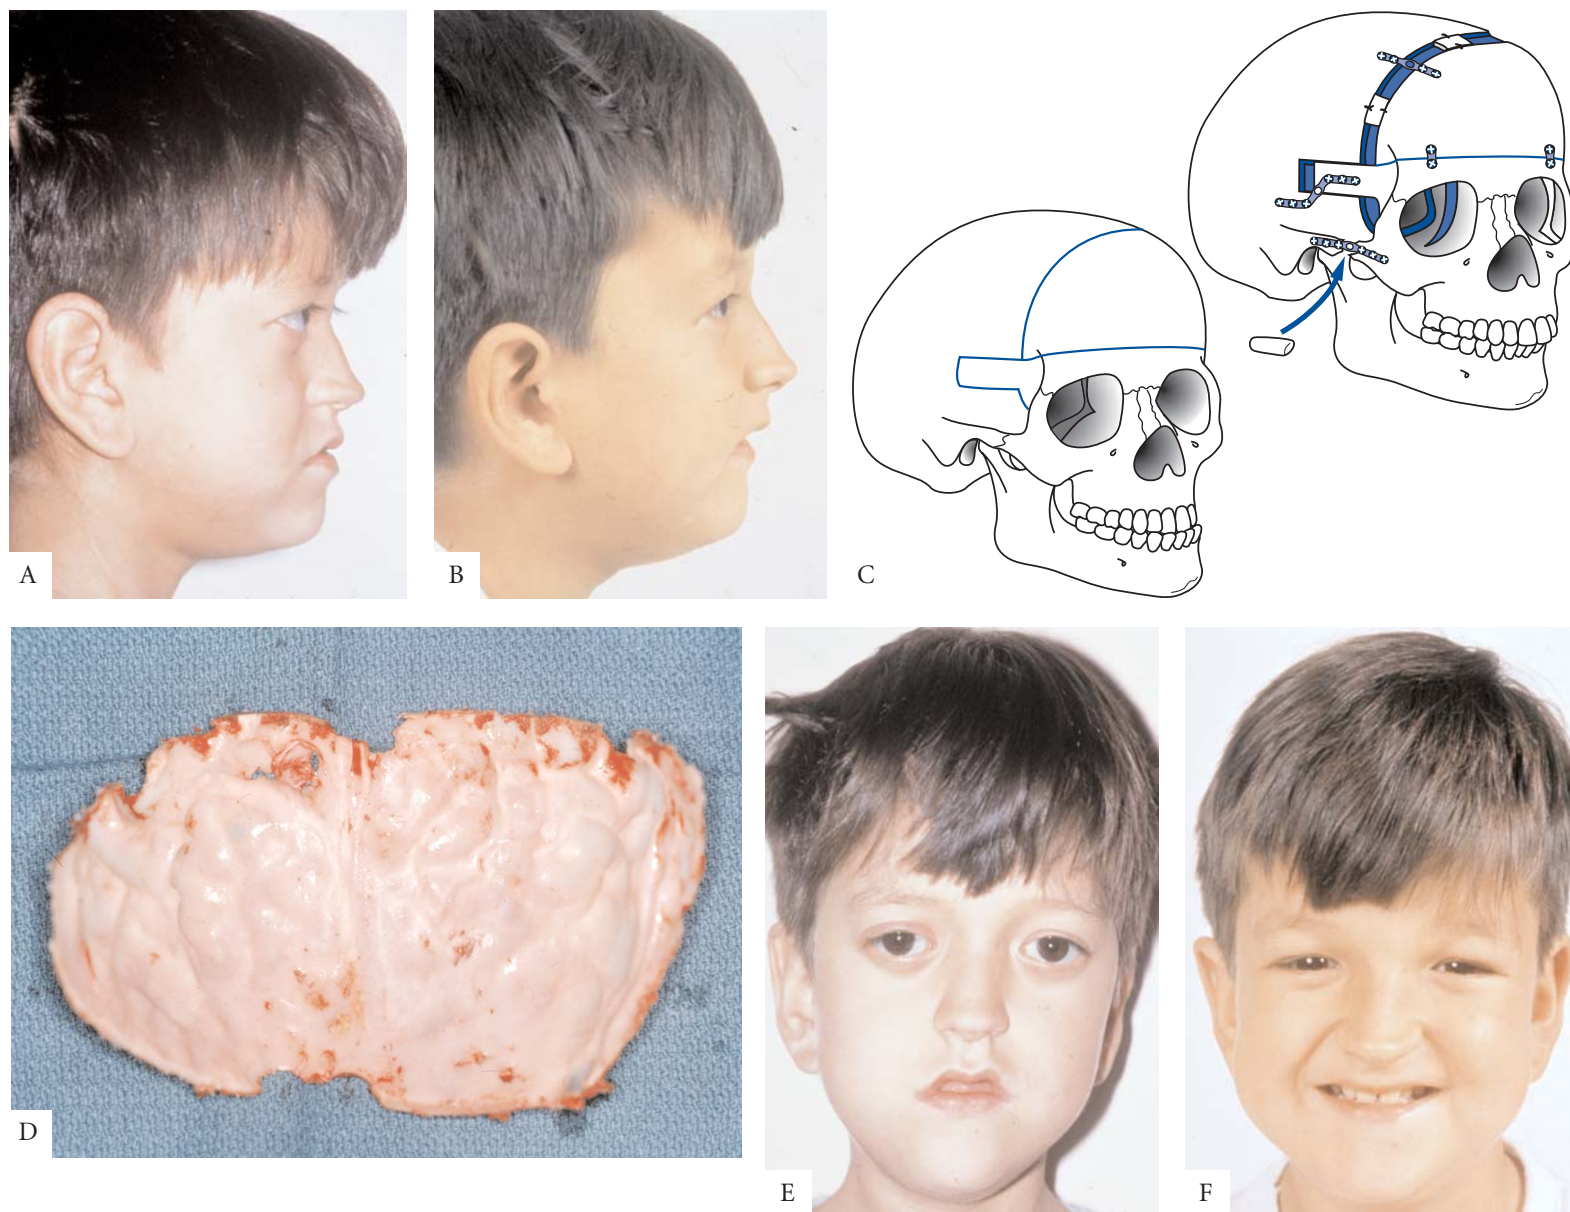

FIGURE 46-4 A child at 8 years of age with Crouzon syndrome who underwent a limited first-stage cranio-orbital procedure at 6 weeks of age. He then underwent anterior cranial vault and monobloc (orbits and midface) osteotomies with advancement. A, Profile view before monobloc procedure. B, Profile view after reconstruction. C, Craniofacial morphology before and after anterior cranial vault and monobloc osteotomies with advancement as carried out. Osteotomy locations indicated. Stabilization with cranial bone grafts and miniplates and screws. D, View of inner surface of frontal bones after bifrontal craniotomy. Compression of brain against inner table has resulted in resorption of the inner skull. This is an indication of long-standing increased intracranial pressure. E, Frontal view before surgery. F, Frontal view after reconstruction. (CONTINUED ON NEXT PAGE)

When evaluating the upper and midface in a child born with Crouzon syndrome, if the supraorbital ridge is in good position when viewed from the sagittal plane (the depth of the upper orbits is adequate), the midface and forehead have a normal arc of rotation in the transverse plane (not concave), and the root of the nose is of normal width (minimal orbital hypertelorism),

there is little need to reconstruct this region (the forehead and upper orbits) any further. In such patients, the basic residual midface deformity is in the lower half of the orbits, zygomatic buttress, and maxilla. If so, the deformity may be effectively managed using an extracranial Le Fort III osteotomy.

If the supraorbital ridges, anterior cranial base, zygomas, nose, lower orbits, and

maxilla all remain deficient in the sagittal plane (horizontal retrusion), then a monobloc osteotomy is indicated (see Figures 46-4 and 46-5). In these patients, the forehead is generally flat and retruded and will also require reshaping and advancement. If upper midface hypertelorism (increased transverse width) and midface flattening (horizontal retrusion) with loss

L, Same view but with coronal incision turned down, indicating degree of advancement at supraorbital ridge level after disimpaction. (CONTINUED ON NEXT PAGE)

of the normal facial curvature (concave arc) are also present, then the monobloc unit is split vertically in the midline (facial bipartition), a wedge of interorbital (nasal and ethmoidal) bone is removed, and the orbits and zygomas are repositioned medially while the maxilla at the palatal level is

widened. The facial bipartition is rarely required in Crouzon syndrome, but the monobloc is. When a monobloc or facial bipartition osteotomy is carried out as the "total midface" procedure, additional segmentation of the upper and lateral orbits for reconstruction may also be required to

normalize the morphology of the orbital esthetic units.

For most patients, a surgeon's attempt to simultaneously adjust the orbits and idealize the occlusion using the Le Fort III, monobloc, or facial bipartition osteotomy in isolation, without completing a separate

FIGURE 46-4 (CONTINUED) M, Lateral view of zygomatic arch and tenon extension of supraorbital rim after monobloc advancement just before miniplate fixation. N, Same view after miniplate fixation of zygomatic arch and tenon extension. O, Bird's-eye view of stabilized monobloc unit after advancement. There is increased intracranial volume (dead space) in the anterior cranial vault for brain expansion. P, Same view with elevated pericranial flaps, which will be turned in to close the opening between the nose and the anterior cranial base. A, B, D–P reproduced with permission and C adapted from Posnick JC.⁹⁸

Le Fort I osteotomy, is an error in judgment. The degree of horizontal deficiency observed at the orbits and maxillary dentition is rarely uniform. This further segmentation of the midface complex at the Le Fort I level is required to establish normal proportions. If a Le Fort I separation of the total midface complex is not carried out and the surgeon attempts to achieve a positive overbite and overjet at the incisor teeth, over-advancement of the orbits with enophthalmos will occur. The Le Fort I osteotomy is generally not performed at

the time of the total midface procedure. This will await skeletal maturity and then be combined with orthodontic treatment. Until then, an Angle Class III malocclusion will remain.

A major esthetic problem specific to the Le Fort III osteotomy when its indications are less than ideal is the creation of irregular step-offs in the lateral orbital rims. This will occur when even a moderate (Le Fort III) advancement is carried out. These lateral orbital step-offs are unattractive and are visible to the casual observ-

er at conversational distance. Surgical modification performed later is difficult, often with less than ideal esthetic results. Another problem with the Le Fort III osteotomy is the difficulty in judging an ideal orbital depth. A frequent result is either residual proptosis or enophthalmos. Simultaneous correction of orbital hypertelorism or correction of a midface arc-of-rotation problem is not possible with the Le Fort III procedure. Excessive lengthening of the nose, accompanied by flattening of the nasofrontal angle, will also occur if the Le Fort III osteotomy is selected when the skeletal morphology favors a monobloc or facial bipartition procedure. It is not possible to later correct the surgically created vertical elongation of the nose.

Final reconstruction, as discussed above, of the cranial vault deformities and orbital dystopia in Crouzon syndrome can be managed in patients as young as 5 to 7 years of age.⁴⁷ By this age, the cranial vault and orbits normally attain approximately 85 to 90% of their adult size.⁴³ When the upper midface and final cranial vault procedure is carried out at or after this age, the reconstructive objectives are to approximate adult dimensions in the cranio-orbitozygomatic region, with the expectation of a stable result (no longer influenced by growth) once healing has occurred (see Figure 46-4). Psychosocial considerations also support the upper midface and final cranial vault procedure taking place in patients 5 to 7 years of age. When the procedure is carried out at this age, the child may enter the first grade with an opportunity for satisfactory self-esteem. Routine orthognathic surgery will be necessary at the time of skeletal maturity to achieve an ideal occlusion, facial profile, and smile.

Orthognathic Procedures for Definitive Occlusal and Lower Facial Esthetic Reconstruction

Although the mandible has a normal basic growth potential in Crouzon syndrome, the maxilla does not. An Angle Class III

FIGURE 46-5 A 12-year-old boy with unrepaired Crouzon syndrome who underwent total cranial vault and monobloc osteotomies with reshaping and advancement. A, Oblique view prior to surgery. malocclusion, resulting from maxillary retrusion, with anterior open bite often results. A Le Fort I osteotomy to allow for horizontal advancement, transverse widening, and vertical adjustment is generally required in combination with an osteoplastic genioplasty (vertical reduction and horizontal advancement) to further correct the lower face deformity. Secondary deformities of the mandible should be simultaneously corrected through sagittal split osteotomies. The elective orthognathic surgery is carried out in conjunction with orthodontic treatment planned for completion at the time of early skeletal maturity (approximately 13 to 15 years in girls and 15 to 17 years in boys) (Figure 46-6).

Apert Syndrome

Apert syndrome has previously been classified on the basis of its clinical findings.^{85,86} Postmortem histologic and radiographic studies suggest that skeletal deficiencies in the patient with Apert syndrome result from a cartilage dysplasia at the cranial base, leading to premature fusion of the midline sutures from the occiput to the anterior nasal septum.⁸⁷⁻⁹¹ In addition, a component of the syndrome is four-limb symmetry complex syndactylies of the hands and feet (Figure 46-7). Fusion and malformation of other joints, including the elbows and shoulders, often occur. The soft tissue envelope also varies from that in Crouzon syndrome, with a greater downward slant to the canthi lateral and a distinctive, S-shaped upper eyelid ptosis. The quality of the skin often varies from normal, with acne and hyperhidrosis being prominent features. At the molecular level, one of two fibroblast growth factor receptor 2 (*FGFR2*) mutations involving amino acids (Ser252Trp and Pro253Arg) have been found to cause Apert syndrome in nearly all patients studied.⁹²⁻⁹⁴

Primary Cranio-orbital Decompression: Reshaping in Infancy

The initial craniofacial procedure for Apert syndrome generally requires bilater-

al coronal suture release and anterior cranial vault and upper three-quarter orbital osteotomies to expand the anterior cranial vault and reshape the upper orbits and forehead (see Figure 46-1).^{95,96} Our preference is to carry this out when the child is 9 to 11 months of age, unless signs of increased intracranial pressure are identified earlier in life. The main goals at this stage are to decompress the brain and provide increased space for it in the anterior cranial vault and to increase the orbital volume to decrease globe protrusion. The fronto-orbital surgical technique is similar to that described for Crouzon syndrome (Figure 46-8).

Further Craniotomy for Additional Cranial Vault Expansion and Reshaping in Young Children

As described for Crouzon syndrome, after the initial suture release, decompression, and reshaping carried out during infancy, the child is observed clinically at intervals by the craniofacial surgeon, pediatric neurosurgeon, pediatric ophthalmologist, and developmental pediatrician and undergoes interval CT scanning.^{76,97,98} Should signs of increased ICP develop, further decompression with reshaping of the cranial vault to expand the intracranial volume is performed (Figure 46-9). In Apert syndrome the posterior cranial vault more commonly requires expansion. The technique is similar to that described for Crouzon syndrome.

Management of the “Total Midface” Deformity in Childhood

In Apert syndrome, for almost all patients, facial bipartition osteotomies combined with further cranial vault reshaping permit a more complete correction of the abnormal craniofacial skeleton than can be achieved through other midface procedure options (ie, monobloc or Le Fort III osteotomies). When using the facial bipartition approach, a more normal arc of

rotation of the midface complex is achieved with the midline split. This further reduces the stigmata of the preoperative “flat, wide, and retrusive” facial appearance. The facial bipartition also allows the orbits and zygomatic buttresses as units to shift to the midline (correction of hypertelorism) while the maxillary arch is simultaneously widened. Horizontal advancement of the reassembled midface complex is then achieved to normalize the orbital depth and zygomatic length. The forehead is generally flat, tall, and retruded, with a constricting band just above the supraorbital ridge, giving the impression of bitemporal narrowing. Reshaping of the anterior cranial vault is simultaneously carried out (see Figures 46-8–46-10). See also Figure 46-9H for preoperative craniofacial morphology and planned and completed osteotomies and reshaping. Note that stabilization was achieved with cranial bone grafts and plate and screw fixation. A Le Fort III osteotomy is virtually never adequate for an ideal correction of the residual upper and midface deformity of Apert syndrome.

Orthognathic Procedures for Definitive Occlusal and Lower Facial Esthetic Reconstruction

The mandible has normal basic growth potential in Apert syndrome. The extent of maxillary hypoplasia will result in an Angle Class III malocclusion with severe anterior open-bite deformity. A Le Fort I osteotomy is required to allow for horizontal advancement, transverse widening, and vertical adjustment in combination with an osteoplastic genioplasty to vertically reduce and horizontally advance the chin, often combined with bilateral sagittal split osteotomies of the mandible. The elective orthognathic surgery is carried out in conjunction with detailed orthodontic treatment planned for completion at the time of early skeletal maturity (approximately 13 to 15 years in girls and 15 to 17 years in boys).

FIGURE 46-6 A 19-year-old boy born with Crouzon syndrome. When he was 11 years of age, the patient was seen by another surgeon and underwent a Le Fort III osteotomy with advancement through an extracranial approach. He presented in his late teenage years with asymmetric and dystopic orbits, zygomatic hypoplasia, a retrusive upper jaw, an asymmetric lower jaw, and a long chin. He underwent a combined orthodontic and orthognathic approach, including a Le Fort I osteotomy (horizontal advancement), bilateral sagittal split osteotomies of the mandible (correction of asymmetry), and an osteoplastic genioplasty (vertical reduction and horizontal advancement). Stabilization was accomplished with miniplates and screws. During the same general anesthesia procedure, he underwent a reopening of his coronal (scalp) incision with harvesting of split cranial grafts to recontour and augment the orbits and zygomas. Pfeiffer Syndrome

In 1964, Pfeiffer described a syndrome consisting of craniosynostosis, broad thumbs, broad great toes, and occasionally partial soft tissue syndactyly of the hands.⁹⁹ This syndrome is known to have an autosomal dominant inheritance pattern with complete penetrance documented in all recorded two- and three-generation pedigrees.¹⁰⁰ Variable expressivity of the cranio-

facial and extremity findings is common (Figures 46-11 and 46-12). Although some authors have found clinical similarities in certain patients with Pfeiffer syndrome, Crouzon syndrome, and Jackson-Weiss syndrome, the three disorders are nosologically distinct.^{47,101} According to Cohen, the phenotypes of the three conditions do not correlate well with the known molecular findings.¹⁰² Patients with these three syn-

dromes may have similar or even identical mutations in exon B of *FGFR2*, yet they breed true within families, an observation that is as yet unexplained by the molecular findings.^{102,103}

Current thinking suggests that Pfeiffer syndrome is heterogeneous because it is caused by a single recurring mutation (Pro252Arg) of *FGFR1* and by several different mutations affecting *FGFR2*.^{104,105}

FIGURE 46-10 A 5-year-old girl with Apert syndrome who underwent decompression and forehead and upper orbital reshaping at 6 months of age. She then presented to us with residual deformity requiring cranial vault and facial bipartition osteotomies with reshaping. She will require orthognathic surgery and orthodontic treatment later in the teenage years to complete her reconstruction. A, Frontal view before facial bipartition surgery. Reproduced with permission from Posnick JC.⁹⁷

Cohen has reviewed the literature and further subgrouped Pfeiffer syndrome according to clinical features, associated low-frequency anomalies, and outcome. According to Cohen, Type I corresponds to the classic Pfeiffer syndrome and is associated with satisfactory prognosis. The Type II subgroup is associated with the cloverleaf skull anomaly while Type III is not. Both Types II and III have a less favorable outcome, with frequent death in infancy. The Type I variant frequently presents with

bicoronal craniosynostosis and midface involvement. The longitudinal evaluation and staging of reconstruction depend on individual variations but is similar to that described for Crouzon syndrome.

Carpenter Syndrome

Carpenter syndrome is characterized by craniosynostosis often associated with preaxial polysyndactyly of the feet, short fingers with clinodactyly, and variable soft tissue syndactyly, sometimes postaxial ply-

dactyly, and other anomalies such as congenital heart defects, short stature, obesity, and mental deficiency.²⁴ It was first described by Carpenter in 1901 and was later recognized to be an autosomal recessive syndrome. In general, the reconstructive algorithm described for Crouzon syndrome can be followed.

Saethre-Chotzen Syndrome

Saethre-Chotzen syndrome has an autosomal dominant inheritance pattern with

Pfeiffer syndrome: evaluation and staging of reconstruction. In: Posnick JC, editor. *Craniofacial and maxillofacial surgery in children and young adults*. Philadelphia (PA): W.B. Saunders Co.; 2000. p. 349.

a high degree of penetrance and expressivity.¹⁰⁶ Its pattern of malformations may include craniosynostosis, low-set frontal hairline, ptosis of the upper eyelids, facial asymmetry, brachydactyly, partial cutaneous syndactyly, and other skeletal

anomalies. As part of the reconstruction, cranio-orbital reshaping will almost certainly be required and is similar to that described for Crouzon syndrome. Evaluation and management of the total midface deficiency and orthognathic deformities

as described for Crouzon syndrome should be followed.

Cloverleaf Skull Anomaly

Kleeblattschädel anomaly (cloverleaf skull) is a trilobular-shaped skull secondary to

craniosynostosis (Figure 46-13).^{107,108} The cloverleaf skull anomaly is known to be both etiologically and pathogenetically heterogeneous. This anomaly is also non-specific: it may occur as an isolated anomaly or together with other anomalies, making up various syndromes (namely, Apert, Crouzon, Carpenter, Pfeiffer, and Saethre-Chotzen). The extent and timing of anterior cranial vault or upper orbital, posterior cranial vault, and midface reconstruction will be dependent on individual variation in the presenting deformity. In general, the protocol described for Crouzon syndrome can be followed.

Summary

Details of the timing and techniques for correction of the varied forms of craniofacial dysostosis syndromes differ from center to center. However, an essential element of successful rehabilitation is the delivery of care by committed, experienced, and technically skilled clinicians. The combined expertise of an experienced craniofacial surgeon and pediatric neurosurgeon working together to manage the cranio-orbital malformation and the experienced maxillofacial surgeon and orthodontist working together to manage the orthognathic deformity are essential to achieve maximum function and facial esthetics for each patient.

Our preferred approach for management of the craniofacial dysostosis syndromes is to stage the reconstruction to coincide with facial growth patterns, visceral (brain and eye) function, and psychosocial development. Recognition of the need for a staged reconstruction serves to clarify the objectives of each phase of treatment for the craniofacial surgeon, team, and most importantly the patient and patient's family.

By continuing to define our rationale for the timing and extent of surgical intervention and then evaluating both function and esthetic outcomes, we will further

FIGURE 46-13 The craniofacial skeleton of a 6-month-old child born with cloverleaf skull anomaly. He underwent tracheostomy and gastrostomy shortly after birth and died of pneumonia before craniofacial reconstruction could be undertaken. A, Frontal view. B, Posterior view. C, Right oblique view. D, Left oblique view. E, Left profile view. F, Right profile view. Reproduced with permission from *Cloverleaf skull anomalies: evaluation and staging of reconstruction*. improve the quality of life for the many hundreds of children born with syndromal forms of craniosynostosis. Our objective is to see each individual achieve personal success in life without special regard for the original malformation.

Part 7

**TEMPOROMANDIBULAR
JOINT DISEASE**

Anatomy and Pathophysiology of the Temporomandibular Joint

Mark C. Fletcher, DMD, MD

Joseph F. Picuch, DMD, MD

Stuart E. Lieblich, DMD

Classification

The temporomandibular joint (TMJ) is composed of the temporal bone and the mandible, as well as a specialized dense fibrous structure, the articular disk, several ligaments, and numerous associated muscles. The TMJ is a compound joint that can be classified by anatomic type as well as by function.

Anatomically the TMJ is a diarthrodial joint, which is a discontinuous articulation of two bones permitting freedom of movement that is dictated by associated muscles and limited by ligaments.¹ Its fibrous connective tissue capsule is well

innervated and well vascularized and tightly attached to the bones at the edges of their articulating surfaces. It is also a synovial joint, lined on its inner aspect by a synovial membrane, which secretes synovial fluid. The fluid acts as a joint lubricant and supplies the metabolic and nutritional needs of the nonvascularized internal joint structures.

Functionally the TMJ is a compound joint, composed of four articulating surfaces: the articular facets of the temporal bone and of the mandibular condyle and the superior and inferior surfaces of the articular disk. The articular disk divides

the joint into two compartments. The lower compartment permits hinge motion or rotation and hence is termed *ginglymoid*. The superior compartment permits sliding (or translatory) movements and is therefore called *arthrodial*. Hence the temporomandibular joint as a whole can be termed *ginglymoarthrodial*.

Bony Structures

The articular portion of the temporal bone (Figure 47-1) is composed of three parts. The largest is the articular or mandibular fossa, a concave structure extending from the posterior slope of the articular emi-

FIGURE 47-1 A, The left temporomandibular joint viewed from the sagittal aspect on a dry skull. B, The left temporomandibular joint viewed from the oblique/coronal aspect on a dry skull. C, The left glenoid fossa and articular eminence.

FIGURE 47-2 The mandibular condyle. Reproduced with permission from Piecuch JF, Lieblch SE. *Anatomy and pathology of the temporomandibular joint*. nence to the postglenoid process, which is a ridge between the fossa and the external acoustic meatus. The surface of the articular fossa is thin and may be translucent on a dry skull. This is not a major stress-bearing area. The second portion, the articular eminence, is a transverse bony prominence that is continuous across the articular surface

mediolaterally. The articular eminence is usually thick and serves as a major functional component of the TMJ. The articular eminence is distinguished from the articular tubercle, a nonarticulating process on the lateral aspect of the zygomatic root of the temporal bone, which serves as a point of attachment of collateral ligaments. The third portion of the articular surface of the temporal bone is the preglenoid plane, a flattened area anterior to the eminence.

The mandible is a U-shaped bone that articulates with the temporal bone by means of the articular surface of its condyles, paired structures forming an approximately 145° to 160° angle to each other. The mandibular condyle (Figure 47-2) is approximately 15 to 20 mm in width and 8 to 10 mm in anteroposterior dimension. The condyle tends to be rounded mediolaterally and convex anteroposteriorly. On its medial aspect just below its articular surface is a prominent depression, the pterygoid fovea, which is the site of attachments of the lateral pterygoid muscle.

In: Peterson LF, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1859.

Cartilage and Synovium

Lining the inner aspect of all synovial joints, including the TMJ, are two types of tissue: articular cartilage and synovium (Figure 47-3). The space bound by these two structures is termed the *synovial cavity*, which is filled with synovial fluid. The articular surfaces of both the temporal bone and the condyle are covered with dense articular fibrocartilage, a fibrous connective tissue. This fibrocartilage covering has the capacity to regenerate and to remodel under functional stresses. Deep to the fibrocartilage, particularly on the condyle, is a proliferative zone of cells that may develop into either cartilaginous or osseous tissue. Most change resulting from function is seen in this layer.

Articular cartilage is composed of chondrocytes and an intercellular matrix of collagen fibers, water, and a nonfibrous filler material, termed *ground substance*. Chondrocytes are enclosed in otherwise hollow spaces, called lacunae, and are arranged in three layers characterized by different cell shapes (Figure 47-4A). The superficial zone contains small flattened cells with their long axes parallel to the surface.² In the middle zone the cells are larger and rounded and appear in columnar fashion perpendicular to the surface. The deep zone contains the largest cells and is divided by the “tide mark” below which some degree of calcification has occurred. There are few blood vessels in any of these areas, with cartilage being nourished primarily by diffusion from the synovial fluid.

Collagen fibers are arranged in arcades with an interlocking meshwork of fibrils parallel to the articular surface joining together as bundles and descending to their attachment in the calcified cartilage between the tide mark (Figure 47-4B). Functionally these arcades provide a framework for interstitial water and ground substance to resist compressive forces encountered in joint loading. Formed by intramembranous processes the TMJ’s

FIGURE 47-4 Articular cartilage. Adapted from Albright JA and Brand RA.²

articular cartilage contains a greater proportion of collagen fibers (fibrocartilage) than other synovial joints, which are covered instead by hyaline cartilage.

The ground substance contains a variety of plasma proteins, glucose, urea, and salts, as well as proteoglycans, which are synthesized by the Golgi apparatus of the chondrocytes. Proteoglycans are macromolecules consisting of a protein core attached to many glycosaminoglycan chains of chondroitin sulfate and keratan sulfate. Proteoglycans play a role in the diffusion of nutrients and metabolic breakdown products. Ground substance permits the entry and release of large quantities of water, an attribute thought to be significant in giving cartilage its characteristic functional elasticity in response to deformation and loading.

Lining the capsular ligament is the synovial membrane, a thin, smooth, richly innervated vascular tissue without an epithelium. Synovial cells, somewhat undifferentiated in appearance, serve both a phagocytic and a secretory function and are thought to be the site of production of hyaluronic acid, a glycosaminoglycan found in synovial fluid. Some synovial cells, particularly those in close approxi-

mation to articular cartilage, are thought to have the capacity to differentiate into chondrocytes. The synovium is capable of rapid and complete regeneration following injury. Recently, synovial cells (as well as chondrocytes and leukocytes) have been the focus of extensive research regarding the production of anabolic and catabolic cytokines within the TMJ.³

Synovial fluid is considered an ultrafiltrate of plasma.² It contains a high concentration of hyaluronic acid, which is thought to be responsible for the fluid's high viscosity. The proteins found in synovial fluid are identical to plasma proteins; however, synovial fluid has a lower total protein content, with a higher percentage of albumin and a lower percentage of α_2 -globulin. Alkaline phosphatase, which may also be present in synovial fluid, is thought to be produced by chondrocytes. Leukocytes are also found in synovial fluid, with the cell count being less than 200 per cubic millimeter and with less than 25% of these cells being polymorphonuclear. Only a small amount of synovial fluid, usually less than 2 mL, is present within the healthy TMJ.

Functions of the synovial fluid include lubrication of the joint, phagocytosis of particulate debris, and nourishment of the

articular cartilage. Joint lubrication is a complex function related to the viscosity of synovial fluid and to the ability of articular cartilage to allow the free passage of water within the pores of its glycosaminoglycan matrix. Application of a loading force to articular cartilage causes a deformation at the location. It has been theorized that water is extruded from the loaded area into the synovial fluid adjacent to the point of contact. The concentration of hyaluronic acid and hence the viscosity of the synovial fluid is greater at the point of load, thus protecting the articular surfaces. As the load passes to adjacent areas the deformation passes on as well, while the original point of contact regains its shape and thickness through the reabsorption of water. Exact mechanisms of flow between articular cartilage and synovial fluid are as yet unclear. Nevertheless the net result is a coefficient of friction for the normally functioning joint—approximately 14 times less than that of a dry joint.

The Articular Disk

The articular disk (Figure 47-5) is composed of dense fibrous connective tissue and is nonvascularized and noninnervated, an adaptation that allows it to resist

FIGURE 47-5 The temporomandibular joint (lateral view). Adapted from Bell WE.⁴

pressure.⁴ Anatomically the disk can be divided into three general regions as viewed from the lateral perspective: the anterior band, the central intermediate zone, and the posterior band. The thickness of the disk appears to be correlated with the prominence of the eminence. The intermediate zone is thinnest and is generally the area of function between the mandibular condyle and the temporal bone. Despite the designation of separate portions of the articular disk, it is in fact a homogeneous tissue and the bands do not consist of specific anatomic structures. The disk is flexible and adapts to functional demands of the articular surfaces.⁵ The articular disk is attached to the capsular ligament anteriorly, posteriorly, medially, and laterally.⁶ Some fibers of the superior head of the lateral pterygoid muscle insert on the disk at its medial aspect, apparently serving to stabilize the disk to the mandibular condyle during function.

Retrodiskal Tissue

Posteriorly the articular disk blends with a highly vascular, highly innervated structure—the bilaminar zone, which is involved in the production of synovial fluid. The superior aspect of the retrodiskal tissue contains elastic fibers and is termed the *superior retrodiskal lamina*, which attaches to the

tympanic plate and functions as a restraint to disk movement in extreme translatable movements.⁵ The inferior aspect of the retrodiskal tissue, termed the *inferior retrodiskal lamina*, consists of collagen fibers without elastic tissue and functions to connect the articular disk to the posterior margin of the articular surfaces of the condyle. It is thought to serve as a check ligament to prevent extreme rotation of the disk on the condyle in rotational movements.

Ligaments

Ligaments associated with the TMJ are composed of collagen and act predominantly as restraints to motion of the condyle and the disk. Three ligaments—collateral, capsular, and temporomandibular ligaments—are considered functional ligaments because they serve as major anatomic components of the joints. Two other ligaments—sphenomandibular and stylo-mandibular—are considered accessory ligaments because, although they are attached to osseous structures at some distance from the joints, they serve to some degree as passive restraints on mandibular motion.

The collateral (or diskal) ligaments (see Figure 47-3) are short paired structures attaching the disk to the lateral and medial poles of each condyle. Their function is to restrict movement of the disk away from

the condyle, thus allowing smooth synchronous motion of the disk-condyle complex. Although the collateral ligaments permit rotation of the condyle with relation to the disk, their tight attachment forces the disk to accompany the condyle through its translatable range of motion.⁶

The capsular ligament (see Figures 47-3, 47-5, 47-6, and 47-7) encompasses each joint, attaching superiorly to the temporal bone along the border of the mandibular fossa and eminence and inferiorly to the neck of the condyle along the edge of the articular facet. It surrounds the joint spaces and the disk, attaching anteriorly and posteriorly as well as medially and laterally, where it blends with the collateral ligaments. The function of the capsular ligament is to resist medial, lateral, and inferior forces, thereby holding the joint together. It offers resistance to movement of the joint only in the extreme range of motion. A secondary function of the capsular ligament is to contain the synovial fluid within the superior and inferior joint spaces.

The temporomandibular (lateral) ligaments (see Figure 47-7) are located on the lateral aspect of each TMJ.⁵ Unlike the capsular and collateral ligaments, which have medial and lateral components within each

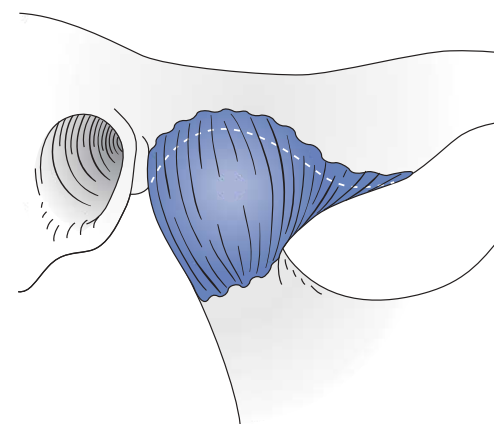

FIGURE 47-6 Capsular ligament (lateral view). Adapted from Piecuch JF, Liebllich SE. *Anatomy and pathology of the temporomandibular joint*. In: Peterson LF, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1861.

FIGURE 47-7 Temporomandibular joint (lateral aspect). Adapted from Okeson JP.

joint, the temporomandibular ligaments are single structures that function in paired fashion with the corresponding ligament on the opposite TMJ. Each temporomandibular ligament can be separated into two distinct portions, that have different functions.⁶ The outer oblique portion descends from the outer aspect of the articular tubercle of the zygomatic process posteriorly and inferiorly to the outer posterior surface of the condylar neck. It limits the amount of inferior distraction that the condyle may achieve in translatory and rotational movements. The inner horizontal portion also arises from the outer surface of the articular tubercle, just medial to the origin of the outer oblique portion of the ligament, and runs horizontally backward to attach to the lateral pole of the condyle and the posterior aspect of the disk. The function of the inner horizontal portion of the temporomandibular ligament is to limit posterior movement of the condyle, particularly during pivoting movements, such as when the mandible moves laterally in chewing function. This restriction of posterior movement serves to protect the retrodiskal tissue.

The sphenomandibular ligament (Figure 47-8) arises from the spine of the sphenoid bone and descends into the fan-like insertion on the mandibular lingula, as well as on the lower portion of the medial side of the condylar neck.¹ The sphenomandibular ligament serves to some degree

as a point of rotation during activation of the lateral pterygoid muscle, thereby contributing to translation of the mandible.

The stylomandibular ligament (see Figure 47-8) descends from the styloid process to the posterior border of the angle of the mandible and also blends with the fascia of the medial pterygoid muscle. It functions similarly to the sphenomandibular ligament as a point of rotation and also limits excessive protrusion of the mandible.

Vascular Supply and Innervation

The vascular supply of the TMJ arises primarily from branches of the superficial temporal and maxillary arteries posteriorly and the masseteric artery anteriorly. There is a rich plexus of veins in the posterior aspect of the joint associated with the retrodiskal tissues, which alternately fill and empty with protrusive and retrusive movements, respectively, of the condyle-disk complex and which also function in the production of synovial fluid. The nerve supply to the TMJ is predominantly from branches of the auriculotemporal nerve with anterior contributions from the masseteric nerve and the posterior deep temporal nerve.¹ Many of the nerves

to the joint appear to be vasomotor and vasosensory, and they may have a role in the production of synovial fluid.

Musculature

All muscles attached to the mandible influence its movement to some degree. Only the four large muscles that attach to the ramus of the mandible are considered the muscles of mastication; however, a total of 12 muscles actually influence mandibular motion, all of which are bilateral.¹ Muscle pairs may function together for symmetric movements or unilaterally for asymmetric movement. For example, contraction of both lateral pterygoid muscles results in protrusion and depression of the mandible without deviation, whereas contraction of one of the lateral pterygoid muscles results in protrusion and opening with deviation to the opposite side.

Muscles influencing mandibular motion may be divided into two groups by anatomic position. Attaching primarily to the ramus and condylar neck of the mandible is the supramandibular muscle group, consisting of the temporalis, masseter, medial pterygoid, and lateral pterygoid muscles. This group functions predominantly as the elevators of the

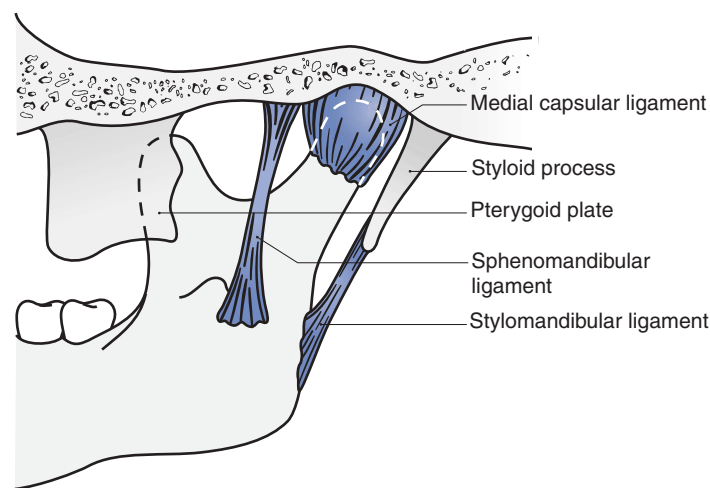

FIGURE 47-8 Temporomandibular ligament (medial view). Adapted from Piccuch JE, Lieblch SE. *Anatomy and pathology of the temporomandibular joint*. In: Peterson LF, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1863.

mandible. The lateral pterygoid does have a depressor function as well.⁷ Attaching to the body and symphyseal area of the mandible and to the hyoid bone is the inframandibular group, which functions as the depressors of the mandible. The inframandibular group includes the four suprahyoid muscles (digastric, geniohyoid, mylohyoid, and stylohyoid) and the four infrahyoid muscles (sternohyoid, omohyoid, sternothyroid, and thyrohyoid). The suprahyoid muscles attach to both the hyoid bone and the mandible and serve to depress the mandible when the hyoid bone is fixed in place. They also elevate the hyoid bone when the mandible is fixed in place. The infrahyoid muscles serve to fix the hyoid bone during depressive movements of the mandible.

Supramandibular Muscle Group

The temporalis muscle (Figure 47-9) is a large fan-shaped muscle taking its origin from the temporal fossa and lateral aspect of the skull, including portions of the parietal, temporal, frontal, and sphenoid bones. Its fibers pass between the zygomatic arch and the skull and insert on the

mandible at the coronoid process and anterior border of the ascending ramus down to the occlusal surface of the mandible, posterior to the third molar tooth.¹ Viewed coronally the temporalis muscle has a bipennate character in that fibers arising from the skull insert on the medial aspect of the coronoid process, whereas fibers arising laterally from the temporalis fascia insert on the lateral aspect of the coronoid process. In an anteroposterior dimension the temporalis muscle consists of three portions: the anterior, whose fibers are vertical; the middle, with oblique fibers; and the posterior portion, with semihorizontal fibers passing forward to bend under the zygomatic arch. The function of the temporalis muscle is to elevate the mandible for closure. It is not a power muscle. In addition contraction of the middle and posterior portions of the temporalis muscle can contribute to retrusive movements of the mandible. To a small degree unilateral contraction of the temporalis assists in deviation of the mandible to the ipsilateral side.

The masseter muscle (Figure 47-10), a short rectangular muscle taking its origin

from the zygomatic arch and inserting on the lateral surface of the mandible, is the most powerful elevator of the mandible and functions to create pressure on the teeth, particularly the molars, in chewing motions. The masseter muscle is composed of two portions, superficial and deep, which are incompletely divided, yet have somewhat different functions. The superficial portion originates from the lower border of the zygomatic bone and the anterior two-thirds of the zygomatic arch and passes inferiorly and posteriorly to insert on the angle of the mandible. The deep head originates from the inner surface of the entire zygomatic arch and on the posterior one-third of the arch from its lower border. The deep fibers pass vertically to insert on the mandible on its lateral aspect above the insertion of the superficial head. The superficial portion in particular has a multipennate appearance with alternating tendinous plates and fleshy bundles of muscle fibers, which serve to increase the power of the muscle. Both the superficial and deep portions of the masseter muscle are powerful elevators of the mandible, but they function independently and reciprocally in other movements. Electromyographic studies show that the deep layer of the masseter is always silent during protrusive movements and always active during forced retrusion, whereas the superficial portion is active during protrusion and silent during retrusion.⁸ Similarly the deep masseter is active in ipsilateral movements but does not function in contralateral movements, whereas the superficial masseter is active during contralateral movements but not in ipsilateral movements.

The medial pterygoid muscle (Figure 47-11) is rectangular and takes its origin from the pterygoid fossa and the internal surface of the lateral plate of the pterygoid process, with some fibers arising from the tuberosity of the maxilla and the palatine bone. Its fibers pass inferiorly and insert on the medial surface of the mandible,

FIGURE 47-10 The masseter muscle. Adapted from Picuch JE, Lieblisch SE. *Anatomy and pathology of the temporomandibular joint*. In: Peterson LF, Indresano AT, Marciani RD, Roser SM. *Principles of oral and maxillofacial surgery*. Vol. 3. Philadelphia (PA): J.B. Lippincott Company; 1992. p. 1865.

inferiorly and posteriorly to the lingual. Like the masseter muscle the medial pterygoid fibers have alternating layers of fleshy and tendinous parts, thereby increasing the power of the muscle. The main function of the medial pterygoid is elevation of the mandible, but it also functions somewhat in unilateral protrusion in a synergism with the lateral pterygoid to promote rotation to the opposite side.

The lateral pterygoid muscle (see Figure 47-11) has two portions that can be considered two functionally distinct muscles. The larger inferior head originates from the lateral surface of the lateral pterygoid plate.⁹ Its fibers pass superiorly and outward to fuse with the fibers of the superior head at the neck of the mandibular condyle, inserting into the pterygoid fovea. The superior head originates from the infratemporal surface of the greater sphenoid wing, and its fibers pass inferiorly, posteriorly, and outward to insert in the superior aspect of the pterygoid

fovea, the articular capsule, and the articular disk at its medial aspect, as well as to the

medial pole of the condyle. Anatomic studies have shown that the majority of the superior head fibers insert into the condyle rather than the disk.

The inferior and superior heads of the lateral pterygoid muscle function independently and reciprocally.^{8,10} The primary function of the inferior head is protrusive and contralateral movement. When the bilateral inferior heads function together, the condyle is pulled forward down the articular eminence, with the disk moving passively with the condylar head. This forward movement of the condyle down the inclined plane of the articular eminence also contributes to opening of the oral cavity. When the inferior head functions unilaterally the resulting medial and protrusive movement of the condyle results in contralateral motion of the mandible. The function of the superior head of the lateral pterygoid muscle is predominantly involved with closing movements of the jaw and with retrusion and ipsilateral movement. A summary of the movements of the lateral pterygoid muscle and the other supramandibular muscles is given in Table 47-1.

Inframandibular Muscle Group

The inframandibular muscles can be subdivided into two groups: the suprahyoids and the infrahyoids. The suprahyoid group consists of the digastric, geniohyoid, mylohyoid, and stylohyoid muscles; lies between the mandible and the hyoid bone; and serves to either raise the hyoid bone, if the mandible is fixed in position by the supramandibular group, or depress the mandible, if the hyoid bone is fixed in position by the infrahyoids. The infrahyoid group, consisting of the sternohyoid, omohyoid, sternothyroid, and thyrohyoid muscles, attaches to the hyoid bone superiorly and to the sternum, clavicle, and scapula inferiorly. This group of muscles can either depress the hyoid bone or hold the hyoid bone in position, relative to the trunk, during opening movements of the mandible.

Biomechanics of Temporomandibular Joint Movement

Complex free movements of the mandible are made possible by the relation of four distinct joints that are involved in mandibular movement: the inferior and superior joints—bilaterally. Two types of movement are possible: rotation and translation.

The inferior joints, consisting of the condyle and disk, are responsible for rotation, a hinge-like motion. The center of rotation is considered to be along a horizon-

tal axis passing through both condyles.^{4,5} In theory pure hinge motion of approximately 2.5 cm measured at the incisal edges of the anterior teeth is possible. Nevertheless most mandibular movements are translatory as well, involving a gliding motion between the disk and the temporal fossa, which are the components of the superior joints. The mandible and disk glide together as a unit because they are held together by the collateral ligaments. The maximum forward and lateral movement of the upper joint in translation is approximately 1.5 cm.

All movements of the mandible, whether symmetric or asymmetric, involve close contact of the condyle, disk, and articular eminence. Pure opening, closing, protrusive, and retrusive movements are possible as a result of bilaterally symmetric action of the musculature. Asymmetric movements, such as those seen in chewing, are made possible by unilateral movements of the musculature with different amounts of translation and rotation occurring within the joints on either side.

The positioning of the condyle and disk within the fossa, as well as the constant contact between the condyle, disk, and eminence, is maintained by continuous activity of the muscles of mastication, particularly the supramandibular group. The ligaments associated with the TMJ do not move the joint. Although they can be lengthened by movements of muscles, they do not stretch (ie, do not have an elastic recoil that returns them to a resting position automatically).

Instead the role of the ligaments is that of a passive restriction of movement at the extreme ranges of motion. During normal function rotational and translational movements occur simultaneously, permitting the free range of motion necessary in speaking and chewing.

Pathology of the Temporomandibular Joint

The demand for treatment of temporomandibular joint dysfunction (TMJD) is well known. Most studies estimate the prevalence of clinically significant TMJ-related jaw pain to be at least 5% of the general population. Approximately 2% of the general population seeks treatment for a TMJ-related symptom.^{11,12} TMJD may be the result of muscular hyperfunction or parafunction, and/or underlying primary or secondary degenerative changes within the joint. It is important to note however that no single causative factor leading to TMJD has been unequivocally demonstrated in scientifically based studies.¹³ Classification of TMJD is separated into nonarticular and articular categories and has been eloquently described by de Bont and colleagues.¹³

Nonarticular disorders include muscle disorders such as myofascial dysfunction, muscle spasm (with splinting, pain, and muscle guarding), and myositis. Articular disorders, often accompanied by internal derangement, include noninflammatory and inflammatory arthropathies, growth disorders, and connective tissue disorders. In diagnosing and treating TMJD it is helpful to assess patients with the above classification as a frame of reference Table 47-2. Treatment modalities can vary significantly depending on this classification.

Nonarticular Temporomandibular Disorders

Nonarticular TMJ disorders most commonly manifest as masticatory muscle dysfunction. Approximately one-half or more of all TMJDs are forms of masticatory

Table 47-2 General Classification of Synovial Disorders*Articular Disorders*

Noninflammatory arthropathies
Primary osteoarthritis (no clear predisposing factor)
Secondary osteoarthritis (trauma, previous surgery, avascular necrosis)
Mechanical derangements
Bone and cartilage disorders with articular manifestations
Inflammatory arthropathies
Synovitis
Capsulitis
Rheumatoid arthritis
Juvenile rheumatoid arthritis
Seronegative polyarthritis
Ankylosing spondylitis
Psoriatic arthritis
Reactive arthritis (bacterial, viral, fungal)
Growth disorders
Non-neoplastic: developmental (hyperplasia, hypoplasia, dysplasia)
Non-neoplastic: acquired (ie, condylolysis)
Neoplasm
Pseudotumors (synovial chondromatosis)
Benign (chondroma, osteotoma)
Malignant (primary, metastatic)
Diffuse connective tissue disorders
Miscellaneous articular disorders

Nonarticular Disorders

Muscle disorders
Muscle spasm (strain)
Myofascial pain and dysfunction (MPD)
Fibromyalgia
Myotonic dystrophies
Myositis ossificans progressiva
Growth disorders

Adapted from de Bont L et al.¹³

myalgia.^{14,15} They include such conditions such as acute muscle strain and spasm, myofascial pain and dysfunction (MPD), chronic conditions such as fibromyalgia, and less commonly, myotonic dystrophies and myositis ossificans. They invariably contribute to decreased mandibular range of motion and pain. The important role of

the supramandibular and inframandibular muscle groups on mandibular movement and function is evident in these conditions. Other nonarticular disorders include growth disorders affecting TMJ function and miscellaneous factors such as heterotopic bone formation leading to TMJD.

MPD is most commonly related to masseter or temporalis muscle spasm.¹⁶ Additionally it can involve the pterygoids or any combination of the supramandibular or inframandibular muscle groups. Parafunctional habits such as bruxism and jaw clenching are thought to be the main contributors to MPD and have also been found to be causative in acute closed-lock conditions. The literature is replete with various treatment modalities for MPD. Such treatments include occlusal adjustments (for gross discrepancies), night-guard appliances (for joint unloading, jaw repositioning, and occlusal protection), nonsteroidal anti-inflammatory medications, muscle relaxants, and physical therapy. These treatment modalities, alone or in combination, remain the standard of care for the treatment of nonarticular TMJD, particularly MPD.

Fibromyalgia is a systemic condition marked by poor sleep, generalized pain with absence of localization to joints, and a history of somatization in other organ systems such as irritable bowel syndrome and headaches.¹⁷ It is typically observed in an older population than MPD and has a female predilection. Fibromyalgia is often difficult to differentiate from MPD and is treated in similar fashion; that is, nonsurgically, with anti-inflammatory medications, dietary modifications, home-care techniques, bite appliances, and physical therapy. There appears to be a poorer overall response to the treatment of fibromyalgia when compared with MPD.

Rarely other nonarticular conditions such as myotonic dystrophy and myositis ossificans progressiva can lead to signifi-

cant loss of function and pain in the TMJ region. Myotonic dystrophy is a dominantly inherited multisystem disorder that may affect facial muscles in fully developed disease states.¹⁸ This condition may contribute to atrophy and fibrosis of the supramandibular and inframandibular musculature. Clinically there are a variety of types of myotonic dystrophies. They tend to exert their pathologic effects in similar fashion, sometimes resulting in trismus, loss of function, and pain. Myositis ossificans progressiva is a rare condition resulting in fibrosis of soft tissues after apparent minor trauma. This condition has been reported to affect TMJ function after local trauma, including surgery, and can result in significant loss of mandibular range of motion, trismus, and pain.¹⁹ Soft tissue ossification can sometimes occur after head trauma, severe burns, or neurogenic stimulus. In these cases heterotopic bone formation is observed and can lead to ankylosis in multiple joints throughout the body including the TMJ.²⁰

Articular Temporomandibular Disorders

Noninflammatory articular disorders of the TMJ, the most common of which is osteoarthritis, are often idiopathic. Osteoarthritis can manifest as chondromalacia (softening of the cartilage), temporary or permanent disk displacement, degenerative changes within bone and cartilage often with osteophyte formation and remodeling, fibrosis, or any combination of the above. Noninflammatory articular disorders may also be secondary to trauma, infection, previous surgery, crystal deposition disorders (gout and pseudogout), avascular necrosis, or structural damage to joint cartilage resulting in disk displacement and/or perforation (Figure 47-12). TMJ disk displacement has been categorized through a widely accepted staging system by Wilkes, using such criteria as severity of displacement and chronicity (Table 47-3).²¹

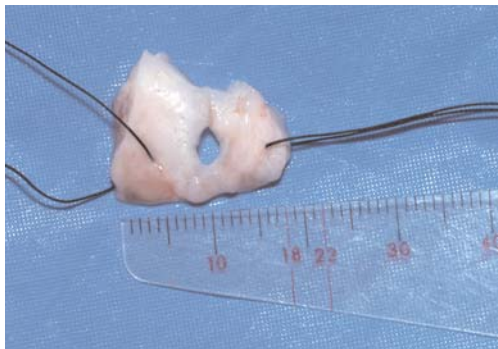

FIGURE 47-12 Perforated disk (Wilkes stage V patient).

Noninflammatory arthropathies are distinctly limited in their amount of overt inflammation and may be clinically silent or focal in nature. Alternatively if the condition becomes more severe, symptoms will ensue. If degenerative changes progress to synovitis, joint effusion (secondary to increased vascular permeability), or capsulitis, it is then considered to have transformed into an inflammatory arthropathy.

Inflammatory arthropathies are primarily due to such conditions as rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, or arthritis resulting from infectious causes (see Table 47-2). Secondary causes of inflammatory arthropathies include synovitis, capsulitis, traumatic arthritis, or acute inflamed crystal-induced arthritis, such as gout. As discussed previously non-inflammatory arthropathies can progress to the inflammatory types through increasing concentrations of degradation products within the joint. Degenerative changes resulting in the release of inflammatory mediators have been demonstrated to worsen the degree of tissue destruction and dysfunction within the TMJ. This pathologic inflammatory cascade has been the primary focus of current TMJ research.

The past decade has shed new light on the cause and treatment of articular disorders (mainly, internal derangement) of the TMJ. Gross evaluation of disk position and disk integrity has traditionally been the mainstay of diagnosis and surgical treat-

ment. More recently the physiologic activity of synovial cells, chondrocytes, and inflammatory cells in symptomatic joints have been associated with pathogenesis. This fundamental shift in focus has changed the primary treatment approach from open-joint surgery aimed at restoring the functional anatomy of the TMJ, to less invasive techniques directed toward lysis of adhesions and intracapsular lavage.²² TMJ arthrocentesis and arthroscopy are thought to achieve an alteration in the joint milieu favoring a reduction in symptoms and improved joint function. Open-joint surgery nonetheless may still have a role in severe degenerative disease when preoperative criteria are met and surgery is indicated.

Milam and Schmitz have proposed a variety of molecular biologic mechanisms for TMJD.²³ Synovoid cells, chondrocytes, and inflammatory cells in the TMJ produce a physiologic balance between anabolic and catabolic cytokines.²³ Anabolic cytokines such as insulin-like growth factor-I and transforming growth factor beta are instrumental in the formation of extracellular joint matrix molecules. Collagen, proteoglycans, and glycoproteins are essential in load-bearing joints like the TMJ. Alternatively catabolic cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor alpha (TNF- α) have been identified with the formation of proteases within the TMJ. These proteases (aspartic, cysteine, serine, and metalloproteases, among others) operate at low and neutral pH to exert their pathologic effects leading to degenerative changes.

Oxidative stress, often found associated with pathologic joints, is thought to contribute to free radical formation in the TMJ. The presence of free radicals has been postulated as an amplifying factor in the activation of cytokines, enzymes, neuropeptides, and arachidonic acid metabolites leading to degenerative joint disease.²⁴ Nitric oxide, a free radical involved in regulating vascular tone, has been observed at higher concentrations in arthritic joints. Nitric oxide has

direct effects on prostaglandin synthesis and cyclooxygenase-2 enzymes leading to synovial inflammation and tissue destruction.²⁵ In a normal functioning joint a delicate balance is maintained between anabolic and catabolic mechanisms. In symptomatic joints catabolic processes have been found to exert greater overall effects thus disrupting the balance between anabolic physiologic maintenance and the negative effects of catabolic cytokines.

TMJ synovial fluid analysis has proven to be an excellent vehicle for evaluating the proposed contribution of cytokines, proteinases, and other catabolites to TMJD. Multiple independent studies support the hypothesis of catabolic imbalance within the joint. Kubota and colleagues demonstrated increased levels of IL-1 β , IL-6, and active matrix metalloproteinases in TMJs with internal derangement and osteoarthritis when compared with control samples.²⁶ This study suggests the presence of elevated concentrations of these cytokines and proteinases serving as potential catabolic markers for cartilage degradation in the human TMJ. Murakami and colleagues reported high concentrations of chondroitin-4 and chondroitin-6 sulfates compared with hyaluronic acid in the TMJ synovial fluid of patients with internal derangement suggesting glycosaminoglycan components as markers of joint pathology.²⁷ Israel and colleagues demonstrated the prevalence of synovitis and osteoarthritis through arthroscopic evaluation in symptomatic TMJs.²⁸ These findings correlated with increased levels of keratan sulfate in the synovial fluid

Table 47-3 Wilkes Classification

Stage I	Early reducing disk displacement
Stage II	Late reducing disk displacement
Stage III	Nonreducing disk displacement: acute/subacute
Stage IV	Nonreducing disk displacement: chronic
Stage V	Nonreducing disk displacement: chronic with osteoarthritis

of these joints suggesting its role as a potential biochemical marker for articular cartilage degradation.²⁸ Recently osteoclastogenesis inhibitory factor/osteoprotegerin (OCIF/OPG), a member of the TNF receptor family, has been studied in synovial fluid samples of TMJD patients.²⁹ Increased osteoclastic activity has been seen histologically in diseased mandibular condyles. Osteoclast differentiation requires cell-to-cell contact between osteoclast progenitors and bone marrow stromal cells. The presence of OCIF/OPG is thought to inhibit osteoclast differentiation by preventing the cell-to-cell contact needed for such activity. Synovial fluid samples in this study demonstrated decreased amounts of OCIF/OPG in osteoarthritic and internally deranged joints suggesting its physiologically important function in healthy joints. Although further investigation of synovial fluid components in TMJD is necessary to formulate definitive conclusions, it continues to shed new light on the pathogenesis and treatment of such disorders.

Treatment of patients with internal derangement of the TMJ typically begins with nonsurgical treatment modalities. Bite appliance therapy, diet modifications, nonsteroidal anti-inflammatory medications, muscle relaxants, moist heat or ice, and physical therapy have been found to be efficacious.³⁰ Surgical intervention is typically employed only after failure of nonsurgical treatment objectives.

A variety of surgical treatment modalities have been used in the treatment of articular TMJD. Arthrocentesis and TMJ arthroscopy have been found to be minimally invasive effective treatments for articular TMJD by decreasing pain and increasing mandibular range of motion. (Surgical techniques for arthroscopy are addressed in Chapter 49, "Temporomandibular Joint Arthrocentesis and Arthroscopy: Rationale and Technique.") Indications for these modalities include, but are not limited to, acute closed-lock degenerative joint disease accompanied by pain and limited range of

motion and joint effusion. Arthrocentesis and arthroscopy have also been reported to be useful in severe, often sudden onset, closed-lock disease due to an anchored or "stuck disk" phenomenon. This proposed phenomenon involves the disk becoming adherent to the glenoid fossa through increased intra-articular friction, with or without the formation of adhesions within the joint. Lysis of adhesions with joint lavage has been reported efficacious in restoring mandibular range of motion and decreasing pain in these clinical scenarios.^{31,32} TMJ arthrocentesis and arthroscopy show promising results using the above criteria of pain symptoms and mandibular range of motion.³³ Based on the pathophysiology discussed in this chapter, a hypothesis explaining the efficacy of joint lavage relates to a proposed alteration in the biochemical constituents of the joint fluid, thus shifting the balance toward anabolic processes while reducing the amount of active catabolites contained within the joint.³⁴

Indications for open arthrotomy include but are not limited to joint ankylosis, the need for reconstruction due to condylar resorption or growth disturbance, history of previous surgery, removal of foreign bodies, neoplasia, trauma, or severe degenerative disease precluding less invasive interventions. (Indications and techniques for open TMJ surgery are addressed more thoroughly in Chapter 50, "Surgery for Internal Derangements of the Temporomandibular Joint," and Chapter 51, "Management of the Patient with End-Stage Temporomandibular Joint Disease.") Open-joint surgery is primarily based on restoration of the functional anatomy of the TMJ when less invasive techniques are not feasible or unsuccessful. Recent data suggest comparable outcomes between open and closed surgery in the TMJ with lower morbidity associated with the latter.³⁵ Open TMJ surgery remains a viable treatment option at the end of the surgical treatment algorithm. New insight into the pathogenesis of TMJD has opened the

door to less invasive (albeit equally effective) treatment options for a large number of TMJD patients.

Infections of the Temporomandibular Joint

Infections of the TMJ are not common. Prompt diagnostic and therapeutic intervention is required when an infection of the TMJ is suspected because joint distention is usually painful and permanent changes in joint function can occur. On examination patients usually exhibit a posterior open bite on the ipsilateral side as a result of the increased joint fluid. The patient will also maintain a posture toward the contralateral side.³⁶ The surface overlying an infected joint is often warm, and fluctuance is occasionally felt.

The bacteria causing an infected joint are usually spread through a hematogenous route. The synovium is vascular and lacks a basement membrane, which permits bloodborne bacteria to gain access to the joint space.³⁷ Joints with underlying arthritic disease tend to be more susceptible to distant infection. Although the source of the bacteria is usually at a distant site, spread from dental infections of maxillary teeth has been reported in which the bacteria are thought to spread through the pterygoid plexus of veins to the joint.³⁸ Direct inoculation of a joint area following a traumatic injury is also possible. Complications of infections of the TMJ include fistula formation, fibrosis or bony ankylosis, temporal bone osteomyelitis, and intracranial abscess formation.

A thorough history and review of systems aids in the diagnosis of acute infectious arthritis of the TMJ. Active infection in adjacent sites, especially the ipsilateral maxillary molars, should be searched for. Other joints must be assessed to determine if they are involved. Initially aspiration of the joint should be considered to both relieve the pain from the joint capsular distention and to help in the identification

of the infecting organism(s). The aspiration is performed by using a 20-gauge or larger needle under sterile conditions. The synovial fluid should be Gram stained and cultured for both aerobic and anaerobic bacteria. Sedation or general anesthesia may be required for the arthrocentesis.

In sexually active adults 60% of general acute infectious arthritis is due to *Neisseria gonorrhoeae*.³⁹ The majority of these patients have a prodrome of malaise, anorexia, headaches, fever, and chills. A few days of migratory arthritis usually precedes the localization of infection in one or two joints. Markowitz and Gerry reported a TMJ involvement rate of 3% in patients with disseminated gonococcal arthritis.⁴⁰ In children under 2 years of age almost 50% of acute infectious arthritis is due to *Haemophilus influenzae*. No reports of TMJ involvement are available. Other gram-positive cocci have been isolated from TMJ infections in all age groups, including staphylococci (particularly in the elderly) and β -hemolytic streptococci. The adherence characteristics of *Staphylococcus aureus* and *Neisseria gonorrhoeae* to synovium account for their prevalence.⁴¹ Thus, the best choice for initial empiric antibiotic therapy for an acute infectious TMJ arthritis is an agent that combines a penicillin with a β -lactamase inhibitor. The combination of ampicillin and sulbactam will cover infections from the staphylococcal and streptococcal groups. Sulbactam, a derivative of penicillin, inactivates bacteria-produced β -lactamase and also has direct bactericidal activity against the *Neisseria* organisms. Therefore, this combination may have an advantage over the combination of a penicillin and clavulanic acid. It should be noted that bacterial resistance has become increasingly more problematic. Reference to up-to-date antibiotic regimens is recommended.

Effective treatment of septic arthritis by oral antibiotics has not been well studied, therefore the parenteral administra-

tion of antibiotics should be used initially.³⁷ Choices include ampicillin and sulbactam (Unasyn) 3 g intravenous (IV) every 6 hours, or clindamycin 600 mg IV every 6 hours in penicillin-allergic patients. A third generation cephalosporin, cefotaxime 6 to 12 g IV per day, could be used for a gram-negative infection in a nonhospitalized patient.³⁷ Tobramycin 3 mg/kg/day in four doses should be considered to treat a possible presence of *Pseudomonas aeruginosa* in infections that develop in hospitalized or immunocompromised patients.

The duration of treatment depends on the clinical response and the organism isolated. Based on information available for treatment of septic arthritis involving *Neisseria gonorrhoeae*, the patient with a septic TMJ could be placed on oral ampicillin or tetracycline after a 2-week course of IV therapy. Reportedly infections involving *Staphylococcus aureus* and gram-negative bacilli require 4 weeks of total therapy, and 2 to 3 weeks of therapy is adequate for streptococci and *Haemophilus* species.⁴² Thus, it appears that a 30-day total course of antibiotic therapy for acute TMJ infection is appropriate.

In addition to culture and sensitivity testing, the aspirate from the infected joint should be submitted for white blood cell (WBC) count and differential, and examined for the presence of crystals and fibrinogen. Fibrinogen is usually present in the synovial fluid of acutely infected joints. Therefore, some of the synovial fluid collected should be placed into a heparinized tube to prevent clotting. It is important to note that ethylenediaminetetraacetic acid (EDTA) interferes with crystal analysis, therefore synovial fluid should not be placed in tubes containing it. The synovial fluid of an inflamed joint commonly contains greater than 2,000 WBC/mm³ (normal < 200 WBC/mm³). Septic joints normally have WBC counts greater than 50,000/mm³. The cells are primarily mononuclear, as opposed to a predominance of polymorphonuclear cells in

infected joint fluid. An exception to this occurs in fungal or mycobacterial joint infections in which the synovial fluid usually contains less than 20,000 WBC/mm³ and shows a greater proportion of mononuclear cells.⁴³

Following the institution of antibiotic therapy, lavage of the joint may be useful. Removing the joint fluid containing the products of the inflammation, reducing the bacterial load within the joint, and relieving the joint distention will usually markedly relieve the patient's symptoms and may also decrease the likelihood of spread to the temporal bone. Murakami and colleagues have reported on the use of the arthroscope for monitoring and treating an acutely infected TMJ.³⁸

Following the resolution of an acute TMJ infection, a program must be started to minimize joint disability and to monitor for recurrence of infection. The acute inflammatory process that accompanies an infection can result in the deposition of fibrinogen and other products, which can predispose the joint toward a fibrous or bony ankylosis. Active range of motion exercises are started as soon as possible to prevent intra-articular adhesions. The patient's range of motion should be documented at weekly intervals. If the range of motion is still limited 1 month following the resolution of the infection, a brisement procedure or an arthroscopic procedure to lyse intra-articular adhesions should be considered. However, before this, extracapsular causes of limited opening, such as masseter muscle trismus, need to be differentiated from intracapsular disorders. Intracapsular restrictions are usually accompanied by restriction of lateral excursions to the contralateral side and deviation on opening. Recurrence of joint infection (of all joints) has been reported to occur at a rate of 10.5%.⁴⁴ Newman noted that infection recurred as long as 1 year following the initial episode.⁴⁴ The patient should be advised of this possibility.

Neoplastic Diseases

Tumors affecting the TMJ area are exceedingly rare. The tissues from which a neoplasm may arise include the synovium, bone, cartilage, and associated musculature. Neoplasms of this region can present with signs and symptoms similar to those occurring with internal derangement (preauricular pain and dysfunction) and thus can result in a delay in the diagnosis. The clinician should be aware of this when treating temporomandibular disorders, especially if the patient fails to respond to traditional therapy.

Benign Tumors

The most common benign bone tumors of the TMJ include the osteoma and condylar enlargement or condylar hypertrophy. Both present signs related to the increase in size of the condyle, a shift in the mandible to the contralateral side, and an ipsilateral open bite. Often the range of motion is decreased as the increased size of the condylar head prevents normal translation. Radiographs, including tomograms and computed tomography scans, should be obtained to delineate the extent of the condylar growth and to determine involvement of the glenoid fossa and associated structures. Radionuclide scans should be performed to determine if the process is still active and bone is being produced. Treatment includes a condylar head resection (partial or complete) for active lesions or a condyloplasty to reduce condylar size and restore the occlusion for nongrowing lesions. Condylar reconstruction is usually not necessary. The disk should be preserved or replaced (if it has been damaged) with a temporalis muscle flap or cartilage graft. Physical therapy is usually required to reduce dysfunction. Postoperative maxillomandibular fixation is not usually necessary, but guiding elastics may be helpful with muscle retraining. An active physical therapy program to reduce joint adhesions prevents permanent restriction of the joint.

Virtually all other benign bone tumors have been reported to occur in the TMJ. These bone tumors behave as they would in other areas of the mandible and therefore should be treated in a similar fashion.

Synovial Tumors

Synovial chondromatosis is the most commonly reported neoplasm of the TMJ synovium. Lustman and Zelster reported a series of 50 cases in which the mean age was 47 years.⁴⁵ This is in contrast to synovial chondromatosis involving other joints, which is more commonly found in the 20- to 30-year-old age group.⁴⁶ Pain and swelling of the preauricular area are the most common initial signs. Depending on the degree of calcification present, radiographs may reveal the presence of loose radiodense bodies within the joint. These loose bodies are formed by metaplastic synovial tissues. Foci of metaplastic synovium detach from the synovial lining and remain viable while suspended in the synovial fluid. While suspended they form a perichondrium and continue to grow and enlarge. Although the reason is unknown this process most frequently occurs in the superior joint space. The loose bodies are composed of cartilage containing multinucleated cells. The presence of cellular atypia and hyperchromatism is common and a careful review of all histologic material removed is necessary to rule out the possibility of chondrosarcoma.

Treatment of synovial chondromatosis involves extirpation of the loose bodies and removal of the synovial lining. Lustman and Zelster reported that a condylectomy was necessary in 13 of 47 cases to gain access to the anteromedial portion of the joint.⁴⁵ The condyle itself is not involved and therefore should only be removed for access. Recurrence of synovial chondromatosis is quite rare and is thought to be caused by an incomplete excision of the original lesions. No cases of TMJ synovial chondromatosis transform-

ing into chondrosarcoma have been reported, although this has been reported in the knee.⁴⁷

Ganglion Cysts

Ganglion cysts have also been reported to occur in association with the TMJ. These are cystic structures that arise subcutaneously in association with the joint capsule or tendon sheaths. Histologic examination of a ganglion reveals a true cyst, containing a mucinous fluid and hyaluronic acid. These lesions present as a preauricular mass and may produce classic "TMJ symptoms," such as pain and limitation of function. The swelling produced by the ganglion in the preauricular region can be confused with a parotid mass. Surgery is indicated to remove the cyst and recurrences have not been reported.⁴⁸

Malignant Tumors

Malignancies of the TMJ are very rare and are usually the result of direct extensions of primary lesions of adjacent structures. Metastatic disease has been reported to involve the TMJ, but is more commonly found in the mandibular angle region. This may be due to the relative paucity of cancellous bone in the condylar head region.⁴⁹ The most common lesions to metastasize to the condyle are adenocarcinomas of the breast, kidney, and lungs. As with benign tumors the early signs of malignant disease of the TMJ are pain and dysfunction. Primary malignancies of the TMJ have been reported as intrinsic tumors of the condylar bone, disk, synovium, and cartilaginous linking. Typically patients with malignancies of the TMJ are older than the usual internal derangement patient. Patients with a history of preexisting malignant disease must undergo a thorough search for metastasis if TMJ symptoms develop. Radionuclide scans may be useful, although the inflammation from chronic synovitis can result in activity localizing in the condyle.⁵⁰ Patients presenting with a fracture of the condyle

without a history of trauma should be suspect for the presence of a malignant lesion in the condyle.

Primary TMJ malignancies require aggressive therapy to prevent intracranial extension of the disease. Radiation, surgery, and chemotherapy are all appropriate means of treatment of diseases in this region. Radiation therapy can also be used for palliation in disseminated disease to control pain from the TMJ region and to prevent pathologic fractures.

Nonsurgical Management of Temporomandibular Disorders

Vasiliki Karlis, DMD, MD

Robert Glickman, DMD

Temporomandibular disorder (TMD) is the general term used to describe the manifestation of pain and/or dysfunction of the temporomandibular joint (TMJ) and its associated structures. Up to 5% of the population are affected by TMD, with significantly more frequent and more severe signs and symptoms appearing in women and older adults.^{1,2} The etiology of TMD is presumed to include trauma, parafunctional habits, malocclusion, joint overloading, arthritides, psychological factors, and ergonomic positioning of the head. The impact of psychological factors is difficult to calculate, but approximately 10 to 20% of patients with TMD also manifest some form of psychiatric illness.³ As symptoms of TMD are quite variable and remain exceedingly difficult to attribute exclusively to one or more events (such as the true contribution or extent of involvement of muscles of mastication), the joint itself or psychological factors is best understood in terms of interdependence. When a diagnosis of TMD is suspected or confirmed, therapy should be directed to improve function and reduce pain and discomfort. There is ample literature to suggest that nonsurgical treatment modalities may account for as much as a 74 to 85% favorable response rate in patients with TMD.^{4,5} In one study, Suvinen and colleagues reported that 81% of their

patients showed 50% or greater improvement after conservative physical therapy with a 6-month follow-up, attributing the improvement to a possible placebo-type effect.⁶ Other sources report significant relief in 30 to 60% of patients when under some form of treatment.⁷ Additionally, long-term follow-up studies have suggested that almost all patients with TMD will improve with time, regardless of the type of treatment they may receive.^{4,8-12} Thus, it appears well established in the literature that the majority of patients with TMD achieve some relief of symptoms with nonsurgical therapy. The dilemma for the surgeon is exacerbated by the broad spectrum of results and claims that use a seemingly endless variety of surgical and nonsurgical strategies. Since the extent or severity of symptomatology is apparently unrelated to etiology, and the overwhelming number of symptoms respond to conservative management, the question of whether and how to incorporate surgical and nonsurgical treatment into the care of these patients becomes challenging for the attending physician. There are absolute indications where surgical intervention would be of primary benefit, and the questions would be whether there is still a role for nonsurgical therapy in these patients, and if so, when it should be instituted and for how long.

One approach is to consider the concept of nonsurgical versus surgical therapy misleading and incomplete. There are many times when it is inappropriate to consider surgery. At other times nonsurgical therapy precedes and almost always follows surgical intervention. Therefore, it is essential for the surgeon to have a deep appreciation of the available techniques and their limitations in order to know when and how to properly manage TMDs. The purpose of this chapter will be to delineate those techniques that are adjunctive or discriminating to surgical considerations.

Treatment Considerations

The primary goal in treatment of TMD is to alleviate pain and/or mandibular dysfunction. Pain and alterations in function (ie, mastication and speech) can become quite debilitating, greatly affecting oral health care and diminishing the quality of life for these individuals. Another critical objective relates to patient counseling and education on the predisposing factors for TMD. Depending on the degree of impairment, patients can often be assured that TMD is a benign condition and clinical improvement can be expected with appropriate therapy. However, it is prudent if not incumbent upon the surgeon to inform patients that complete elimination

of symptoms is at times unattainable. Nonsurgical techniques that can decrease unintentional overloading of the masticatory system, eliminate pain, reduce dysfunction, decrease chronicity, and promote healing are essential in all phases of therapy. A patient home care program may prevent further injury and allow for a period of healing. In general patients can be instructed to limit mandibular function, modify habits, avoid stress, and start a home exercise program.⁸

Clicking and popping of the TMJ is quite common in TMD and normal joints. It is difficult to eliminate, usually reoccurs, and there is inconclusive evidence to suggest whether this poses a problem for the patient. There is considerable support that joint sounds without pain or dysfunction should not be treated (Table 48-1).

Once a diagnosis of TMD has been established, frequent follow-up appointments are necessary once therapy is instituted, to determine whether there is any improvement. Initial impressions may require modification after several weeks of therapy, and further diagnostic procedures may be warranted to rule out vascular, neurologic, neoplastic, psychological, or otolaryngologic abnormalities. TMD is a complex disorder that is molded by many interacting factors, and strong consideration should be given to a multidisciplinary approach. The role of the dentist, physical therapist, neurologist, psychologist/psychiatrist, anesthesiologist, and oral and maxillofacial surgeon cannot be understated, and should be key constituents of any facial pain/TMD center. We cannot precisely dictate timing or length of therapy. This must still be determined by the surgeon and based on severity of symp-

Table 48-1 Goals of Nonsurgical Therapy for Temporomandibular Disorders

<p>Alleviate pain Decrease or eliminate jaw dysfunction Educate and counsel patients</p>
--

toms and supporting diagnostic parameters. As with other joints consideration must be given to rule out pathology, decrease inflammation, allow unimpeded joint motion, and restore range of motion. To accomplish this in a ginglymoarthrodial joint that is permanently attached to the opposite side and is intimately involved in oral health is indeed a challenge.

The remainder of this chapter provides basic guidelines for nonsurgical therapeutics. It is not intended to eliminate or preselect adjunctive dental or surgical treatment.

Nonsurgical Therapy

Diet

A soft diet is often overlooked in the management of TMD. A soft diet prevents overloading of the TMJ and decreases muscle activity that may be hyperactive. The extent of time that a patient should be placed on a soft food diet is dependent on the severity of symptoms. Patients should be instructed to cut their food into small pieces and abstain from eating chewy, hard, or crunchy foods. Uncooked vegetables and meats represent examples of foods that should not be eaten by these patients. A strict liquid diet is reserved for those patients experiencing severe TMD symptoms (Table 48-2).

Pharmacotherapy

Medications are often prescribed for managing the symptoms associated with TMD. Patients should understand that these medications may not offer the cure to their problem but can be a valuable adjunctive aid when prescribed as part of a comprehensive program. With pharmacotherapy there is always a danger of drug dependency and abuse, particularly with narcotics and tranquilizers. Since many TMD symptoms are periodic, there is a tendency to prescribe medications on a “take as needed” philosophy. This can provide brief periods of pain relief, but more frequent

Table 48-2 Soft Diet

--

pain cycles can result in less effectiveness of the drugs and ultimate overuse or abuse of the medications.¹²⁻¹⁵ The general recommendation is that when pharmacotherapy is employed, the medications should be prescribed at regular intervals for a specific period of time (eg, four times daily for 2 wk). The clinician must always be cognizant of potential personality traits that may contribute to drug dependence or abuse. Other obvious factors are concurrent medical ailments or medications, patient age, occupation, and each patient's attitude toward pharmacotherapy.

The most common pharmacologic agents used for the management of TMD are analgesics, anti-inflammatory agents, anxiolytic agents, antidepressants, muscle relaxants, antihistamines, and local anesthetics. Analgesics, corticosteroids, and anxiolytics are useful for acute TMD pain. Anti-inflammatory medications and antidepressants are primarily indicated for chronic pain management. Muscle relaxants, nonsteroidal anti-inflammatory drugs (NSAIDs), and local anesthetics can be used for both acute and chronic pain.

Analgesics Analgesic medications are either opiate or nonopiate preparations. Nonopiate analgesics (salicylates and acetaminophen) can be added to the anti-inflammatory regimen to assist in pain relief. The salicylates (ASA) are commonly used in TMD and are the benchmark medications to which other analgesics are usually compared. Salicylates are antipyretic, analgesic, and anti-inflammatory. For

those patients who cannot take aspirin, a nonacetylated aspirin such as choline magnesium trisalicylate or salsalate may be effective. As with all salicylates, however, choline magnesium trisalicylate and salsalate should not be prescribed for children or teenagers with chickenpox, influenza, or flu symptoms or exposure.

Opioid analgesics (oxycodone, propoxyphene, and hydrocodone) should be prescribed only for moderate to severe pain of limited duration, due to the high potential for addiction. These drugs are often administered in conjunction with NSAIDs or acetaminophen (Vicodin, Lortab, Percocet, Darvocet, etc). They act on opioid receptors in the central nervous system, producing analgesia and sedation. Because patients can quickly become dependant on the narcotic analgesics, it is recommended that these drugs not be prescribed for longer than 2 to 3 weeks. Other side effects include constipation secondary to decreased gastric motility.

Anti-inflammatory Medications There are two types of anti-inflammatory medications useful in treating TMD: NSAIDs and corticosteroids (Figure 48-1). Glucocorticosteroids prevent the release of arachidonic acid, a key component of the inflammation cascade. NSAIDs inhibit cyclooxygenase, which inhibits prostaglandin synthesis from arachidonic acid.¹⁶⁻¹⁸

NSAIDs The advantages of NSAIDs in TMD patients are analgesia and their anti-inflammatory properties (Tables 48-3 and 48-4). NSAIDs may offer relief for patients with synovitis, myositis, capsulitis, symptomatic disk displacement, and osteoarthritis.¹⁹ This type of therapy helps alleviate the inflammation, which thereby causes a decrease in pain perception. Side effects include gastric irritation, allergies, and liver dysfunction. An ideal NSAID would be one that has minimal gastric irritation, a quick onset with long-lasting effects, low dosage requirements, is tolerated at high levels,

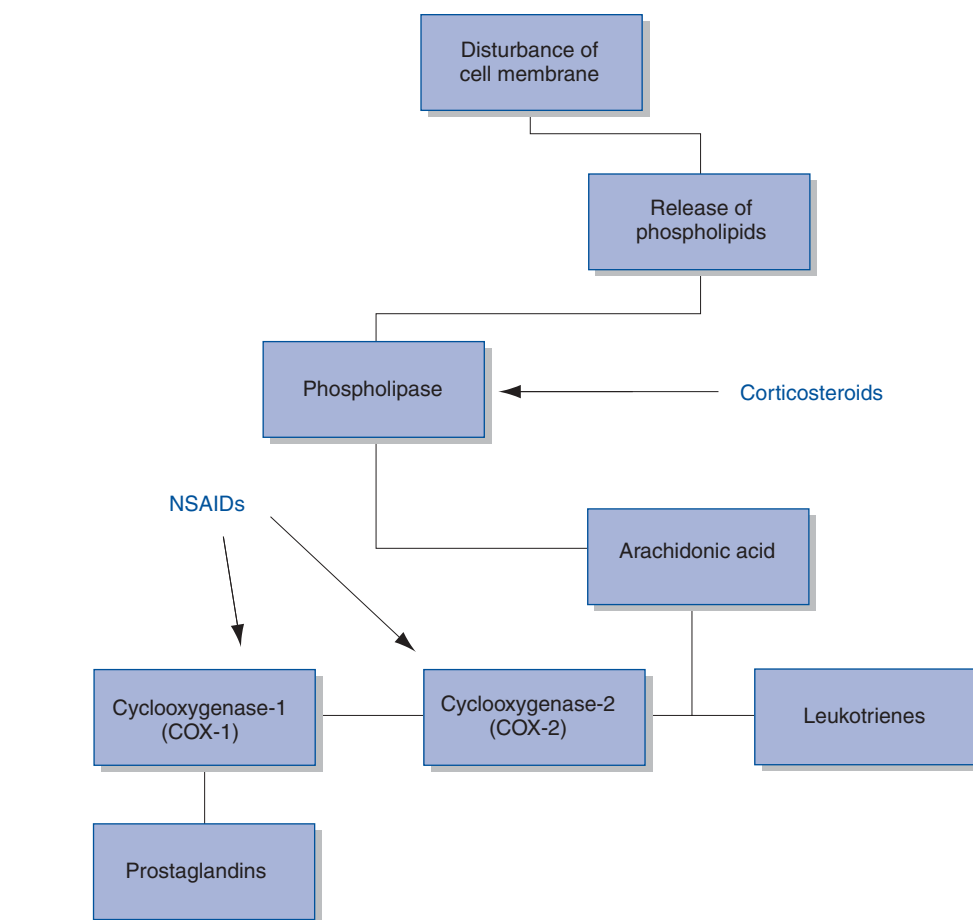

FIGURE 48-1 Inflammation cascade. The corticosteroids prevent the release of arachidonic acid and thereby interrupt most of the inflammation cascade. The NSAIDs inhibit cyclooxygenase, which inhibits prostaglandin synthesis from arachidonic acid. NSAID = nonsteroidal anti-inflammatory drugs.

and is low in cost. NSAIDs are divided into seven groups based on their chemical structure: salicylates (ASA), propionic acids (ibuprofen, naproxen), acetic acids (indomethacin, ketorolac), fenamic acids (meclofenamate), oxicams (piroxicam), and the cyclooxygenase (COX)-2 inhibitors (celecoxib, rofecoxib). The most common NSAIDs used are ibuprofen, diclofenac, and naproxen, but because of purported fewer gastrointestinal (GI) side effects and minimal effect on platelets, COX-2 inhibitors are becoming more popular. Recent studies have found that COX-2, an important inflammatory mediator, is present in the TMJ synovial tissue and fluid of patients with internal derangements. This offers the possibility that the COX-2 inhibitors might be more effective for TMJ

pain and arthralgias than other analgesics.^{20,21} Enteric coating, prodrugs (nabumetone), taking agents after meals or in conjunction with antacids, and taking gastric protective agents (ranitidine and sucralfate) have been reported to reduce the gastric irritation from NSAIDs.²²

Corticosteroids By completely blocking the arachidonic acid cascade, corticosteroids produce a greater anti-inflammatory response than do NSAIDs. Systemic steroids are indicated only for short-term therapy (5 to 7 d) due to their long-term possible complications. Osteoporosis, diabetes, hypertension, electrolyte changes, and clinical Cushing's disease are sequelae of long-term systemic corticosteroid treatment.²³ Steroids have also been directly injected into the TMJ

Table 48-3 Commonly Used Nonsteroidal Anti-inflammatory Agents			
Category	Generic	Brand	Half-Life (hours)
Salicylates	Acetylsalicylic acid (aspirin)	Bayer	2.5
	Enteric coated	Ecotrin	2.5
	Aspirin with buffering agent	Bufferin	2.5
	Aspirin with caffeine	Anacin	2.5
	Diflunisal	Dolobid	8–12
	Choline magnesium trisalicylate	Trilisate	9–17
	Salsalate	Disalcid	16
Propionic acid	Ibuprofen	Motrin, Advil, Nuprin, Rufen	1.8–2.5
	Fenoprofen	Nalfon	2–3
	Suprofen	Suprol	2–4
	Naproxen	Naprosyn	12–15
	Naproxen sodium	Anaprox	12–15
Acetic acid	Indomethacin	Indocin	4.5–6
	Sulindac	Clinoril	7.8 (16.4)*
	Tolmetin	Tolectin	1–1.5
Fenamic acid	Meclofenamate	Meclomen	2 (3.3)*
	Mefenamic acid	Ponstel	2
Pyrazolones	Phenylbutazone	Butazolidin	84
Oxicam	Piroxicam olamine	Feldene	30–86
COX-2 inhibitors	Celecoxib	Celebrex	11–12
	Rofecoxib	Vioxx	17

*Active metabolite.

in an attempt to decrease inflammation or mediate the inflammatory response (ie, following arthroscopy), but long-term or excessive use is associated with condylar hypoplasia by inhibiting osteoblastic activity and increasing loss of calcium in the urine and GI tract.²⁴

Anxiolytics Anxiolytic medications reduce the anxiety, insomnia, and muscle hyperactivity associated with TMD

Table 48-4 Nonsteroidal Anti-inflammatory Drugs: Ideal Properties
Minimal gastric irritation
Quick onset with long-lasting effects
Lower dosage
Tolerated at high levels
Low cost

(Tables 48-5 and 48-6). These drugs often help the patient reduce the perception of, or reaction to, stress. Benzodiazepines (diazepam) decrease anxiety, relax skeletal

Table 48-5 Commonly Used Benzodiazepines			
Generic	Brand	Usual Dosage (mg/d)	Elimination (half-life [h])
Alprazolam	Xanax	0.5–1.5 (ddd)	12–15
Chlordiazepoxide	Librium	15–60 (ddd)	5–30
Diazepam	Valium	2–40 (ddd)	20–50
Flurazepam	Dalmane	30 (at bedtime)	47–100
Lorazepam	Ativan	2–6 (ddd)	10–18
Oxazepam	Serax	30–60 (ddd)	5–15
Prazepam	Verstran	20–40 (ddd)	30–100
Temazepam	Restoril	15–30 (at bedtime)	10–20
Triazolam	Halcion	0.25–0.5 (at bedtime)	1.5–5

ddd = divided daily doses
Adapted from Syrop SB.²⁵

muscle, and cause sedation and may be selected according to their more favorable characteristics (ie, less sedation). The muscle relaxant properties may be used to decrease the effects of bruxism secondary to hyperactivity of muscles of mastication. It is recommended that the benzodiazepines not be used for more than a 2-week period because of the high potential for dependency, although this can be increased up to 3 weeks only at bedtime to control bruxism.¹⁹ Buspar (azaspirodecanedione) is an anxiolytic; however, it does not produce either sedation or muscle relaxation. It may be used to control anxiety in TMD patients without producing drowsiness.

Antihistamines (promethazine and hydroxyzine) antagonize central and peripheral H₁ receptors, and have a sedative effect as well as anxiolytic properties. Antihistamines, unlike the benzodiazepines, do not have the potential for abuse. They can be used more safely in children and the elderly and for the treatment of vertigo and nausea that may accompany TMD.²⁵

Antidepressants Antidepressants include monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants, and selective serotonin reuptake inhibitors (Tables 48-7 and 48-8). They are pre-

Table 48-6 Antianxiety Medications: Benzodiazepines

Bind GABA receptors
 Serotonergic (5-HT) in the amygdala
 Beneficial for treatment of anxiety, insomnia, muscle hypertonicity
 Potential abuse
 Avoid short-acting or high-potency drugs (ie, triazolam, alprazolam, lorazepam)
 Taper gradually to avoid withdrawal, rebound anxiety

GABA = γ -aminobutyric acid; 5-HT = 5-hydroxytryptamine (serotonin).

scribed for chronic pain, headaches, sleep disorders, obsessive-compulsive disorders, and central-mediated pain disorders. The relationship between pain and depression is a challenge and often necessitates treating both simultaneously. Depression in the TMD or chronic pain population is greater than in the general population. Studies report that up to 30% of TMD patients have major depression at the time of presentation for treatment, and up to 74% of patients with chronic TMD have had an episode of major depression.^{26,27}

MAOIs are not routinely prescribed for TMD due to their numerous side effects and dietary restrictions. Benefits of tricyclic antidepressants have been well documented in chronic pain or depression populations and are probably due to analgesic and antidepressant actions. The analgesic properties are independent of the antidepressant effect, which requires higher doses. It has

been shown that low doses of amitriptyline (10 mg) before sleep can have an analgesic effect on chronic pain but have no relationship to the antidepressant actions that require doses up to 20 times greater.²⁸ Tricyclic antidepressants may also help treat nocturnal bruxism and any sleep disturbance associated with TMD.²⁹ Side effects are related to anticholinergic activity causing xerostomia, constipation, blurred vision, and urinary retention. Selective serotonin reuptake inhibitors can also be used for treating the depressed TMD patient. These medications often need to be taken for several months and patients must be counseled appropriately. Fluoxetine (Prozac) may increase bruxism and anxiety and should be carefully monitored.

Muscle Relaxants Centrally acting muscle relaxants (cyclobenzaprine, methocarbamol, and carisoprodol) may be used to relax hyperactive musculature associated with TMD (Tables 48-9–48-11). These relaxants may also act as sedatives, and they are commonly combined with NSAID use. Cyclobenzaprine (Flexeril) has a similar chemical structure to the tricyclic antidepressants and if given over an extended period of time will produce antidepressant and sedative actions as well as the anticholinergic side effects of the tricyclics. Central muscle relaxants can be very effective for acute myofascial pain (ie, trauma).

One peripheral muscle relaxant, baclofen, has been used in myofascial pain but is best reserved for severe muscle spasm or neurogenic pain. Recently botu-

Table 48-8 Antidepressant Medications

Tricyclics are most used and studied for chronic pain and depression
 Monoamine oxidase inhibitors (MAOIs) not first choice due to adverse reactions
 Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine can increase anxiety and bruxism

linum toxin has been used to treat severe bruxism. By providing muscle relaxation, inflammation of the masseter muscle and TMJ capsule can be reduced.^{30,31}

Local Anesthetics Local anesthetics act on the nerve cell membrane to prevent generation and conduction of impulses (Table 48-12). Local anesthetics can be used as diagnostic blocks intra-articularly and/or intramuscularly to alleviate pain and increase range of motion. For example, injection behind the maxillary tuberosity will permit the lateral pterygoids to be anesthetized, thereby allowing maximal protrusion and retrusion of the mandible. There should be no vasoconstrictor used in conjunction with the anesthesia, as the decrease in blood flow may increase muscular pain. The intrinsic vasodilation effect of the anesthesia may improve perfusion and thereby further alleviate pain. It has been shown that an intra-articular injection of mepivacaine along with physiotherapy in patients with anteriorly displaced disks has yielded favorable results in pain relief and masticatory efficiency.³²

Physical Therapy

There are many factors contributing to limited range of motion. They include muscular pain, anterior disk displacement (closed lock), and fibrotic scar tissue preventing rotation or translational movements. It is well accepted that immobilization has deleterious effects on both joints and muscles.

Table 48-7 Commonly Used Antidepressants

Generic	Brand	Dosage (mg/d)	Side Effects
Amitriptyline	Elavil	10–300	High
Desipramine	Norpramin	50–300	Moderate
Doxepin	Sinequan	25–300	High
Imipramine	Tofranil	20–300	Moderate
Nortriptyline	Pamelor, Aventyl	25–150	Moderate
Fluoxetine	Prozac	5–20	Moderate

Immobilization may cause degenerative changes to the joint surfaces, synovial fluid, and surrounding tissues. Reduced motion also results in rapid muscle fatigue, muscle weakness, and contractures. Synovial fluid generation is reduced or halted when joints are immobile. Additionally it has been observed that the synovial fluid of patients with pain and limited motion often contains inflammatory byproducts. Kaneyama and colleagues listed a variety of cytokines such as interleukin (IL)-1 β , tumor necrosis

factor (TNF)- α , IL-6, and IL-8 in symptomatic joints, not observed in asymptomatic joints.³³ This high level of cytokine activity is believed to be related to the underlying pathogenesis of TMD. Cytokines such as IL-6 and IL-1 β may induce the “inflammatory cascade.” As a result of the release of proteinases, there may be destruction of articular cartilage and bone resorption. Each cytokine has its unique properties, not only affecting the surrounding tissues but also aiding in the release of other

cytokines.³³ Thus, the role of functional motion and the synovium may be an indeterminate factor in the health of the TMJ (Table 48-13).

Exercise Therapy Physical therapy and exercise are an important part of any TMD program. Mild or acute symptoms can be initially managed with soft diet, jaw rest, heat/ice packs, jaw/tongue posture opening exercises, lateral jaw movements, and passive stretching exercises. Once again the exact sequence of therapy is unknown but is usually based on degree of pain and limitation of function. Further reduction of pain and inflammation may require an office-based physical therapy program. From our experience, ultrasonography,

Table 48-13 Physical Therapy
<i>Home Treatment Program (good for mild acute symptoms)</i>
Soft diet Decrease function Heat/ice packs Jaw/tongue posture opening exercise Lateral jaw movement Control passive motion (ie, Therabite)
<i>Office Treatment (reduction of pain and inflammation)</i>
Ultrasonography Transcutaneous electrical nerve stimulation Range of motion Soft tissue manipulation Trigger point injections Acupuncture (reestablishing proper energy flow by adding electric current or heat to the placed acupuncture needle)

transcutaneous electrical nerve stimulation (TENS), soft tissue manipulation, trigger point injections, and acupuncture have also been advocated as effective in the management of the TMD patient.

Jaw exercise therapy can be described as passive, active, or isometric. Passive jaw exercise allows the patient to manually (or with a device such as Therabite Jaw Motion Rehabilitation System, Atos Medical, Milwaukee, WI, USA) increase interincisal opening (Figure 48-2). Passive jaw exercise has received a great deal of attention recently. Many authors report significant improvement in pain and mobility in the nonsurgical phase of treatment for TMD as well as for the postoperative TMD patients.³⁴⁻³⁷ Passive jaw exercise is also very effective for patients experiencing muscular trismus and myofascial pain dysfunction (MPD). It may be contraindicated in patients with severely displaced disks, due to the possibility of damage to the disk or retrodiskal tissues.

Active exercise using the patient's jaw musculature may be incorporated into a home therapy program. One regimen allows the patient to activate, for example, their suprahyoid muscles (geniohyoid, mylohyoid, digastric, and stylohyoid), thereby inactivating the elevators of the jaw

(medial pterygoid, masseter, temporalis). This may allow for relaxation of hyperactive muscles of mastication and may assist in increasing maximal incisal opening. In the active stretch phase patients are advised to keep their mouth open for several seconds and relax. They are instructed to open until they perceive pain and then advised to hold for several seconds and repeat this exercise several times a day. An active lateral stretch permitting the contralateral lateral pterygoid to be stretched may be accomplished by visualizing themselves in a mirror. In the active protrusion, also performed in front of the mirror, the mandible is protruded forward stretching the lateral pterygoids bilaterally. All active excursions are maintained for several seconds and slowly released.

Isometric exercises have been recommended for patients with severe pain and trismus. There is no movement during this exercise while the depressor muscles are activated, allowing for relaxation of the opposing elevator musculature (medial pterygoids, masseter, temporalis). These exercises are performed by holding the mandible stationary as the muscles are activated isometrically. The lateral pterygoids may also be exercised in a similar isometric fashion.

Mongini describes a three-stage office technique of mandibular manipulation for patients with pain, decreased mobility, and disk displacement without reduction.³⁸ Right and left lateral movements are initiated by the patient. The patient continues the movement while the clinician applies light pressure in the same direction, and in the last stage the mandible is moved to the opposite side with patient assistance.³⁸ Kurita and colleagues described a technique of placing one thumb on the last molar on the affected side while the other hand supports the head in the temporal region.³⁹ The mandible is then moved downward and forward. The patient is instructed to protrude and move their jaw laterally, and open their mouth while the clinician manipulates the jaw. Following this movement the mandible is pushed back so that the condyle is positioned posterosuperiorly in the glenoid fossa. Only 18% of the patients received significant benefit from the manipulation, and the more advanced the displacement, the less the success of the treatment.³⁹ Yuasa and Kurita suggested that physical therapy along with administration of NSAIDs (for a 4-week period) is a more effective way to treat TMJ disk displacement without osseous changes.⁴⁰ Nonetheless, there is no shortage of recommended exercises, and care must be taken to do no harm (Table 48-14).

Patient has no control; pain relief immediate but short lived

Thermal Agents Thermal agents are often incorporated in the management of TMD. The use of cold and heat can alleviate muscle pain and play an equal role during stretching and strengthening exercises.⁴¹⁻⁴³ Heat therapy has been reported to reduce muscle pain by increasing nerve conduction velocity and local vasodilatation.⁴³ Superficial heat therapy can be implemented with conductive (hot packs, paraffin, whirlpool) or radiant (infrared) agents. The most common types used are a moist hot washcloth, heating pad, or hydrocollator, a pad filled with clay and heated in a water bath to 70° to 88°C. It is wrapped in a towel and placed on the site for 15 to 20 minutes, causing a transient rise in skin temperature to about 42°C. The use of moist heating pads is an effective modality of treatment for myofascial pain associated with TMD.⁴⁴

Cryotherapy is often used as an aid in stretching muscles in an attempt to increase maximal incisor opening limited by pain.⁴¹ The pain perception model described by Melzack and Wall explains why cold therapy stimulates the large A delta fibers (temperature) inhibiting pain, which is stimulated by the small C fibers.⁴³ A physical therapist would place refrigerants on the skin in a sweeping motion followed by stretching of the musculature. Cold therapy should be used with caution because of the potential for increased joint stiffness, contracture, and immobility. Cold can also have analgesic effects after a therapeutic exercise regimen. Ice wrapped in a towel, fluoromethane spray, and reusable ice packs can all be used to deliver cryotherapy to the temporomandibular joint and related muscles. The stretch and spray technique, initially described by Modell and Simons and later modified by Travell and colleagues, is still a mainstay of office physiotherapy.^{41,42} The therapist holds the fluoromethane spray about 30 to 45 cm from the patient and sprays in a sweeping motion multiple times, and this is then followed by stretching exercises.

Possible side effects include frostbite and the potential for joint stiffness. Many therapists follow cryotherapy with moist heat to prevent the muscles from contracting.

Ultrasonography and Phonophoresis

Deep heat can be delivered by ultrasonography or phonophoresis. The ultrasound machine operates above audible frequency sound waves (0.75 to 1.0 MHz), which convert to heat while traveling through soft tissue. The ultrasound machine is applied to the skin along with an acoustic conductive gel, then moved slowly over the affected area in small circular movements. The operator must be careful not to keep the machine in one place for too long as it may cause overheating of the connective tissue, causing structural damage. The deep heat is intended to increase perfusion to the area, decreasing pain and increasing mobility.⁴⁵ Reported effects of ultrasound therapy include altered cell membrane permeability, intracellular fluid absorption, decreased collagen viscosity, vasodilatation, and analgesia. The beneficial effects to joints are reduced capsular contracture, break up of calcium deposits, and decreasing hyaluronic acid viscosity.⁴⁶ Because ultrasonography delivers heat to the deeper structures, it may have some advantage in treating tendonitis, capsulitis, muscle spasm, and tight ligaments.

Phonophoresis is an application of ultrasound heat therapy that incorporates a pad filled with a steroid or anesthetic cream placed over the affected area. As the ultrasound waves are applied, the medications perfuse into the tissues. The most common indication for phonophoresis is synovitis associated with painful jaw hypomobility. Contraindications for the use of ultrasonography and phonophoresis include areas that may have a reduced circulation, fluid-filled organs, eyes, radiation therapy sites, and malignant tissue. Ultrasound therapy should be used with extreme caution over active bone growth centers.⁴⁷

Electrical Stimulation Transcutaneous Electrical Nerve Stimulation TENS has become a viable home therapy in treating TMD. The precise mechanism of action is unknown, but it has been suggested that the gate control theory, counter-irritation, neurohumoral substance release, and peripheral blockade are all involved.⁴⁸ TENS uses a low-voltage electrical current that is designed for sensory counterstimulation in painful disorders. It is used to decrease muscle pain and hyperactivity and for neuromuscular re-education.^{49,50} TENS units are small and portable. Electrodes are placed along dermatomes or over acupuncture and trigger points. The patient can control the settings with variable frequency, amplitude, waveform, width, and pulse mode. Treatment can last several hours. TENS emits an asymmetric biphasic wave of 100 to 500 ms pulse. The efficacy of TENS for analgesia and muscle relaxation in myofascial pain has been documented.⁵¹ Electrode placement is contraindicated over the carotid sinus, transcranially, directly on the spine, on a pregnant womb, or on patients with demand-type pacemakers.⁵²

High-Voltage Stimulation High-voltage stimulation units deliver currents of positive and negative polarity with voltages greater than 100 V, which are delivered in a constant or intermittent pattern. The positive polarity produces vasoconstriction, whereas the negative polarity produces vasodilatation. The positive polarity reduces nerve irritability, and negative polarity enhances it. Negative polarity softens the affected tissue thus decreasing muscle tension. Treatment with high-voltage stimulation has improved jaw mobility and relieved pain intensity in TMD patients.⁵³ It can be used for pain relief, reduction of edema, and neuromuscular stimulation.⁵³

Iontophoresis Iontophoresis transfers ions from a solution through intact skin by

passing a direct current between two electrodes.⁵⁴ Positive ions are transmitted at the cathode, and negative ions are transmitted at the anode. Examples of negatively ionizing drugs are dexamethasone and methylprednisolone. Other drugs used in iontophoresis include lidocaine and salicylates. Iontophoresis was introduced in treating TMD and postherpetic neuralgia in 1982.⁵⁵ It appears to be most effective against inflammation, muscle spasm, and calcium deposits. The deep penetration of the medication aids in the treatment of severe joint inflammation and pain (Table 48-15).

Trigger Points and Muscle Injections A trigger point is an area of hyperirritability in a tissue that, when compressed, is locally tender, hypersensitive, and gives rise to referred pain and tenderness.⁵⁶ Trigger point development may be due to trauma, sustained contraction, or acute strain. When a needle penetrates this area it may cause a twitch response and referred pain.⁵⁶ Injection of local anesthetic agents without epinephrine may cause a temporary anesthesia, which enables the clinician to stretch the muscles in the affected area. A vasodilator effect of the local anesthetic may improve perfusion to the area, thus allowing harmful metabolites which may induce pain to be more readily removed by the vasculature.

Stress-Reduction Techniques

Relaxation and Biofeedback Relaxation and stress-reduction techniques for patients with TMD can be very effective treatment modalities. Various techniques

exist, an example being contracting and releasing skeletal muscles, starting from the feet and moving toward the head and neck region. Patients can also use audiotapes that teach breathing and specific relaxation techniques. Biofeedback techniques incorporate the use of electromyography (EMG) and skin temperature to measure the patient’s physiologic function. The information is then conveyed back to the patient by a meter or sound. The patient can gauge their level of relaxation and measure progress accordingly.⁵⁷ The aim is to achieve psychological self-regulation and to monitor the relationship between muscular tension and pain. In a review of the literature Crider and Glaros reported 69% of subjects rated as improved or symptom free following biofeedback and relaxation treatments, whereas only 35% of patients receiving placebo intervention showed any improvement.⁵⁸ Furthermore, on follow-up examination the patients showed no decline from post-treatment levels.⁵⁸ Scott and Gregg advocate that relaxation techniques and EMG feedback can yield good results, especially in patients who are not depressed and have temporomandibular pain for a short period of time.⁵⁹ The chief hurdle is the difficulty to motivate patients in pain (Table 48-16).

Acupressure and Acupuncture Acupressure and acupuncture may be implemented along with other modalities during nonsurgical treatment. Acupuncture uses the relationship between energy flow through meridians, natural elements, and positive and negative life forces. Fine needles

are used to reestablish proper energy flow. There are several theories on the mechanism of action of acupuncture and acupressure. The first is the gate control theory, which states that the needle produces a painless stimulation, causing gates to close and preventing signal propagation to the spinal cord.⁶⁰ Other explanations include release of endorphins from the pituitary gland which block pain sensation, promotion of alpha waves (associated with stress reduction and relaxation), and rebalancing the electric ion flow pattern (when disrupted, it may elicit pain).⁶⁰ There are several different acupressure techniques including Jin Shin (two acupressure points held for 30 s to 5 m), Shiatsu (more rapid, held 3 to 10 s), reflexology (acupressure on feet, hands, and ears corresponding to areas of the body), Do-In (self-acupressure and breathing exercises), and G-Jo (acupressure for first aid purposes). Some studies have reported favorable results when these techniques are combined with other modalities (splint therapy), but overall data are limited.^{61,62} These pain therapies can be offered as an alternative to conventional therapy.

Psychotherapy In some cases TMD may be the somatic expression of an underlying psychiatric or psychological disorder such as depression or conversion.^{63,64} The

clinician should screen for personal or familial history of psychiatric disease, physical or sexual abuse, and substance abuse. Anxiety disorders occur at greater rates in patients with chronic pain.⁶⁵ Once identified these patients should be referred to a psychiatrist and/or psychologist for adjunctive treatment. Psychological treatments include behavioral therapy, cognitive-behavioral therapy, and self-management/support groups. Psychiatric treatments include medications with behavioral therapy. Often as a last resort TMD patients are referred to pain clinics for treatment, whether a psychological component exists or not, often out of frustration.

Occlusal Appliance Therapy

An occlusal appliance is a removable device, usually made of hard acrylic, which is custom fit over the occlusal surfaces of the mandibular or maxillary teeth. The splint is constructed so that there is even occlusal contact with the teeth of the opposing arch in centric and anterior contact only, in lateral and protrusive excursions of the mandible. The physiologic basis of treatment is not well understood but the effectiveness of the occlusal splint has been attributed to a decreased loading on the TMJs and reduction of the neuromuscular reflex activity. Alleviation of bruxism and MPD may be due to the change in vertical dimension, altering the proprioception in the postural position of the mandible.⁶⁶⁻⁶⁸ There are generally two types of appliances: stabilization (flat plane) and anterior repositioning.

Table 48-17 Stabilization Appliance

Stabilizes temporomandibular joints
Redistribution of forces
Relaxation of masticatory muscle
Hard acrylic
Maxillary arch
Wear 24 h (except during meals)

Stabilization (Flat Plane) Appliance A stabilization appliance covers all the teeth in one arch and is indicated to relax the muscles of mastication, aid in joint stability, and protect teeth from bruxism (Table 48-17, Figures 48-3 and 48-4).^{68,69} Additional indications for stabilization appliances may include myalgia, inflammation, and retrodiscitis secondary to trauma. With a stabilization appliance the condyles are placed in the most muscularly stable position while the teeth are contacting evenly and simultaneously.⁷⁰ There must be bilateral equal posterior contacts so that an environment of stable physiologic posture is possible. Canine guidance is created for protrusive and lateral excursions. As the patient's symptoms improve, the splint should be adjusted to maintain even contacts bilaterally. The splint is usually fabricated on the maxillary arch because it covers more tissue, especially with Class II or Class III patients where fabrication of a mandibular appliance can be difficult. On the other hand major advantages of the mandibular stabilization appliance include better speech and less visibility, which may contribute to better patient compliance.⁷⁰ The appliance should be worn 24 hours a day and taken out at mealtimes. Stabilization appliances can be weaned post-TMJ arthroscopy and/or as the patient's symptoms subside.

Major and Nebbe reported effective reduction in headaches and muscle pain using stabilization appliances, but occlusal stabilization appliances have limited value in reducing joint pain.⁷¹ Lundh and colleagues concurred with the fact that the stabilization splints have little value in painful disk displacement without reduction.⁷² Kai and colleagues reported that after treatment with a stabilization occlusal splint of the maxillary arch, clinical signs and symptoms of nonreducing anteriorly displaced disks decreased but osteoarthritic findings increased.⁷³

Anterior Repositioning Appliance The anterior repositioning splint is an interoc-

FIGURE 48-3 Stabilization appliance. Hard acrylic full-coverage occlusal splints used for nonsurgical phase of treatment.

FIGURE 48-4 The stabilization appliance does not change the anterior/posterior jaw position.

clusal appliance that permits the mandible to assume a position more anterior than normal (Table 48-18, Figures 48-5 and 48-6). The purpose of these appliances is to alter the structural condyle-disk-fossa relationship in an effort to decrease joint loading.⁷⁴ Indications for this device are primarily disk derangement disorders. The maxillary appliance is preferred and it is fabricated with a guide ramp that permits the anterior repositioning of the mandible.⁷³ Anterior repositioning appliances are used less frequently because repositioning of the mandible over a period of time can result in irreversible occlusal changes such as posterior open

Table 48-18 Repositioning Appliance

In therapy it attempts to recapture the anterior displaced disk
Need for possible occlusal equilibration and constant adjustment

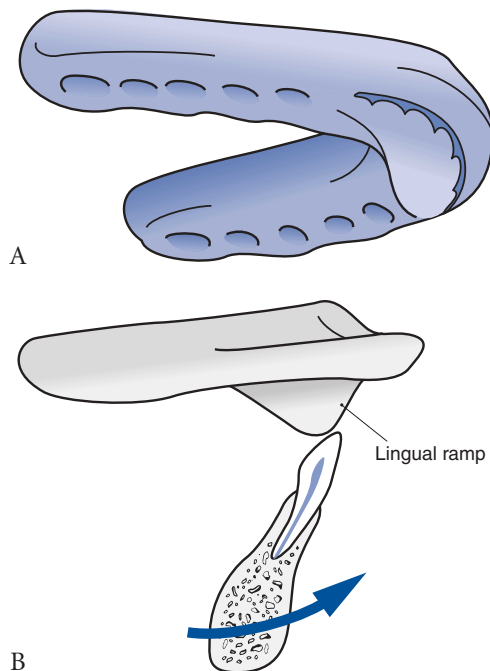

FIGURE 48-5 A, Maxillary repositioning appliance. B, The lingual ramp engages the mandibular incisors and guides the lower jaw forward. A forward repositioner may carry a commitment to restore the patient to a new jaw position. Adapted from Syrop SB. Nonsurgical management of temporomandibular disorders. bites, which could require extensive prosthetic rehabilitation.

Occlusal Adjustment There is a limited role for occlusal adjustment or selective grinding in the treatment of TMD.⁷⁵ The purpose of selectively grinding the teeth is

FIGURE 48-6 Repositioning appliance. Hard acrylic repositioning appliance that changes the anterior/posterior jaw position and may require further dental rehabilitation.

to permanently position the dentition into a better occlusion. It is an irreversible process and is best suited for the acute TMD symptoms arising from overcontoured restorations or postorthognathic surgery. In these select cases the occlusal equilibration allows for proper condylar positioning and prevents muscular problems associated with improper interferences.

Causes of Failure

As a singular modality it is very difficult to assess the clinical success or failures of nonsurgical treatments over time. DeLeeuw and colleagues reported long-lasting satisfactory results for patients treated with nonsurgical therapy for internal derangements and osteoarthritis with a 30-year follow-up.⁷⁶ Symptoms such as joint noises persisted, whereas pain and discomfort generally subsided.

There are several possibilities that could explain the cause of failure of nonsurgical therapy for TMDs: incorrect history taking, improper diagnosis and treatment, lack of patient compliance, emotionally debilitated patient, or coexisting morbidities.⁷⁷ When significant symptoms persist after 3 to 6 months of nonsurgical therapy, alternative therapies and/or diagnoses should be considered, including surgery.

Summary

TMD is a complex disorder with common presenting signs and symptoms. In this chapter we have presented nonsurgical strategies used to alleviate the pain and dysfunction associated with the TMJ. Since an exact correlation between diagnosis and treatment is not always possible, success or failure with nonsurgical modalities is not a reliable outcome, even though this therapy may aid in diagnosis and be the first step for most patients. When surgery is indicated or evidence-based, nonsurgical techniques are a crucial adjunct perioperatively, if not forever.

Temporomandibular Joint Arthrocentesis and Arthroscopy: Rationale and Technique

Jeffrey J. Moses, DDS

Since the seventh century BC, papyrus images have revealed attempts at temporomandibular disorder (TMD) management through relocation of dislocations. Over a long and arduous route clinicians have sought to relieve the painful dysfunction of this structure through various mechanical, anatomic, and biochemical evaluations and correctional means. Through the relatively recent advances of technology, and partly because of the equivocal successes of historic management outcomes, modern maxillofacial surgeons now have the access to micronized minimally invasive techniques to assist in TMD management. From the diagnostic evidence produced by the thin intra-articular arthroscope and the evaluation of the fluid effudate comes new information turning this era into a valuable epoch of discovery. Successful long-term outcomes from relatively simplified therapeutics have led many surgeons to decrease the incidence of open-joint arthroplasties and their potential negative complication sequelae. While this chapter focuses on the techniques of arthroscopy and arthrocentesis, the current stage of the evolution of treatment philosophies and understanding of these

techniques as applied to the pathophysiology of the discussed temporomandibular joint (TMJ) for successful outcome in patient management are emphasized.

History of Orthopedic Development

The development of biomechanical and optical accesses for the examination of intra-articular structures in the early twentieth century was accomplished by Kenji Tagaki in 1918 by his use of a 7.3 mm diameter pediatric cystoscope allowing him to examine a knee joint.¹ His later development of a 3.5 mm diameter scope made this procedure practical. Of historic significance, in 1921, Bircher published an independent report of the results of his arthroscopic studies of the knee joint using a laparoscope with gaseous distention of the joint space using oxygen or carbon dioxide.² Another report using arthroscopy was published by Kreyscher in 1925, predicting that it would become the definitive diagnostic modality for derangements of the knee.³

Following Tagaki's modification of the cystoscope and diameter reduction to 3.5 mm in the early 1930s and the use of saline for joint distention, several other

pioneers went on to improve arthroscope design and used these in a patient series, publishing their clinical experiences.⁴ Unfortunately, due to the technologic restraints at the time of lack of illumination and having only direct eyepiece visualization with electronic assistance, there was limited acceptance of this method as a valuable diagnostic modality.

A major turning point in the field came in the early 1950s with the recognition that the technologic advances in electronics and optical design could assist in endoscopic equipment development. This was appreciated and used by one of Tagaki's students, Masaki Watanabe. Watanabe and colleagues' design of the no. 21 arthroscope with 100° field of vision and a 6.5 mm diameter using tungsten light illumination and camera attachments turned the direction of this field of interest around.⁵ The work done by Casscells as well as Jackson and Abe built on this foundation clinically, which was credited to Watanabe's performance of the first surgical procedure on the human knee joint in 1955.^{6,7}

Enthused with the potential, Richard O'Conner returned home from a trip to Japan in 1970 and subsequently developed

an operative arthroscope in 1974. He used this to perform a meniscal resection, the results of which he published in 1977.⁸ A generalized instrumentation explosion, coupled with the development of motorized equipment by Lanny Johnson then ensued, which led to further technique developments in arthroscopic managements of intra-articular pathology.⁹ Realizing that these techniques would be best learned in specifically designed courses with hands-on experience, in 1973, John Joyce III and Michael Hardy, an anatomist, organized the first of many courses that developed. This greatly enhanced the spread of this treatment modality throughout the orthopedic community. Many of these early courses were personally overseen by the pioneering experts, including Dr. Watanabe himself.

Development of Temporomandibular Joint Arthroscopy

A major breakthrough for small joint endoscopic access occurred in 1970 with the development of the Watanabe no. 24 Selfoc arthroscope with a 1.7 mm diameter.¹⁰ This was introduced into the TMJ by Masatoshi Ohnishi using a fiberoptic light source and arthroscopic device manufactured by Olympus in the early 1970s. Ohnishi published both the puncture technique and the anatomic findings and later went on to describe the usefulness of this technique for clinical applications in the treatment of TMJ disease in 1980, including photographic documentation of normal anatomy as well as providing early information on traumatic pathology and joint fibrosis.¹¹⁻¹⁴

In 1978 an animal study on rabbits by Hilsabeck and Laskin demonstrated that TMJ arthroscopy was a safe technique that revealed the appearance of intra-articular structures.¹⁵ In 1980 Williams and Laskin went on to introduce pathologic conditions in the rabbit joint and concluded that these could be

diagnosed by the arthroscope.¹⁶ Holmlund and colleagues published similar results in 1986.¹⁷ In 1982 Ken-Ischiro Murakami and Kazumasa Hoshino reported their procedural terminology and arthroscopic anatomy, excellently illustrating the human TMJ with color photography.¹⁸ During a visit to the United States in 1984 Dr. Murakami introduced this concept to Bruce Sanders who, along with Joseph McCain but on separate US coastlines, began to perform the procedures clinically for patients with TMD. Drs. Ronald Kaminishi, Jeffrey Moses, Christopher Davis, as well as others were introduced to the puncture and arthroscopic visualization of the TMJ during this time. Wanting again to develop the training of this technique along the same lines as their orthopedic counterparts, the maxillofacial surgeons sought to develop educational symposia and hands-on training. The first international hands-on course using fresh cadaveric specimens for technique development was initiated by J.J. Moses in late 1985 and continued on through the sponsorship of The Pacific Clinical Research Foundation. Many of the initial surgeons exposed to the modality independently went on to develop a variety of techniques and courses using the communal efforts of the international pioneers at these sessions.

In 1985, with references to the arthroscopic observations, Murakami and Hoshino described histologic cellular characteristics of the inner surfaces of the TMJ.¹⁹ Also in 1985 Holmlund and Helling published their landmark paper on the concept of reproducible puncture sites correlating measurements along the tragal-canthal line.²⁰ These are recommended for surgeons' early learning stages in technique development.²¹

Continued efforts by Murakami and Ono to improve surgical techniques were published in 1986, and McCain presented an abstract at the 1985 Annual Meeting of

the American Association of Oral and Maxillofacial Surgeons (AAOMS) on his investigations.^{22,23} A pivotal work was published in 1987 by Sanders in the treatment of closed lock condition with the surgical application of arthroscopic lysis and lavage over a 2-year period.²⁴

In 1986 the first major didactic symposium on arthroscopy of the TMJ was guided by Drs. Kaminishi and Davis and sponsored by the Southern California Society of Oral and Maxillofacial Surgeons. This started the movement toward academic research and clinical investigations. Notably Dr. Ohnishi provided a demonstration of his puncture technique at this symposium, where many of the pioneers of this group began to prepare themselves for the 1986 meeting of the First Annual Symposium on Arthroscopy of the Temporomandibular Joint led by Dr. McCain, hosted in New York, and sponsored by the Hospital for Joint Diseases. It was at this subsequent meeting that the International Study Group (ISG) for the Advancement of Temporomandibular Joint Arthroscopy was formed. This pioneering group provided many of the national and international liaisons for future collaborations and collective dissemination of information, as well as expertise at the didactic and hands-on cadaveric symposium to follow.

An explosion of papers and presentations on multiple techniques, equipment development, and clinical studies ensued. Partly in an effort to curtail the potential for similar untoward sequelae as has been experienced in the field of open TMJ surgery in the past, the ISG worked together for the development of standards in credentialing, technique workshops, and recording of clinical results and provided clarification criteria for insurance coverage. As a result of much of this work the AAOMS formed an ad hoc committee and issued an official statement regarding TMJ arthroscopy, going on in 1988 to form an adjunctive insurance task force.

Important research over the early years contributed to knowledge showing that although disk position may be indicative of pathologic history, its lack of mobility more closely correlated to pathologic presence.²⁵ Also, the chronicity of the patient's TMD history seemed to lend itself to the development of articular remodeling in the absence of pain and limitation of motion in the postoperative phases.²⁶ Studies aimed at the identification of chemicophysiological markers and mediators were done through joint fluid analysis. It was found that arthroscopic surgery was successful even in Wilkes stage III and stage IV diseases. Recently more work has been done on diskal reshaping procedures as well as arthroscopic functional diskectomy through superior-anterior capsular release combined with physical therapy for joint space enlargement.

Technique enhancements still on the horizon include early intervention with injectable joint lubricants like sodium hyaluronate (HA) following initial arthrocentesis or even the use of modified HA as an operating medium or for use as an intra-articular bandage.

Even though arthroscopic surgery is not the panacea for TMJ surgical care, it has proven itself as one of the basic techniques to be mastered by modern oral and maxillofacial surgeons in their complete management armamentarium.

Patient Selection and Evaluation

Although many patients present with pain in and around the TMJ, relatively few are selected for surgery. At the centers working with the Pacific Clinical Research Foundation, manned by teams of dentists, psychologists, physical therapists, and ancillary medical managers, only 10 patients in 400 evaluated actually have intracapsular joint derangements or pathology amenable to invasive procedures.

I have found arthroscopic management to be successful in 8 out of those 10 patients, with only 2 out of the original

400 requiring open surgery. A key to successful outcomes in any surgical care is careful patient selection and perioperative team management.

While patients certainly present with pain originating outside of the joint itself (such as atypical facial pain and neuralgias and some pains related to systemic diseases such as rheumatoid arthritis), for the purposes of this chapter we will limit our discussions to those with intracapsular etiology.

In general one has to screen the patient for the basic premise of pain origin. Is it from within the joint or from the muscles? As always there are etiologic factors affecting both possibilities that need to be identified. The most valuable screening technique comes through a valid history and physical examination that can be fairly succinct.

History

First it is comforting to the patient to address their primary chief complaint. This is done even though it is often secondary to the interest of the surgeon who wants to discover how it originated and what secondary damage has occurred so that corrections can be planned for the patient's condition and to prevent recurrence. This is done by asking the patient to identify the location, onset, and frequency of the pain, in addition to asking what the aggravating factors are and the maneuvers used to relieve the pain. Notice how the patient responds when answering the location question, whether they use a finger pointed to the joint as opposed to a flat hand palm placed on the face. The pointed location tends to lend credibility to capsular-intracapsular joint problems. The character and history of the progression of the joint noise is also helpful, paying close attention to how clicks proceeded to catching and locking, or crepitus. Also ask about the nonsymptomatic side since frequently there may be a history of the same sequence indicating the possibility of

more advanced degenerative disease on that side, which will be evidenced on the radiograph and through the range of mandibular motion examination.

Patients often report pain in the shoulders and neck, headaches, earaches, and feelings of fullness in the ears or dulled hearing. It is important to inquire as to the patient's generalized physical or emotional status regarding recent pregnancy, childbirth, or menopause as well as their condition socially with jobs or family. This frequently adds significant overlay and insight to associated etiology and treatment management.

Positive answers to pointed questions regarding the history of recent or childhood trauma, habits of bruxism or clenching, and medications used, such as those initiating dyskinesia, should be explored. Also, one should inquire into past gnathologic treatments such as prior orthodontic care for closure of open bites, retrognathic treatment with class II elastics or positioners, extensive crown-and-bridge prosthetics, and equilibration for balancing contact occlusal interferences.

Physical Examination

The examination can likewise be fairly concise and takes a close second to the history in importance. The generalized physical examination can follow the focused joint and facial structure examination in order to let the patient know that their chief complaint has been heard, thus giving them more confidence and trust. Clinicians examine the location of pain, skeletofacial form, and the TMJ first followed by the nerve function, muscles, and dentition/occlusion. Initially noting the form of the skeletofacial structures, look for open bites, retrognathism (with or without deep bites), asymmetries of the jaw and facial bones, and pseudobites where the habitual position of the mandible is off of the skeletal position. Careful checking of capsular tenderness as well as palpating and auscultating for

joint sounds, such as reciprocal clicks, pops, catching, and crepitus, all lend valuable information. Be certain to load the affected and nonaffected sides in occlusion to ascertain the effect on the pain as well.

Next generally check sensory nerve function and muscle response to cognitive motor stimulus. The muscle examination naturally follows with observations being made for hypertrophy, asymmetry, and tenderness to palpation. Frequently with longstanding symptoms a cascading of protective muscle splinting will lead to neck and shoulder symptoms. The ears and eyes are checked with notations for later specialist referrals if abnormalities are found or complaints are elicited.

Finally the teeth and occlusion are examined, looking for masked asymmetric skeletal characteristics secondary to orthodontic treatments applied during growth, pseudobite secondary to class II elastics, wear facets and balancing interferences, supraerupted teeth, or loss of posterior support. It is at this point that the mandibular range of motion is measured and observed, and deviations, limitations, or hypermobilities are noted.

Presurgical Diagnostics and Therapeutics

Following the history and physical examination and screening panoramic examination, clinicians usually initiate presurgical conservative therapy. The use of a presurgical orthotic appliance designed to deprogram the habitual occlusion and skeletal positions, as well as provide relief to the muscular splinting and resultant myositis, cannot be overemphasized. This not only assists physical therapists in their assessment and therapeutic care but also provides the surgeon with valuable information as to whether true skeletal asymmetries or open bites are preexisting, which may have been masked by neuromuscular programming through prior clinical care. Usually this is accomplished

with a maxillary splint built with cuspid guidance in order to prevent the dental movement and opening of the interdental spaces produced with clenching or bruxism. If an open bite exists, which would require a mandibular splint due to the undesirable excessive bulk of acrylic on a maxillary splint, the splint should also be designed for lateral disclusion using the bicuspid instead of the cuspid teeth.

The use of the orthotic splint appliance, combined with physical therapy and nonsteroidal anti-inflammatory drugs (NSAIDs), should allow most experienced physical therapists and surgeons to determine whether an intracapsular pathology will be responsive to nonsurgical therapy within a matter of 6 to 8 weeks.

Occasionally the decision is made for therapeutic muscular trigger-point injections or intracapsular superior joint compartment diagnostic blocks of diluted local anesthetic solution in order to segregate pain etiologic foci before proceeding to either arthrocentesis or combined arthroscopic surgery.

Imaging

Traditionally the panoramic view is the first revealing image of the TMJ. Current concepts of management have been expanded through visualization of axially corrected sagittal tomography based on the submental vertex view with the alignment of the x-ray beam along the medial-lateral pole axis of each of the condyles, taken in the open mouth and closed occlusion positions. This is augmented by the coronal views in the protruded occlusion position with the incisors placed edge to edge in order to visualize the medial, lateral, and superior condylar anatomy in relation to the superior condyle's proximity along the functional area of the eminentia. These views can reveal osteophytes, erosions, and remodeling impingements that would otherwise be undetected from other bone imaging techniques.

For the shape, position, mobility, and intrinsic structural integrity of the disk itself, magnetic resonance imaging (MRI) has proven to be extremely reliable.²⁷ Whereas studies have shown that history and clinical examination are reliable for predicting similar MRI diagnosis for anterior disk displacements without reduction, and arthroscopic examinations have been shown to be statistically reliable for disk displacements as well, additional information of disk immobility with normal disk position and diskal structure and integrity loss with myxomatous changes can be ascertained by MRI, proving its overall value and reliability for additional soft tissue information compared with other techniques such as arthrography.^{28,29}

For patients with conditions that are suspect for partial bony ankylosis, which occurs with the advanced disease process associated with repetitive surgery or with a fibrous ankylosis, a computerized axial tomography scan will sometimes provide the best possible information. Whether one chooses to proceed with arthroscopy on basic imaging techniques and the history and physical examination alone or to add more sophisticated imaging to the presurgical diagnostic package is a decision to be made by each clinician who is involved with the individual patient.

Indications and Contraindications

Indications

Early meetings of the International Study Group for the Advancement of TMJ Arthroscopy were convened to formulate international consensus on the various indications and contraindications for TMJ arthroscopy. Resolutions were forwarded for acceptance to the AAOMS, which finalized the position paper on TMJ arthroscopy in 1988.³⁰ This paper separated indications for diagnostic and operative arthroscopy with generalized

examples given of patients in whom disorders were found that were not explained by other means and for which a diagnostic confirmation would affect the patient's care and outcome. It also included indications for diagnostic arthroscopy in order to enhance treatment decisions. Examples include the following:

- Biopsy of suspected lesions or disease
- Confirmation of other diagnostic findings that could warrant surgical intervention
- Unexplained persistent TMJ pain that is nonresponsive to medical therapy

The indications for surgical arthroscopy are matched carefully with the diagnosis before application. Helpful criteria of disease staging should be applied through the combined use of the Wilkes staging classification for internal joint derangement (Table 49-1), which was based on clinical, radiologic, and anatomic divisions, and the Bronstein and Merrill arthroscopic staging of internal joint derangements (Table 49-2) correlated at the time of arthroscopic surgery. Intraoperatively, internal joint surface procedures are applied individually to the significant finding.

Internal joint derangement (IJD) is known to be a preoperative indication for surgical arthroscopy. The AAOMS position paper defines IJD as a disruption of the internal aspects of the TMJ with either diskal displacements or alterations in the normal dynamic motions of the intracapsular elements. This would include adhesions or impingements in the face of even normal disk position. The paper goes on to describe surgical arthroscopy as indicated for joint conditions that constitute a disability for the patient and which are refractory to medical treatments and require structural modification.³⁰

Whereas internal derangements associated with hypomobility due to adhesions, disk immobility, and disk displace-

Table 49-1 Wilkes Staging Classification for Internal Derangement of the Temporomandibular Joint

I. Early Stage
A. Clinical: no significant mechanical symptoms other than early opening reciprocal clicking; no pain or limitation of motion
B. Radiologic: slight forward displacement; good anatomic contour of the disk; negative tomograms
C. Anatomic/pathologic: excellent anatomic form; slight anterior displacement; passive incoordination demonstrable
II. Early/Intermediate Stage
A. Clinical: one or more episodes of pain; beginning major mechanical problems consisting of mid- to late-opening loud clicking, transient catching, and locking
B. Radiologic: slight forward displacement; beginning disk deformity of slight thickening of posterior edge; negative tomograms
C. Anatomic/pathologic: anterior disk displacement; early anatomic disk deformity; good central articulating area
III. Intermediate Stage
A. Clinical: multiple episodes of pain; major mechanical symptoms consisting of locking (intermittent or fully closed), restriction of motion, and difficulty with function
B. Radiologic: anterior disk displacement with significant deformity/prolapse of disk (increased thickening of posterior edge); negative tomograms
C. Anatomic/pathologic: marked anatomic disk deformity with anterior displacement; no hard tissue changes
IV. Intermediate/Late Stage
A. Clinical: slight increase in severity over intermediate stage
B. Radiologic: increase in severity over intermediate stage; positive tomograms showing early to moderate degenerative changes—flattening of eminence; deformed condylar head; sclerosis
C. Anatomic/pathologic: increase in severity over intermediate stage; hard tissue degenerative remodeling of both bearing surfaces (osteophytosis); multiple adhesions in anterior and posterior recesses; no perforation of disk or attachments
V. Late Stage
A. Clinical: crepitus; scraping, grating, grinding symptoms; episodic or continuous pain; chronic restriction of motion; difficulty with function
B. Radiologic: disk or attachment perforation; filling defects; gross anatomic deformity of disk and hard tissues; positive tomograms with essentially degenerative arthritic changes
C. Anatomic/pathologic: gross degenerative changes of disk and hard tissues; perforation of posterior attachment; multiple adhesions; osteophytosis; flattening of condyle and eminence; subcortical cystic formation

Adapted from Bronstein SL and Thomas M.⁷⁹

ments with blockade are likely candidates for structural modifications, those joints with recent trauma, degenerative disease, synovial disease, and even hypermobility are included in the conditions indicated for arthroscopic surgical intervention.

Contraindications

Even though there are relatively few absolute contraindications to joint arthroscopy, it is generally recognized that underlying medical instabilities, overlying skin infections, and risks associated with

Table 49-2 Bronstein and Merrill Arthroscopic Staging of Internal Joint Derangements Correlated with the Wilkes Staging

I. Early Stage	Roofing, 80% (closed position) to 100% (open or protrusive positions); incipient bilaminar zone elongation; normal disk flexure at junction of diskal eminence and superior lamina; normal synovium; incipient loss of articular surface smoothness; normal superior compartment recesses and vascularity
II. Early/Intermediate	Roofing, 50% (closed) to 100% (open or protrusive); bilaminar elongation with decreased flexure; early adhesive synovitis with beginning adhesion formation; slight lateroanterior capsular prolapse
III. Intermediate	Advanced bilaminar elongation with accordion-shaped redundancy and loss of flexure; prominent synovitis; diminished lateral recess; advanced adhesion formation; anterior pseudowall formation in substage B Substage A: Roofing, 5% (closed) to < 15% (open or protrusive); chondromalacia grades I–II (softening, blistering, or furrowing) Substage B: No roofing, more severe anterior recess changes; chondromalacia grades II–III (blistering, furrowing, ulceration, fraying, fibrillation, surface rupture)
IV. Intermediate/Late	Increase over intermediate stage disease; hyalinization of posterior attachment; chondromalacia grades III–IV (ulceration, fraying, furrowing, fibrillation, surface rupture, cratering, bone exposure)
V. Late Stage	Prominent fibrillations on articular surfaces; perforation; retrodiskal hyalinization; false-capsule formation anteriorly; generalized adhesions; advanced synovitis; chondromalacia grade IV (cratering, bone exposure)

malignant tumor seeding represent relative contraindications.³¹

Arthroscopic Instrumentation and Anesthesia Consideration

Surgeons performing arthroscopic surgery should be familiar with not only the surgical technique but the supportive electronics and operating room set-up as well. As a guide for the surgeon a recommended schematic of room set-up is shown in Figure 49-1.

Video Monitoring Equipment

Even though the interior surfaces of the joint can be visualized directly via the eyepiece, most arthroscopists prefer to use video electronic enhancement and documentation equipment. A video monitor

and recording device are placed at the head of the patient, easily orienting everyone in attendance to the 12:00 (twelve o'clock) position of the joint with the video camera attached to the arthroscopic eyepiece. A video monitoring cart (Figure 49-2) contains the monitor, light source, and recording units with the cumbersome cords draped on the contralateral side of the patient's head to the surgeon's position. The clear imaging of the joint allows all people involved with the case to clearly participate with interest. This has the additional benefit of allowing them to better anticipate the progress and needs of the surgeon.

Irrigation System

A constant flow of irrigation fluid is essential to providing a clear view of the

joint surfaces through the distention of the potential joint space, as well as for washing blood and debris away from the lens objective. The inflow is attached to the arthroscopic cannula, and an outflow needle is placed elsewhere in the joint space. The diameter of the outflow portal should be of a lesser size than the inflow portal, which allows a slight pressure differential in order to maintain sufficient joint distention.

For routine arthroscopic procedures a 1½ inch 18-gauge short-beveled needle is ideal. If laser débridement is anticipated a second arthroscopic cannula with a stopcock and rubber obturator should be placed so that the outflow volume can be adjusted to the higher flows of irrigation fluid required for the prevention of excessive thermal synovial damage that is possible from the heat generated by the laser photovaporization. Additional benefits of the irrigation include those associated with the therapeutic effects of lavage and arthrocentesis.³²

The components of a simplified approach to an irrigation system include several units of extension tubing with Luer-loc attachments, a 30 mL or 60 mL syringe, a three-way stopcock, the arthroscopic cannula, and a 1½ inch 18-gauge short-beveled needle. For most cases the drainage may be collected in a small basin with the end of the exit tubing taped to the basin's edge, allowing the surgical technician visible evidence that the fluid pushed into the point is equal to that coming back out to prevent extravasation into the periarthicular tissues.

Alternatively for the higher volumes necessary in cases requiring laser-assisted techniques, a pneumatic-assisted compression unit may be used instead of the syringes to provide constant pressure on a 500 mL bag of irrigation solution. This provides a consistent joint distention as well as a cooling flow of solution across the joint surfaces. The outflow in these cases is usually voluminous and is collected in an

FIGURE 49-1 Position of surgical team and equipment for arthroscopic surgery. The surgeon and surgical assistant may change positions freely without disturbing the positions of the equipment or other persons helping.

orthopedic shoulder arthroscopy bag, which has a drainage portal at the apex.

Arthroscope

The manufacturers use four basic techniques for arthroscope construction. The early design, in 1966, of the rod-lens endoscope by H.H. Hopkins improved the traditional achromatic lens system, which made arthroscopic examination

FIGURE 49-2 Video monitoring cart.

practical by reducing the diameter of the instrument. By placing at least two different types of glass into the system, secondary advancements made color correction possible. This led to brighter images due to a reduced separation of spaces between the rod lenses when compared with the achromatic focusing lens system, and lessened the likelihood of breakage.⁵

A third advance came with the development of a unique type of glass with a nonuniform refractive index called the Selfoc lens. The characteristic of this gradient-index system is that curved surfaces are not required, and the spacing between the lenses could be eliminated using optional cements which allowed a thinner diameter with brighter images and an equivalent breakage resistance.³³ The glass structure itself provides the focusing power of the system (Figure 49-3).

In the fourth alternative, optical lenses are placed at either end of a fiberoptic

relay, focusing the image along the fiber relay, which transmits the image from the objective to the output ocular lens or eyepiece. These are primarily used in work requiring extreme flexibility such as vascular exploration. However, there are new disposable fiberscopes now available for needle access to the small joint.

No matter whether a rod lens or Selfoc lens is used in arthroscopic surgery, any bending of the lens sheath will produce a dark halo crescent and heralds possible lens damage or fracture.

Visual Fields and Angles

The angle of vision consists of the angle formed extending from the outermost margin of the objective lens to the subject viewed.

The field of vision consists of the three-dimensional circular area within those angles of the angle of vision.

The angle of inclination is commonly termed the direction of view, which can be altered by the lens construct itself. Usual angles of inclination are 10°, 30°, and 70°. Through the careful use of rotation of the angled arthroscope in an arc-like fashion, a wider field of vision can be produced (Figure 49-4).

Another valuable insight into the optical characteristics of the arthroscope is the fact that the field of view will be dimmed by magnification without providing increased resolution. Light transmission is critical in order to keep the image definition clear and is reduced by increasing the angle of inclination from 0° to 70° incrementally.

A good general rule to remember is that as the diameter of the scope decreases and the angle of the scope increases, the apparent field of view and brightness of the image decreases.

There are two ways to overcome these obstacles: (1) through the use of an integrated video arthroscopic system with zoom camera couplers, and (2) through the enhancement of light. Even though a quartz-halogen light may be sufficient for

FIGURE 49-3 A, Conventional endoscopic lens system showing the narrow angle of vision. B, Rod-lens system showing the wider angle of vision. C, Cross-sectional representation of endoscope.

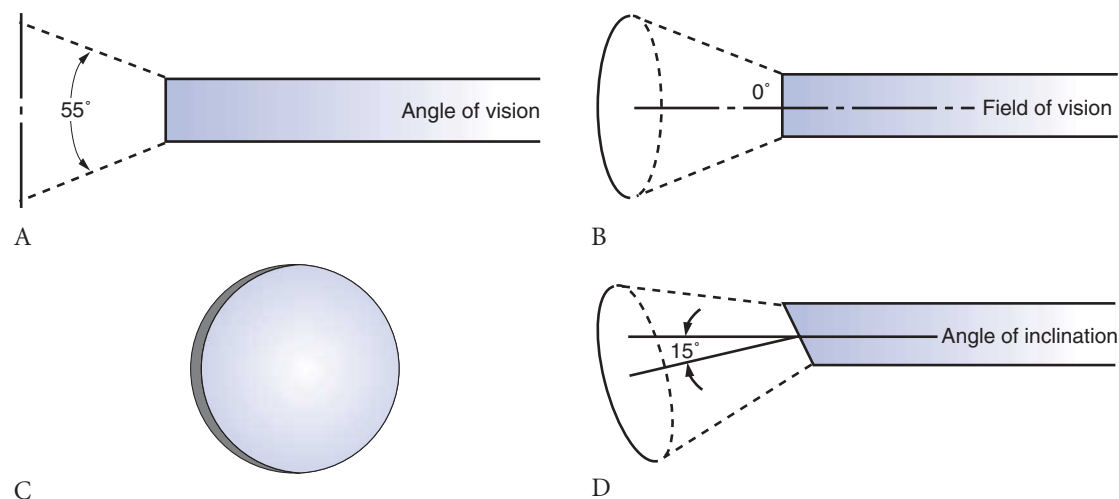

FIGURE 49-4 A, Angle of vision. B, Field of vision. The zero degree angle of inclination gives a straight-ahead view. C, Dark crescent at the edge of the field of vision caused by bending of the arthroscope. D, Angle of inclination (direction of view). Rotation of an arthroscope with an oblique angle of inclination around its axis increases the field of vision.

direct visualization in small joints, video work is greatly improved through the use of a xenon or mercury-xenon arc lamp light source.

The light transmission through the arthroscope is accomplished by the light fibers surrounding the lens system (see Figure 49-3) and is connected at the side of the arthroscope to a fiber light-cord coupler, which, in turn, attaches it to the light source. This light source is usually fitted with an automatic light level adjustment system connected to the camera's console for a feedback loop (Figure 49-5).

Instruments: Cannula, Trocars, Obturators, Elevators

The cannula is a sheath through which either the arthroscope or the instruments may be passed into the joint space repeatedly. A Luer-loc attachment together with stopcock valve is used for inflow where the cannula is housing the arthroscope and used for outflow when on a second cannula that is used for instrumentation access.

Excess outflow can be restricted by partly closing the valve and adding a rubber stopper with a small hole through which the instruments are passed during a triangulation procedure. These cannulae are passed into the joint space after intro-

ducing the sharp trocar into the cannula, which is used to puncture through the skin and joint capsule. The joint capsule is distended with irrigation solution during this maneuver from a needle injection (see section in this chapter "Functional Anatomy and Joint Entry Techniques"). The blunt obturator then replaces the sharp trocar within the cannula as further entry into the joint is accomplished, in order to avoid scuffing of the articular cartilage.

In the superior joint space, after visual confirmation of joint space access has been achieved, the blunt trocar can sometimes be incorrectly used as a release elevator. This can often lead to bending of the cannula and, with repetition, can lead to eventual breakage. It is recommended to use a hardened metal release elevator if further procedures are anticipated (Figure 49-6).

A series of dilation cannulae are also available for enlarging the diameter of the access tube in order to facilitate the use of graspers to remove debris or broken instruments.

Specialized Instruments

A variety of hand and motorized instrumentation is available to the arthroscopic surgeon. The most commonly used are the hooked probe, grasping and biopsy or cutting forceps, scissors, and retrograde (pull) knives. Again, sufficient cannulae diameters to incorporate the grasping forceps after it holds the object are critical in providing a safe and smooth retrieval of the object without having to remove the cannula along with the grasper. This avoids the risk of subcutaneous loss of the object on the way out of the joint space.

Lasers

The use of laser energy in arthroscopic surgery has fought a long battle for acceptance. The carbon dioxide laser proved ineffective for practical reasons relating to the joint insufflation with gasses.^{33,34} The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser was abandoned because it was shown to result in

FIGURE 49-5 Schematic of equipment hook-up sequence.

excessive depth of tissue damage.³⁵ However, the holmium:YAG (HO:YAG) laser seems to have won approval within the orthopedic community and has been shown to be effective for the TMJ reduction of synovial and vascular hyperplasias, as well as débridement of fibrous tissues.³⁶ It can be used for the release of the anterior capsule and, in the defocused mode, used for reduction of chondromalacia. Once again generalized synovial damage must be avoided through the use of copious irrigation during the use of laser energy within the joint compartment.

Anesthesia and Medication Considerations

TMJ arthroscopy can be performed in the outpatient or inpatient setting. When local anesthesia alone is used auriculotemporal and intracapsular anesthetic blocks are placed. This technique is usually reserved

FIGURE 49-6 Moses' release elevator, trocar, and switching stick.

for fine-needle diagnostic arthroscopy. Alternatively it can be performed combined with intravenous sedation for lysis of adhesions as well as eminentia release capsular stretch procedures.

Whereas most surgeons tend to segregate the general anesthesia requirements from the surgical, modern oral and maxillofacial surgeons naturally integrate the two for enhanced outcome. Initially led by requests for controlled hypotension required for beneficial effects during orthognathic surgery, considerations followed that were specific to the arthroscopic surgical arena.

Requests are made for the anesthesiologist to administer certain drugs at the onset of the intravenous (IV) access, as well as muscle relaxants, and even to perform deep extubations at the conclusion of surgery. Injection of methylprednisolone at 125 mg for adults and 40 mg for children is given in order to help stabilize the mast cell membranes to help to inhibit the release of histamines due to tissue injury and to reduce the postoperative edema. Even though postoperative infections are rare, a cephalosporin antibiotic is usually given as well for prophylaxis.

With the anesthesiologist located at the position indicated on Figure 49-1, clear access is given to the surgeons while still affording the anesthesiologist the patient's arm or hand for IV access as needed. Mus-

cle relaxants are given with sufficient length of duration for the entire case in order to allow the surgical assistant better ease of joint mobilization, yielding the surgeon sufficient space for instrumentation.

Even in cases of anticipated short duration it is helpful to explain the requirement for absolute muscular relaxation to the anesthesiologist ahead of time and to allow sufficient postsurgical time for the chemical reversal agents to work adequately for extubation. The surgeon can use this time to organize progress notes or findings and procedural dictation. Also for the more involved cases, a preemergence extubation can help to prevent the Valsalva response to the endotracheal tube and thus limit intra-articular bleeding and hematoma formation.³⁷

Biomechanics of Articular Pathology and Arthroscopic Management

The etiology of pain in the TMJ diagnosed with IJD is unclear. Certain surgical anatomy of the TMJ is important to understand as it relates to the biomechanics of the functioning joint in order to effectively treat the dysfunctional state of the patient.

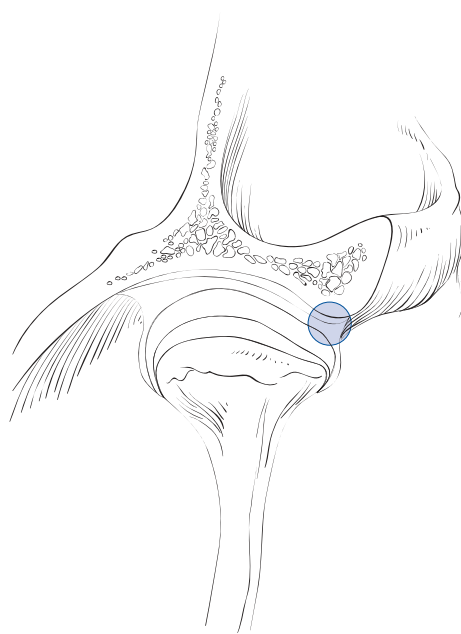

Clinical observations and findings of the synovial lining of the TMJ and correlation of findings of disk perforations, mobility, and blockade also significantly guide the arthroscopic surgeons in their management decisions.

There are many theories regarding TMJ dysfunction. However, the following question arises in almost every discussion: What are the causes of the pain, and why can one joint with disk displacement not hurt whereas another, perhaps with a less serious problem, severely tender?

Part of the answer involves the histochemical characteristics of pain mediators within the joint fluid, but the direct and indirect results of inflammation and resulting fibrosis on the capsule, associated tissues, and musculature also play a role in pain symptoms.³⁸

C

FIGURE 49-7 A, Arthroscopic photograph of endaural view of disk impingement under articular tubercle. Reproduced with permission from Moses JJ.⁴⁷ B, Drawing of location of the endaural view seen in A. C, Drawing of endaural photograph seen in A. B and C adapted from Moses JJ.⁴⁷

A review of studies of similar joint pain and restricted mobility in the shoulder with acromial impingement syndrome shows striking resemblances to observations made on the TMJ (Figure 49-7).³⁹⁻⁴⁵ Additional studies performed

on the basic biomechanics of the TMJ have shown that with jaw rotational mechanics, the linear velocity of rotation (V) will differ between the medial and lateral poles as a consequence of an orthopedic system with two joints func-

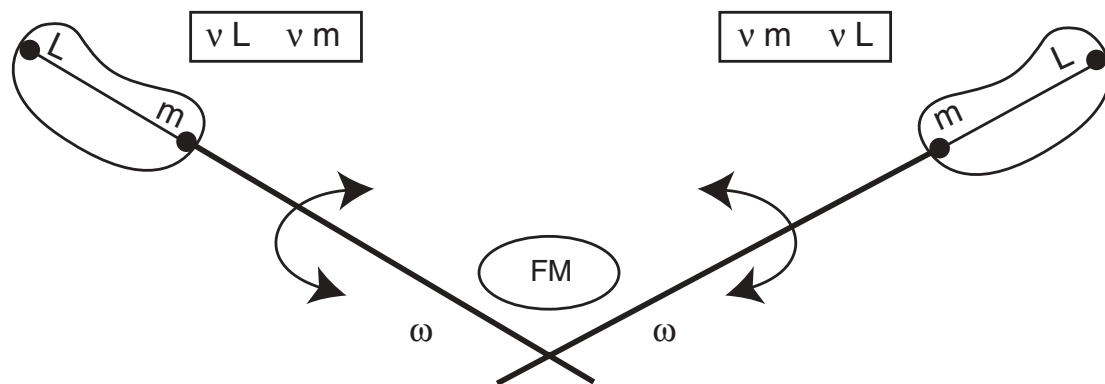

FIGURE 49-8 With jaw rotational mechanics, the linear velocity of rotation (v) will differ between the medial and lateral poles. Given a fixed measurable angular velocity of rotation (r), the velocity of point m (medial pole) will differ from point L (lateral pole). FM = rotational force movement.

tioning simultaneously (Figure 49-8).⁴⁶ An understanding of the force on the load-bearing surfaces with the structural inherent rotational and translational forces and their combined effects on rotational force, moments, torque, and shear, are essential in helping to understand the reasons that lateral condylar pole, eminent, and capsular pathologies are present in higher frequency than at the medial joint location.

This has led to the investigation of the lateral TMJ articulation by coronal MRI and by axial-corrected tomographic laminograms, both taken in the anteroposterior (AP) protruded jaw position performed on patients who had failed nonsurgical efforts to correct TMJ dysfunction and yet did not exhibit classic disk displacement.⁴⁷ These cases were further investigated by direct arthroscopic examinations from the AP view via endaural puncture access. It has become apparent that there is a process of pathology occurring which ranges from seemingly minor capsulitis with proliferative synovial changes to frank degenerative disease with disk/capsular impingements (see Figure 49-7).

Disk displacement actually may occur late in the pathophysiology of internal joint derangement (Table 49-3). Early inflammatory changes, initiated by macrotrauma or microtrauma, may lead to a loss of the lubricating nature of the HA and chondroitin sulfate within the synovial fluid. Capsulitis itself, with the synovium proliferating in an attempt to repair or regenerate damaged intracapsular structures, combines with inflammation and leads to the production of hyaluronidase, which breaks down the HA within the TMJ. A loss of lubrication ensues, leading to increased surface “stickiness,” resulting in capsular fibrosis and relative immobility of the TMJ, especially within the superior joint compartment, on attempted translatory movements of the mandible.

Table 49-3 Progressive Stages of Impingement Lesions

Stage	Diagnosis	Clinical Course	Treatment
I. Inflammation	Acute capsulitis and synovitis	Reversible	NSAIDs, rest, physical therapy, OSA, intracapsular irrigations, and lavage
II. Fibrosis	Chronic adhesive capsulitis, proliferative synovitis, diskal displacement or immobility, synovial plicae	Recurrent pain with activity	Arthroscopic lysis of adhesions, lateral eminencia release and capsular stretch, lavage, physical therapy, OSA
III. Bony remodeling and attachment migration	Diskal displacement or immobility, hyperplastic eminencia tubercle, degenerative joint disease	Progressive disability	Lateral eminencia release, capsular stretch, lateral eminencia osteoplasty, physical therapy, OSA

NSAIDs = nonsteroidal anti-inflammatory drugs; OSA = orthotic splint appliance.

If allowed to mature the adhesions may vascularize and become part of the restrictions (Figure 49-9). On attempted opening, lateral adhesive components can cause incoordination of disk/condyle/eminence dynamics. Strain is placed on the lateral disk attachments as the condyle is forced to begin translation from within the inferior joint compartment. The disk, while relatively immobile in its relationship to the articular eminence, may or may not be displaced at this time (Figure 49-10).

Over a period of time, translation, solely in the inferior joint compartment, may cause a gradually increasing laxity of the lateral disk attachment, allowing the anatomic migration of the disk antero-medially. The patient may also experience a “closed lock,” depending on the morphologic changes within the disk and its ability to form a mechanical obstruction (Figure 49-11).

As the disk slowly migrates forward and medially, movement within the superior joint compartment generally remains

minimal. The inferior joint compartment begins to act as the transitory compartment for the “wide-open” mouth position.

Anterior disk displacement traditionally has been diagnosed via arthrographic studies and now with MRI. A sagittal view may reveal a well-placed disk; however, the MRI coronal view allows diagnosis of medial or lateral disk displacement, as MRI correlative studies on more than 100 arthroscopic confirmations of disk displacement have shown that disks that appeared in normal anatomic position on sagittal views were actually rotated on their condyles with medial displacement (Figure 49-12).

Diagnosis of disk pathologies based on two-dimensional studies can be misleading. In some cases the posterior band almost becomes longitudinally placed anteroposteriorly along the lateral rim of the condyle. This may lead to a “bulging” out of the capsule on coronal MRI (Figure 49-13). In other cases images of a disk more medially displaced may have a “sucked-in” appearance of the lateral capsule on coronal MRI, which is termed lateral capsular prolapse (Figure 49-14). Lateral capsular prolapse may play a role in the development of the lateral impingement phenomenon.

As disk displacement progresses anteromedially the lateral attachment

FIGURE 49-9 A, Arthroscopic photograph of endaural view of articular eminence, demonstrating inflamed synovial proliferative tissue and early adhesions. FIGURE 49-10 A, Drawing depicting relative disk immobility after maturation and vascularization of adhesions: translation is forced to occur in the lower compartment. Arrows indicate the movement of the condyle under the immobile disk. B, Eventually there is laxity of the lateral disk attachments and increased translatory movements in the lower joint compartment. Arrow indicates the location of the lateral disk attachment, which is strained and possibly painful. Adapted from Moses JJ.⁴⁷

migrates forward as a result of the gradual and progressive pull of the condyle, which stretches it during attempted translation in the inferior joint space.^{46–48} The attachment carries with it the bone of the condylar lateral pole, developing the anterior beaking or “lipping” commonly seen in sagittal tomography (Figure 49-15). “Beaking” represents an adaptation of condylar remodeling to forces placed on it rather than a true osteophyte.

If the load is not redistributed, areas of perforation can occur, and further degenerative changes may develop along with adaptive remodeling of both hard and soft tissues (Figure 49-16).⁴⁹ The concept of load distribution is a fundamental biomechanical principle that is crucial to the understanding of joint structure and function. The entire physiologic function of the joint and its associated structures is load distribution, and damage occurs when factors inhibit this function. Dysfunction occurs when metaplasia and adaptive remodeling cannot repair this damage by restructuring load distribution.

A review of arthroscopic cases reveals that the majority of pathologic adhesions

and restricted motion lie within the lateral third of the joint. The soft tissues of the capsule become fibrotic and constricted, with inactivity and/or inflammation restricting mandibular movement. From the endaural arthroscopic approach, viewing anteriorly along the lateral trough of the superior compartment, inflamed synovial proliferation and projection are seen, as well as adhesions binding the disk to the eminence and capsule, leading to restricted mobility and possible pain (see Figure 49-9).

FIGURE 49-11 Disk migration (A) and changes in disk morphology (B) leading to “closed lock.” Superior compartment adhesions restrict translatory movements. Adapted from Moses JJ.⁴⁷

In the advanced stage, areas of lateral condylar resorption, best seen in AP tomograms (Figure 49-17), correlate with the hypertrophic articular tubercles that impinge on the lateral third of the disk (Figure 49-18A–C). If the joint space has diminished with degenerative changes, this becomes especially important as the condyle will articulate more heavily in the lateral area on protrusive and opening movements (Figure 18D and E). In my experience disk perforation occurs most frequently in the lateral posterior bilaminar zone/disk junction correlating with this lateral impingement.

Pain itself is not a disease. “Pain merely halts the function to allow healing. The gradual increase in function allows the programming of mesenchymal cell differentiation.”⁵⁰ The goals of treatment should include decreasing functional load and increasing the capacity of cells to accomplish articular remodeling.

Clinical studies using the lateral eminence release and capsular stretch procedures, combined with routine arthroscopic lysis of adhesions and lavage, have relieved both pain and restricted mandibular mobility in over 92% of patients (see Table 49-3).²⁷ Patients with lateral tubercle impingements on the disk seem to require additional eminoplasty, which gains joint space and

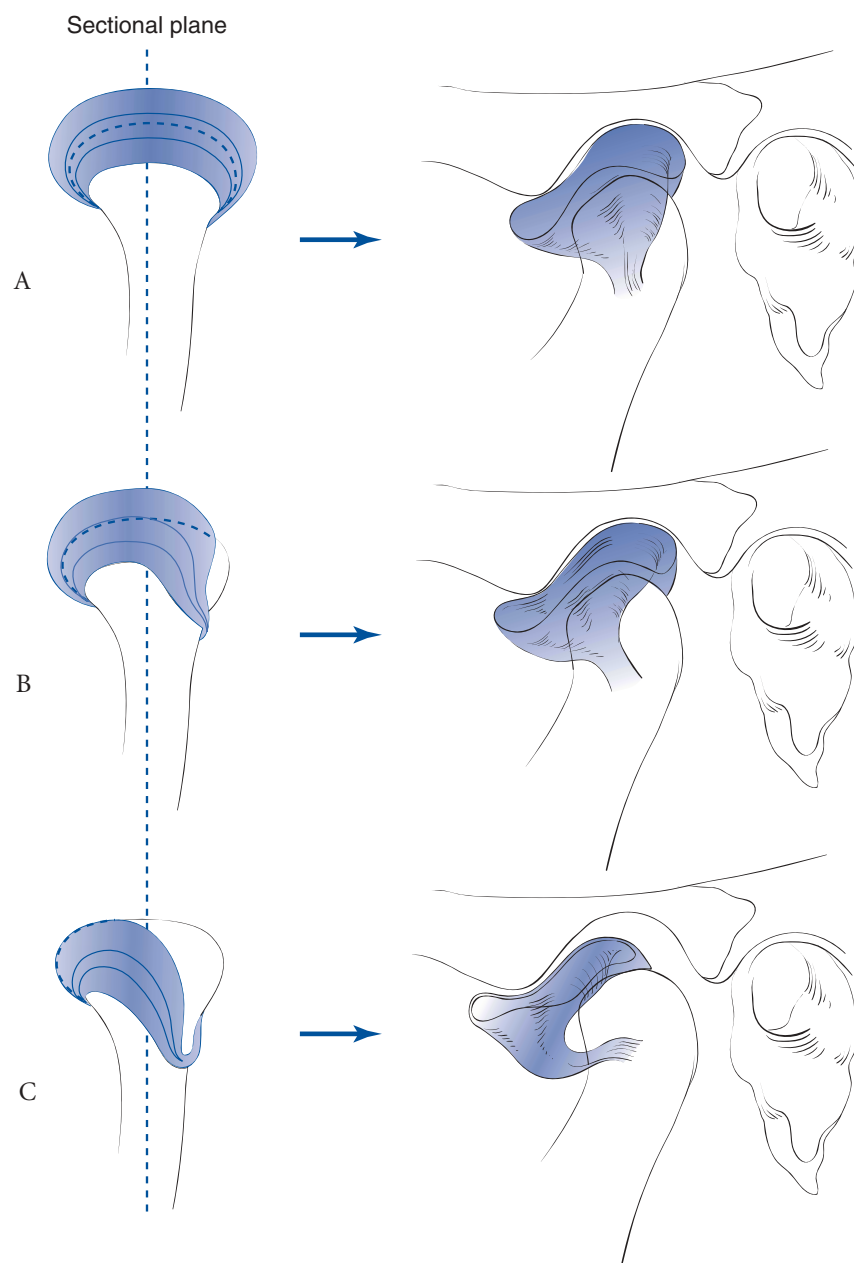

FIGURE 49-12 Disk that appears to be well placed on sagittal imaging (A) actually may be rotated on the condyle with medial displacement (B) and in time may suffer increased laxity of the lateral collateral disk attachments (C). Adapted from Moses JJ.⁴⁷

relieves load concentration from that area (Figure 49-19).⁵¹

MRI analysis study revealed a consistent result of no change in disk position in the closed-mouth status, both before and after arthroscopic surgery in 92 patients.⁵² The study revealed an increase in mobility of the disk following arthroscopic release that was directly correlated with the clinical success of

pain reduction and restoration of normal mandibular function.

The mobilization of tissues within and around the joint, combined with reduction of load concentrations, enhances mesenchymal cell reprogramming, allowing potential formation of pseudodisk articulations and condylar remodeling. Studies are in progress at the present time to investigate whether condylar remodel-

ing occurs long-term following arthroscopic procedures (Figure 49-20).

In a study using standardized tomography, Moses in 1994 showed that disk and capsule mobilizations have effectively restored function with pain reduction, while correlation to chronicity seems to dictate whether or not articular remodeling occurs.²⁶

In certain cases, when the chronicity of the displacement has led to anterior disk displacement, the morphology of the disk can “ball” up and effect a blockade to condylar anterior movements. This phenomenon is termed *obstructive disk blockade*. The traditional approach to this condition’s management is either through open or closed surgical attempts to reshape and reposition the disk or complete disk extirpation.^{53–55}

An arthroscopic surgical alternative is that consisting of an anterior capsular release performed with either the HO:YAG laser or pull-knife assistance under arthroscopic guidance via triangulation portal access. Care is taken not to violate the pterygoid muscle during this procedure, keeping the dissection on top of this structure. This procedure, termed *anterior capsular release*, allows the opening of the anterior joint compartment for functional remodeling to occur during the postoperative rehabilitation enlarging the space for the disk to move.⁵⁶

Functional Anatomy and Joint Entry Techniques

Over the past 15 years arthroscopy of the TMJ region has gained popularity as both a diagnostic tool and as a therapeutic mode for procedures involving IJD and intracapsular dysfunctional pathology. Although this popularity gave rise to many proposed procedures and techniques, which give the surgeon many choices on which to base their treatments, the fundamentals all remain the same. As the skill of surgeons advances, desired access for visibility and instrumentation has led to the increased use of angled view and alternate entry portals combined with triangulation techniques.

General Principles

In any arthroscopic surgical procedure involving small joints it is important to adhere to some basic technical points:

1. The joint should remain fully distended, allowing easier trocar puncture
2. The skin should be punctured with a sharp trocar.
3. All intra-articular procedures should be done with care to prevent articular surface damage.
4. Attention should be given to preserve as much healthy synovium as possible in order to enhance its physiologic effects on the joint.
5. The joint space should be kept expanded during instrumentation by a slow infusion irrigation system.

Puncture Anatomy and Landmarks

The anatomic landmarks relevant for open joint surgery also apply for arthroscopic surgery.

The frontal branch of the facial nerve appears to be the most likely nerve structure to be involved. Whereas Greene and

colleagues reported a mean distance of 22.5 mm from this branch as it crossed the zygomatic arch to the posterior aspect of the tragus with a range of 16 to 29 mm, Al Kayat and Bramley reported the mean distance of 20 mm from its crossing measured to the anterior margin of the bony auditory meatus with a range of 8 to 35 mm.^{57,58}

The tympanic plate was found by Greene and colleagues to be 7 mm anterior to the posterior tragus (range 6 to 9 mm) and perpendicular to the skin at a mean depth of 25.4 mm (range 19 to 32 mm).⁵⁷

Finally, even though the mean distance of the superficial temporal vessels from the posterior aspect of the tragus has been measured at 12.8 mm, there is some variance and this structure occasionally can be vulnerable to puncture lacerations.⁵⁷

There have been reports of cases of arteriovenous fistulas developing as a result of puncture through these structures, requiring subsequent vessel ligations.⁵⁹

An important point to remember during the puncture procedure is the visualization of the directional axis of the trocar angle, which should be anterior

and superior just above the “finger-palpated” lip of the glenoid fossa and not perpendicular or posteriorly directed in order to avoid middle ear or vessel damage. A frequently overlooked situation leading to a loss of perceived direction is improper head positioning. The head should be turned away from the operator and as flat to the operating table as possible.

Several authors have advocated marking the skin with points measured at 10 mm, 15 mm, and 20 mm along the line drawn from the posterior aspect of the midtragus to the lateral canthus. These positions can be helpful for orientation early in the learning curve for the arthroscopist. After time, however, the size and weight of the patient as well as their age can lead to variations of this.⁶⁰ Experience has shown the initial palpation with the mandibular mobilization by the surgical assistant to be more relevant and valuable than measurements alone.

The surgeon can often palpate the pulse of the superficial temporal vessels and the posterior aspect of the condyle while putting the fingernail side of the surgeon's digit along the inferior lip of the glenoid fossa with the mandible distracted downward and forward by the assistant.

Arthroscopic Approaches

The initial puncture of the TMJ is done with a needle and irrigation solution and is administered for joint distention of the potential space of the superior joint compartment. A detailed description of the initial joint puncture and the superior posterolateral and endaural approaches will follow this overview of the various approaches to the joint compartments (Figure 49-21).

Because many of our radiology imaging procedures cannot accurately visualize early lateral capsular synovial proliferation (see Figure 49-9), capsular herniations (Figure 49-22), or diskal impingements (see Figure 49-7), various approaches to capsular access become important to the arthroscopic surgeon in correctly diagnos-

FIGURE 49-21 Arthroscopic approaches to the temporomandibular joint. Adapted from Moses JJ.⁴⁷

ing intra-articular pathologies for the application of treatment modalities.

Superior Posterolateral Approach

In this technique the mandible is distracted downward and forward, producing a triangular depression in the front of the tragus.⁶¹ This depression represents an area bordered superiorly by the glenoid fossa, anteroinferiorly by the dorsal aspect of the condylar head, and posteriorly by the external auditory canal. It is at the roof of this depression, above the gloved fingernail of the surgeon's digit outlining the inferior aspect of the glenoid fossa, that the trocar is inserted. The trocar is directed anterosuperiorly toward the posterior slope of the eminentia. This provides access to the posterosuperior joint space and allows visualization of the superior joint space. The areas that are difficult to visualize are the superoanterior synovial pouch and the medial paradiskal synovial groove.

Inferior Posterolateral Approach

This is a variation of the inferolateral approach, in that the trocar is directed against the lateral posterior surface of the mandibular head.⁶² The inferoposterior synovial pouch and posterior condylar surface can then be examined.

FIGURE 49-22 Capsular herniations noted in the medial wall of a right temporomandibular joint. Reproduced with permission from Moses JJ.⁴⁷

Superior Anterolateral Approach

In this technique the trocar is directed superiorly, posteriorly, and medially along the inferior slope of the articular eminence after first locating the prominence of the lateral articular tubercle as a landmark. The mandibular condyle is distracted inferiorly and positioned posteriorly by the surgical assistant. This approach allows anterosuperior joint compartment instrumentation or visualization.

Inferior Anterolateral Approach

This is a technically more difficult approach than those described above and allows observation of the lower anterior synovial pouch. In this technique the condylar head and articular tubercle are palpated.⁶² The trocar is then inserted at a point anterior to the lateral pole of the condylar head and immediately below the articular tubercle. This places the trocar in the lower anterior synovial pouch, adjacent to the anterior aspect of the condylar head. The technique allows observation of the lower anterior synovial pouch.

Endaural Approach

This access is initiated by a trocar entering the posterosuperior joint space from a point 1 to 1.5 cm medial to the lateral edge of the tragus through the anterior wall of the external auditory meatus. The trocar is directed in an anterosuperior and slightly medial direction toward the posterior slope of the eminentia. This approach provides access and visualization of the posterior superior joint space as well as the medial and lateral paradiskal troughs. Its detailed technique will be covered in this chapter under “Endaural Arthroscopic Approach: Rationale/Technique.”

Joint Distention and Trocar Puncture Technique

The arthroscopic surgical procedures are typically carried out with the patient under general anesthesia via nasal endo-

tracheal intubation and complete neuromuscular relaxation throughout the procedure (Figure 49-23). A 1½ inch 20-gauge short-beveled needle is introduced into the posterior aspect of the superior joint compartment, testing the depth and direction for subsequent trocar/cannula placement. Iced heparinized lactated Ringer’s solution (2000 IU of heparin/L Ringer’s lactate) is administered via a syringe as a joint distension medium (Figure 49-24). To facilitate this maneuver the mandible is distracted downward and forward by the surgical assistant.

The mandibular condyle is then repositioned downward and backward, and a short-beveled 18-gauge outflow needle is attached to the catheter tubing and directed from an anterior lateral approach into the anterior aspect of the superior joint compartment (see Figure 49-24). By slow injection of iced heparinized Ringer’s lactate solution, irrigation of the superior joint compartment should be noted as fluid emerges from the outflow extension tubing. The 20-gauge needle is then removed.

Distention of the capsule is maintained by the slow infusion of the Ringer’s solution temporarily applied to the outflow portal 18-gauge needle prior to trocar puncture. This procedure allows a more distinct feel of the puncture into the joint, which should be done with a sharp trocar. Skin incisions are not required.

Superoposterior Lateral Approach

The sharp trocar is placed into the cannula and, with a fingerstop applied to the cannula grip to prevent inadvertent excessive puncture depth, the trocar is directed into the point above the palpating digit’s fingernail location at the inferior aspect of the glenoid fossa. It is aimed anterosuperiorly toward the posterior slope of the eminentia.

The sharp trocar is then replaced with the blunt obturator and further entry into the joint is executed. The syringe of Ringer’s solution is then removed from the

outflow tubing and connected to the irrigation tubing attached to the arthroscopic cannula stopcock. Bubbles are displaced from the cannula by flushing with irrigation fluid as the arthroscope is placed in the sheath. Examination of the superior joint compartment is then initiated, and systematic examination of the joint is performed prior to further instrumentation.

Lateral Eminentia Release and Capsular Stretch Procedures

Even though these procedures should technically be listed under surgical instrumentation, their importance is assigned not only to therapeutic management but also to the creation of soft tissue mobilization necessary for further joint exploration into the anterosuperior compartment by the endoscope.

Errors in Entry

Occasionally the arthroscopist will encounter difficulty in entry to the superior joint compartment. Most commonly this is due to insufficient joint distention by the irrigation solution. If severe fibrous strands are encountered in a joint not suspected of fibrous ankylosis, the inadvertent positioning of the scope cannula into the retrodiskal tissue is likely to be the cause. In this case removal of the scope from the cannula is recommended, and a repeat process of standardized puncture for superior posterolateral approach with the blunt

FIGURE 49-23 Example of hair taped on headwrap and endotracheal tube stabilizer pad. Reproduced with permission from Moses JJ.⁴⁷

FIGURE 49-24 Initial steps in endaural approach. A, Injection of heparinized Ringer's lactate to distend joint. B, Placement of outflow needle in anterolateral aspect of joint. C, Arthroscopic examination of joint via inferolateral approach. Reproduced with permission from Moses JJ.⁴⁷

probe is done. Only after confirmation of actual joint space access is visually achieved through the camera image can further instrumentation be initiated.

Endaural Arthroscopic Approach: Rationale/Technique

Certain limitations have become evident using the traditional posterolateral and anterolateral arthroscopic approaches to the TMJ. This is especially true for visualization of the lateral trough and anterolateral joint space or where access for instrumentation to the medial and lateral paradiskal grooves is required. Clear visualization of those areas is impeded using the currently available 15° angled scopes and lateral portals.⁶³

To solve these visualization and access problems the endaural entry portal provides clear visualization and enhances instrumentation to the medial and, especially, the lateral spaces (Figure 49-25). This new approach also provides better access for the retrieval of loose bodies and broken instruments. Working with the arthroscope in the endaural portals permits access to other portals for instrumentation.

In order to perform this technique a 30° angled arthroscope is recommended, which increases the panoramic visualization of the joint. The off-axis viewing angulation changes as the scope is rotated and permits a more comprehensive examination of the TMJ in areas difficult to examine with conventional 15° arthroscopes. In order to visualize the lateral capsule and attachment areas it is important to obtain

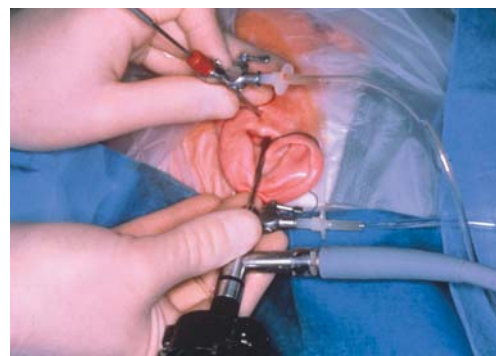

FIGURE 49-25 Clinical view of an arthroscope in the temporomandibular joint that has been placed through the endaural portal. The working portal is now located in the superior posterolateral location. Reproduced with permission from Moses JJ.⁴⁷

an arthroscope that has the visual axis oriented toward the light cord, preventing the impediment of having the light cord forced against the patient's temporal area. Because this is a deviation from the usual manufacturer's product it must be specifically requested during the ordering process.

For the surgeon inexperienced in this technique it is best initially to penetrate the superior joint space from the standard superior posterolateral approach. Once this has been accomplished the arthroscope is then rotated and angled superiorly, posteriorly, and laterally so that the light shines through the anterior wall of the external auditory canal (Figure 49-26). This spot is usually located approximately 1 to 1.5 cm medial to the lateral edge of the tragus in the external auditory canal (Figure 49-27). While the mandible is distracted downward and forward, the anterior wall of the external auditory canal is perforated with the sharp trocar and 30° arthroscopic cannula. The cannula and trocar are angled anterosuperiorly and slightly medially, perpendicular to the posterior slope of the articular eminence. Most important, these instruments enter into the joint above the level of the arthroscope in order to ensure superior compartment puncture (Figure 49-28). Penetration should be carried to a depth of no greater than 1.5 cm using the cannula

FIGURE 49-26 The arthroscope via the inferolateral portal is angled so that the light from the scope is transilluminated through the tragal cartilage, identifying the site for endaural puncture into the joint. Reproduced with permission from Moses JJ.⁴⁷

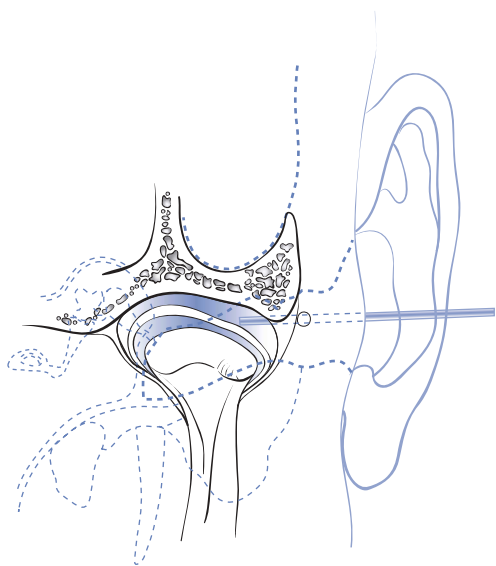

FIGURE 49-27 Diagram indicating approximate site of puncture for the endaural approach. Coronal section is positioned just anterior to the cartilaginous meatus and tragus. Adapted from Moses JJ.⁴⁷

markings as a guide. Visual confirmation of the penetration into the joint space can then be made using the arthroscope, which has been placed in the inferolateral portal. Additional confirmation that the endaural cannula tip lies within the superior joint space can be ascertained when removal of the trocar results in an outflow of irrigation fluid from the endaural cannula. The arthroscope, with the attached fiberoptic cable and inflow tubing, can then be removed from the inferolateral cannula and connected to the endaural cannula. The inferolateral cannula can then be sealed off with a rubber cap to prevent excessive outflow when the TMJ is being irrigated, and the cannula can be used as a working portal while visualization is accomplished via the endaural portal.

By rotating the arthroscope, the medial, lateral, and superior aspects of the TMJ can be examined. This approach is especially helpful in visualizing the anterolateral synovial space, which is difficult to do from either the superior posterolateral or anterolateral portal (Figure 49-29). This technique also allows the superior posterolateral or anterolateral portal to be

used for the instrumentation if necessary (see Figures 49-28 and 49-30).

As skill is acquired, direct puncture through the anterior wall of the external auditory canal into the TMJ can be performed after initial joint distention, without the need for superior posterolateral cannulation. Following the arthroscopic surgical procedure the lateral puncture site receives pressure and round bandage dressings. No sutures are necessary. The endaural puncture is difficult to dress and is left as is. Usually if there is minimal manipulation through this portal, the cartilaginous elastic memory of the canal serves to close the puncture site. A routine otoscopic examination is always made following arthroscopy to visualize the external acoustic meatus and tympanic membrane in order to confirm that no iatrogenic damage has been caused by the procedure.

Perioperative

Preoperative Management

In the preanesthesia holding room several preparatory functions usually help in man-

agement. First, the anesthesiologist assesses the interincisal opening of the patient to determine the extent of the physical blockage versus that of painful restriction. Then, the intravenous line for early administration of the corticosteroid, methylprednisolone, is initiated in order to prepare the patient's mast cell membrane stability which assists in prevention of excessive histamine release on surgical tissue insult. This steroid is followed by an intramuscular injection of 80 mg methylprednisolone acetate at the termination of the case.

Finally, the patient's hair is bundled into a pillowcase and the case is taped to the forehead and nape of the neck with the excess rolled into a "bun" on top of the forehead. This is used to help support the nasoendotracheal tube after intubation (see Figure 49-23). Paper tape is placed along the sideburn hair, holding it up and out of the field. Paper tape with benzoin is used in order to help prevent the "lifting" off of the tape when the surgical prep is applied.

Postoperative Management

Cloth adhesive strips or the ends of cloth bandages are applied to the skin punctures,

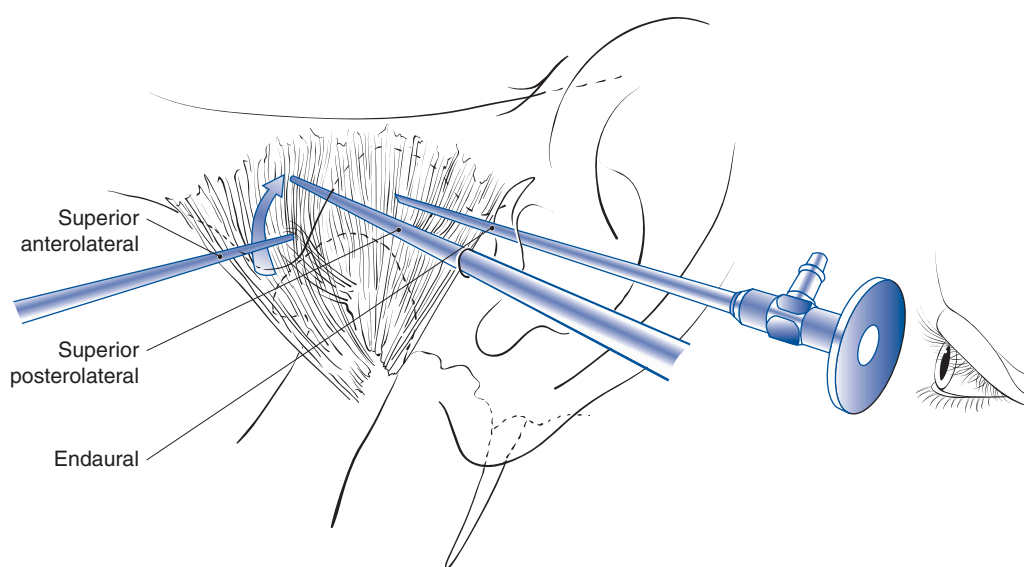

FIGURE 49-28 Diagram of puncture into the temporomandibular joint. The trocar and cannula are directed anterosuperiorly and medially, perpendicular to the posterior slope of the articular eminence and above the inferolateral cannula. The probes, located in either of the working portals, may now be used for the lateral eminence release and the capsular stretch (see arrow). Adapted from Moses JJ.⁴⁷

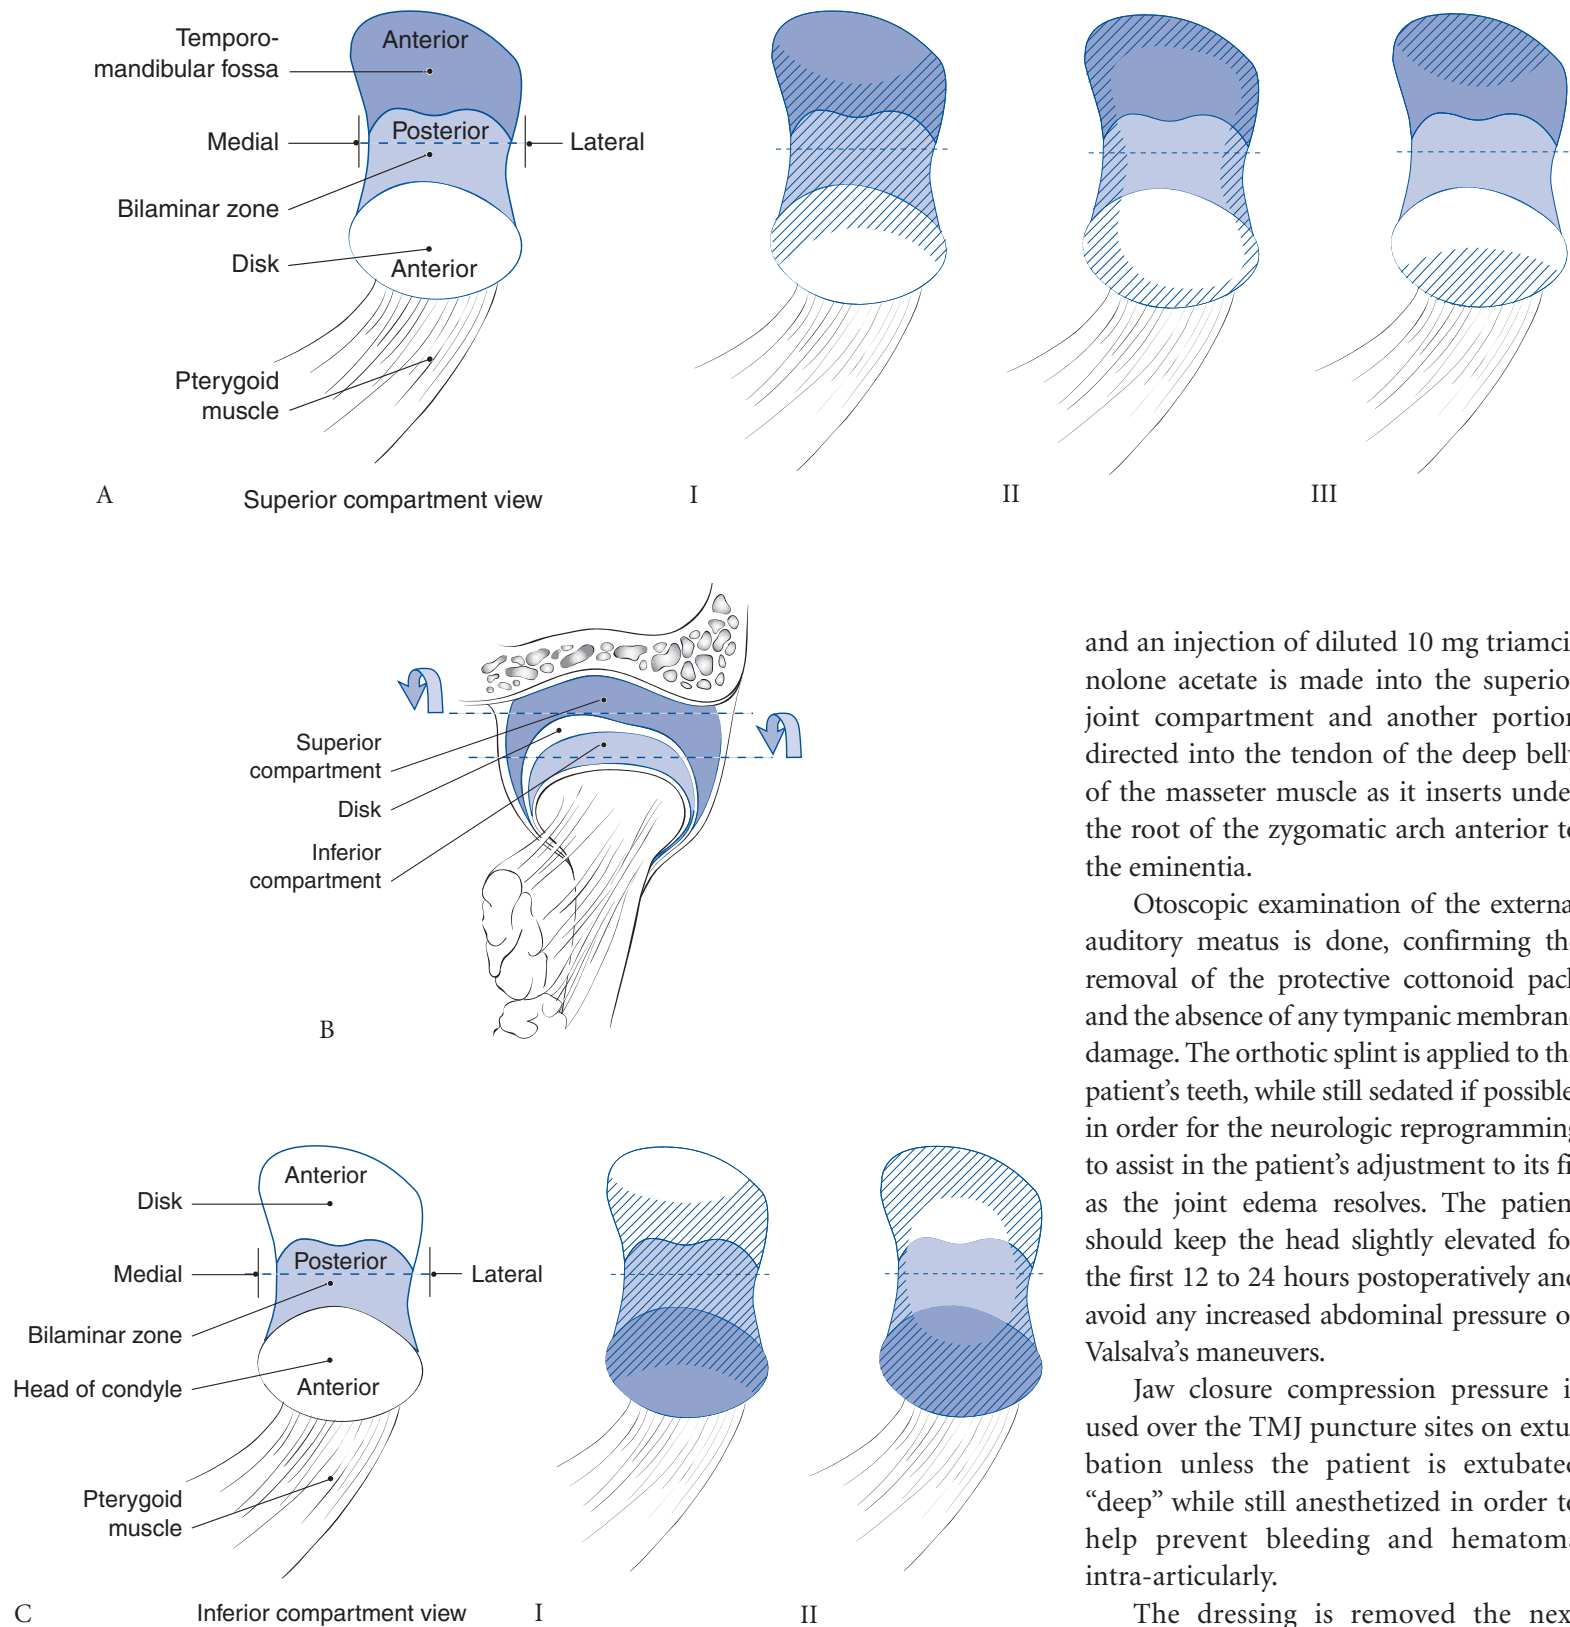

FIGURE 49-29 Visible fields with the various arthroscopic approaches: oriented to the left temporomandibular joint (TMJ) with the roof of the TMJ folded upward. Areas depicted with diagonal lines are difficult to observe arthroscopically. A, Superior compartment, orientation of the sectional planes: I is superior anterolateral area, II is superior posterolateral view, III is inferior anterolateral view. B, Superior and inferior compartment views. C, Inferior compartment, orientation of the sectional planes: I is inferior anterolateral view, II is inferior posterolateral view. Adapted from Moses JJ.⁴⁷

and an injection of diluted 10 mg triamcinolone acetate is made into the superior joint compartment and another portion directed into the tendon of the deep belly of the masseter muscle as it inserts under the root of the zygomatic arch anterior to the eminentia.

Otoscopic examination of the external auditory meatus is done, confirming the removal of the protective cottonoid pack and the absence of any tympanic membrane damage. The orthotic splint is applied to the patient's teeth, while still sedated if possible, in order for the neurologic reprogramming to assist in the patient's adjustment to its fit as the joint edema resolves. The patient should keep the head slightly elevated for the first 12 to 24 hours postoperatively and avoid any increased abdominal pressure or Valsalva's maneuvers.

Jaw closure compression pressure is used over the TMJ puncture sites on extubation unless the patient is extubated "deep" while still anesthetized in order to help prevent bleeding and hematoma intra-articularly.

The dressing is removed the next morning and the adhesive strips are removed. The skin punctures may be washed gently with soapy water and rinsed. They are then coated with a light coat of antibiotic ointment.

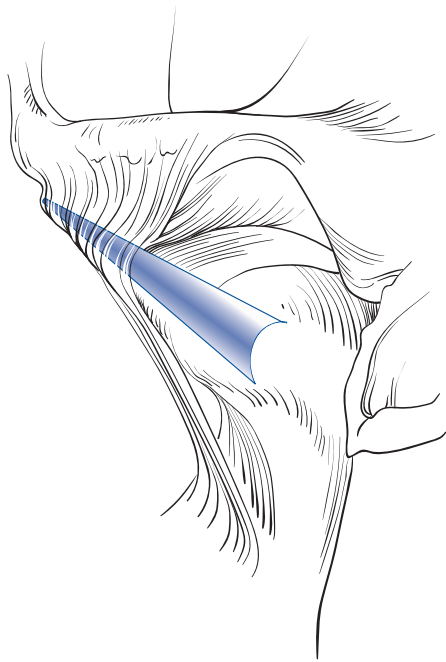

FIGURE 49-30 Diagram showing lateral eminence release. Adapted from Moses JJ.⁴⁷

Postoperative Medications

Routine NSAIDs are given for the postoperative month and muscle relaxants for the first week. Oral cephalosporin following the intraoperative IV bolus of 1 g cephalosporin antibiotics are routinely given for the first week as well. Cortisporin otic suspension eardrops are prescribed for the first 7 to 10 days with 2 drops in the ear canal of the affected side. Narcotic pain medications are rarely, if ever, indicated.

Physical Therapy

Preparatory physical therapy evaluation and management are imperative for a predictable outcome. The patterns for exercise and postoperative mobilization will be well understood and compliance established. Active exercises for the patient consist of opening the jaw, moving it to each side, and protruding the jaw, with each movement performed to the fullest extent ten times and repeated ten times daily for 10 days minimum (Rule of 10's). More important, however, is the passive joint mobilization applied to the patient by the physical therapist. The joint distraction

and mobilization, along with adjunctive therapies, will increase success rates dramatically. This therapy usually can be prescribed with visits three times a week for the first 3 weeks postoperatively, twice a week for the next 2 weeks, and once a week for the next month (Rule of 3-2-1).

Appliance Therapy

An occlusal splint should have been applied postoperatively to deprogram the muscles from periodontal membrane neuromuscular feedback. Occasional skeletofacial deformities of asymmetry or mandibular hypoplasia may be thus revealed, especially in cases where orthodontic elastics have been used during growth and pseudobites have developed.

Sometimes the splint used preoperatively for myositis reduction and other dental attempts for TMJ management may not be applicable for postoperative use following the release of intra-articular pathology. This is explained to the referring clinician as well as the patient, and the new orthotic splint appliance is placed on the patient's teeth on emergence from anesthesia.

The routine use of the splint is dictated by the presence or absence of skeletofacial deformity, muscular symptoms, and the inability to wean off of the device without symptoms. At first the splint is worn full-time (day and night), noting that is especially needed during meals, explaining its similarity to a crutch after knee surgery. If the patient requires orthodontics in preparation for orthognathic surgery, it is usually recommended to maintain the splint on the maxilla while the opposing arch is aligned and leveled and then switch over if necessary to the other arch.

If there is no further concern for either myositis/bruxism control or skeletofacial deformity stabilization, then weaning of the splint from full-time use is indicated. One splint usage routine (Rule of 4's) proven effective is for the patient to wear the splint full-time, including during meals, for 1 month postoperatively until symptoms

and range of motion are normalized. Then weaning takes place over the next 5 months, allowing the patient to reduce wear each month by any selected 4 hours of their choosing, with the exception being the times worn during sleep. This routine yields the final fifth month of wear for nocturnal use only. Many patients wish to maintain the use of the splint at night and a decision can be made at the 6-month postoperative visit, whether this is indicated.

Complications

One might expect there to be a large increase in the complication rate for TMJ arthroscopy when compared with the orthopedic experiences due to the close proximity of many anatomic structures in the head and neck region and their relative complexity of function. At first glance the multicenter retrospective study in 1987 of 2,225 cases showed a global complication rate significantly larger than that reported in a prospective study from orthopedic literature for knees.⁶⁴⁻⁶⁶ The differences in these studies, however, must be measured by the severe limitations of a retrospective design and reliance on surgeon's recall.

One significant conclusion to the multicenter study was that the majority of the complications were perioperative in nature and resolved relatively quickly postoperatively without long-term sequelae. With the learning curve of arthroscopic advancements behind us in this area, the various individual reports of usual and unusual complications have led to a better understanding of prophylactic measures that assist the current surgeon.⁶⁷

Extravasation

Whether or not a mechanical pump or hand-operated syringe is used, extravasation is a continual risk for arthroscopic procedures. Complications include pharyngeal embarrassment of airway requiring overnight hospitalization, periorbital and temporal edema, and transient cranial nerve V and VII effects.⁶⁸ Techniques of

constant inflow-outflow volume monitoring during the procedure with the outflow tubing lifted by taping the end to the edge of a basin help reduce the likelihood of extravasation. Limiting the number of punctures laterally and preventing unnecessary medial capsular wall punctures will keep extravasation down as well.

Procedures should be kept to a minimum duration, and if anterior release procedures are required, they should be done at the end of all the other procedures performed within the joint to help keep the hydraulic distention present and avoid early extravasation limiting operating time.

Neurologic Injury

Nerve injury comprises one of the largest categories of complication reported in the longer retrospective studies.^{64,65} By far the most common are those to the peripheral source of the sensory nerve V and its various branches. While the auriculotemporal branch is most frequently affected, it is commonly transient in its hypoesthesia and usually resolves within 6 months.⁶⁹ The other nerve that is at risk for damage is the inferior alveolar branch which, while usually only transiently affected by extravasation, can be iatrogenically damaged by mandibular angle clamps placed for jaw manipulation.^{70,71} Safer methods of manipulation have been described that use the assistant's hands and thumbs on the teeth for joint positioning or mobilization.⁷² The motor cranial nerve VII (temporozygomatic and masseteric branches) has been reported damaged in arthroscopic procedures, with reporting rates ranging from 0.56% to 4%. The damage typically resolved within 6 months according to reports reviewed.^{64,65,73,74} Management of injury to these motor branches is done postoperatively in a similar fashion to that occurring after open surgery, with artificial tears, eye patching, physical therapy, electrostimulation, and oculo-plastic consultation if needed.

Finally one must constantly be aware of the variation of anatomy present with-

in the TMJ. Rare cases of glenoid fossa defects can result in middle cranial fossae perforation, and more commonly giant cell erosion of bone from previous implant surgery can lead to increased risks of cerebrospinal fluid leakage as well.⁷⁵ Management includes identification, neurosurgical consultations, hospitalization, observation with elevated head and rest, and rarely application of subarachnoid drain placement. Fortunately in most cases the dura seals and the leak resolves.

Vascular

Intraoperative intra-articular hemorrhage as well as retrodiskal hemorrhages can occur with inadvertent medial wall puncture and anterior capsular release. This can sometimes be stopped by the mild hydraulic pressure produced by blocking the outflow portal and allowing inflow pressure to build. If this fails, removal of the instruments and firm compression of the joint, both by shutting the teeth together and lateral compression with gauze overlying the joint capsule, is warranted for a few minutes. Vasoconstrictors may be introduced into the joint space to assist this maneuver.

Another hemorrhagic complication of arthroscopy involves inadvertent puncture or laceration of the overlying vessels on entry. These may include, but are not limited to, superficial temporal artery/vein (A/V), transverse facial A/V, or even the masseteric artery. Very rarely will this event cause such vigorous bleeding as to require intraoperative ligation or subsequent management of an arteriovenous fistula, evidenced by later "whooshing" sounds overlying the joint preauricularly.^{59,65,76} Usually this event can be managed by the application of pressure with gauze overlying the vessel, with the patient's head turned to the opposite side and supported by the operating table headrest, thus allowing continuance of the surgery after homeostasis is achieved.

Intra-articular

The small size of the TMJ and the fact that any joint space is in fact only a potential joint space requires constant hydraulic and mechanical distention in order to negotiate instrumentation safely and without causing unnecessary joint surface scuffing and damage. Entry into the joint space through the capsule may be made with a sharp trocar initially, with the irrigation fluid distending the space, but a blunt trocar should then be used to explore the entry success in order to minimize the possibility of scuffing and damage. Additionally a lateral eminence release and a capsular stretch should be employed early in the procedure to allow easy movements of instruments from the posterior to the anterior recess in order to minimize surface damage and potential instrument breakage.

Instrument Breakage

Due to the minimally invasive nature of arthroscopy and size restraints on the mechanical instruments, metallurgic strengths are sometimes exceeded even with the most careful of techniques. Instrument manufacturers have been encouraged to produce "shear points" within their instruments which, on breakage, keep all of the metallic pieces together. These act as a "fuse" breaker, failing just before the functioning edge of their instrument breaks off into the joint space. Not all manufacturers use this principle, however, and the surgeon must be prepared to retrieve broken instrumentation parts from the joint space, either arthroscopically or via open arthrotomy, thus making it imperative to include this possibility on the operation consent form.

Arthroscopic retrieval can be performed through the use of dilation canulas, which gradually enlarge the access portal to a size sufficient for the grasper or magnetic retriever to hold the broken fragment and come back through the

sheath intact without becoming trapped. If restriction occurs and the sheath has to be removed with the fragment, then there is a strong possibility that the fragment may be lost into the soft tissue between the capsule and the skin. As in standard practice, instrument breakage should require incident reporting.

Otologic

One of the earlier complications of arthroscopic surgery reported was that of injury to the tympanic membrane and the middle ear ossicles and permanent hearing loss.^{73,77} In retrospect it is seen that the anatomic course of the auditory meatus is anterior and medial. This fact, combined with a patient's head position, in anything other than a near-horizontal ear-flat-to-the-table position portends an increased risk of trocar puncture from the posterolateral approach. One must keep constant vigilance to the direction of the entry trocar anteriorly and superomedially *combined* with an awareness of the positioned direction of the patient's head at the onset of surgery.

Other rare otologic events include laceration of the external auditory canal.^{64,65} Treatment usually involves observation, antibiotic drops, or occasional hemostatic control.

More minor events otologically include otitis externa and otitis media, as well as tympanic membrane perforation resulting from too vigorous canal preparation.⁷⁸ Otitis can occur spontaneously postsurgically or from an inadvertent contaminant such as cotton pieces left in the canal.⁷² It is therefore prudent for the surgeon to use an otoscope postoperatively to visualize and dry the canal prior to case conclusion, as well as to prescribe medication such as an antibiotic hydrocortisone suspension for eardrops postoperatively. Patients with nonresolving otologic issues or tympanic membrane damage are referred to an otolaryngology specialist for consultation.

Infection

The low overall infection rate of 1% following arthroscopic surgery of the TMJ follows that of the orthopedic literature.^{64,66} Even the relative contraindication of puncturing through overlying skin infection has had modifications to allow entry into suppurative arthritis with therapeutic benefit and no adverse postoperative dissemination of infection or cellulitis.^{65,75} Although infections are rare, the standard regimen at present for prophylaxis remains at a 1 g bolus of cephalosporin plus oral coverage of cephalosporin 500 mg every 6 hours for 5 days.^{27,68,70} Prophylactic antibiotic corticosteroid eardrops are used for 5 days as well.^{27,68}

Burns

Various procedures using electrocautery and laser have led to concerns regarding adequate protection of tissues to prevent adverse affects. The use of electrocautery within the joint for reduction of inflammatory or granulation tissue can rarely lead to inadvertent contact of the active electrode's end with the metal of the cannula. This can lead to accidental thermal injury.⁷⁹

Additionally, without copious amounts of irrigating solution to flush and cool the synovial lining of the joint, HO:YAG laser débridements can cause thermal damage to these important cells, inhibiting their natural physiologic function of phagocytosis and production of joint lubricants. Not only should the modern arthroscopist have mechanical hand-eye coordination but an awareness of physiologic collateral effects of surgery as well.

Subcutaneous Fat Atrophy

Subcutaneous fat atrophy has been reported both in the literature and in the community anecdotally.³² Triamcinolone is frequently used within the superior joint space postoperatively at the case conclusion and in subsequent visits for management of recurrent fibrosis or ankylosis. Its use in

both the reduction of deep masseter tendonitis by injection and in reduction of capsulitis by iontophoresis is also common. Even though subcutaneous fat atrophy is rare in occurrence, low concentrations and limiting administrations of triamcinolone can be helpful in limiting risk.

Anesthetic Complication

Manipulation of the jaw has been shown to have occasional effects on the carotid body and thus to result in unexpected bradycardia. If such an event is not reversed by relaxing the jaw position, atropine may be administered. Conversely occasionally epinephrine (1:200,000) is administered to assist in hemostasis during arthroscopic surgery *after* the initial examination is complete, so as not to mask the grading of the synovitis. This hemostatic vasoconstrictor may occasionally cause cardiac arrhythmias. Any persistent premature ventricular contractions or ventricular irritabilities may be treated with intravenous lidocaine if indicated.

Outcomes and Discussion

Over the past decade numerous researchers have shown the effectiveness of TMJ arthroscopy, both in the diagnosis and the surgical management of TMJ articulopathies.^{71,80-85}

Although numerous techniques have been developed for both open and arthroscopic surgical management, it would appear that the more complex the procedure applied, the more difficult the postoperative management is, with resulting diminishment of success rates. The overriding factors of similarity for all procedures seem to include the following:

1. Preoperative splint and physical therapy management
2. Release of capsular restrictions, either through incision or blunt obturator release and stretch
3. Release of intra-articular fibrosis and restrictions

4. Application of postoperative physical therapy joint mobilization

The disk position, with the exception of the severely shredded or morphologically obstructed disk, does not appear to affect the patient's outcome of comfort with jaw movements and clinical success.^{25,86} While techniques designed to alter the position of the disk, restrict hypermobility, and the like are certainly sometimes indicated, caution must be taken to rein in the enthusiasm for adding yet more complexity to a system that responds very well to simplicity and is adaptive in its articular remodeling and functional response. Even disks that are perforated and joints with Grades III and IV degeneration respond well to the arthroscopic approach.⁷⁵

Further advancements in arthroscopic techniques and treatment modalities are certainly arising and each advance is weighed with these risk-benefit ratios.

Surgery for Internal Derangements of the Temporomandibular Joint

Leslie B. Heffez, DMD, MS

The chapter on surgery for internal derangements of the temporomandibular joint (TMJ) written for the first edition, published in 1992, has stood the test of time. The surgical procedures described are still being performed today, which is indicative of their acceptance within the surgical community and perhaps of their success. The history of TMJ surgery has paralleled the rise and subsequent all but disappearance of the western cowboy. New surgical techniques that neglected to pay attention to the fundamental underlying symptoms and etiology have been heralded as panaceas, only to rapidly fade into obscurity, leaving a trail of iatrogenia. The new TMJ surgeon must be wary of this past. However, prudence should not lead to avoidance of surgery as a treatment modality.

According to Annandale, Sir Astley Cooper was the first to suspect the existence of altered condyle disk-fossa relations.¹ Later the term *internal derangement* was adopted to describe any pathologic entity that interfered with the smooth function of the TMJ. The term is currently used exclusively to describe alterations in disk-fossa relations. Historically, clinicians have recognized that surgery for internal derangements should be reserved for patients with

pain or dysfunction that is severe and disabling and is refractory to nonsurgical management. These conditions still form the basic indications for surgery. Open surgery of the TMJ for primary disease has undergone a complete metamorphosis as a result of the research and clinical results of surgical arthroscopy. At one time only a handful of surgeons professed the viability of function with a displaced disk and argued against surgical repositioning. Today the tables are reversed, and the majority of surgeons recognize that an internal derangement does not imply an ipso facto need for surgery. Furthermore, the presence of persistent symptoms in light of an internal derangement does not imply that surgical correction is necessary or imminent. Only if the mechanical obstruction is felt to be the primary etiology behind the symptoms is surgery indicated. This philosophy has resulted in a dramatic reduction in the number of open surgical procedures performed. This reduction has, in turn, resulted in dramatically fewer cases deemed to have an iatrogenic pathology; we continue to grapple with the 1980 to 1990 vestiges of such cases.

The chapter begins with sections on criteria for diagnosis and goals for surgical

intervention. A brief discussion of surgical anatomic considerations is followed by a description of the classic surgical approaches to the joint capsule and capsular incisions. A critical review of the history, indications, rationale for performance, and techniques of primary operations of the TMJ is then presented. Numerous references are made to those authors who have fueled the development of surgery for internal derangements. In my discussions I have used the term *posterior attachment* to describe tissue that is an extension of the retrodiskal tissue and inserts onto the posterior aspect of the disk. When the adjective *remodeled* is used to qualify an intra-articular structure, as in *remodeled posterior attachment*, the structure is considered pathologic.

Criteria for Diagnosis

Internal derangements are classically divided into two groups: reducing disk displacements and nonreducing disk displacements. Qualifying descriptors are sometimes included, such as the direction of displacement, degree of displacement, and presence of a perforation. Unfortunately, these large diagnostic rubrics fail to identify the finer stages of the disease

process. Disk morphology and severity of displacement are only gross indicators of the disease process. Although more complicated classifications such as the Wilkes classification exist, the treatments applied to the diagnostic categories have been diverse, rendering specific recommendations ill advised. It suffices to say that an astute clinician must be armed with that rare commodity of common sense rather than a rigid algorithm of treatment modalities. The research and clinical work emanating from arthroscopic trials will, in the future, establish more specific diagnostic criteria for establishing treatment protocols.

In the surgical decision-making process the specific diagnosis is only one piece of information necessary to make the decision to perform surgery. Surgery should be considered when the dysfunction or pain cannot be corrected to a level of patient satisfaction by nonsurgical modalities. Cookbook approaches to the diagnosis and surgical management of internal derangements should not be used. It is important to consider that no dysfunction is identical to another when the surgeon factors into the treatment equation the patient's perception of his or her problem, the effect on daily routine, and the patient psyche. The diagnosis of an internal derangement is achieved predominantly through clinical skills. Imaging of the joint usually is most useful only in the later planning stages of surgery, rather than during the establishment of a working diagnosis. There is the occasional instance in which a diagnostic dilemma exists and magnetic resonance imaging (MRI) is required to elucidate the case.

For the sake of discussion, the condition internal derangement can be identified in three different clinical settings. The first is the occurrence of a primarily functional disturbance. In this condition the chief complaint is functional. The patients may describe a need to perform a special maneuver with the mandible to achieve a wide opening, or they may describe an

annoying terminal jolting associated with closing. Joint pain is typically not chronic and appears to be related to the instability of the condyle-disk relations. Pain occurs with the sudden separation of joint surfaces during disk reduction or displacement. However, pain may not be a feature. Most of these cases demonstrate a reducing disk displacement, in which the disk represents a mobile mechanical obstacle and the condyle is not permanently restricted in its range of motion. Reduction refers to the ability of the condyle to negotiate around the disk. The disk's recoil potential is minimal in the pathologic condition. The inferior surface of the disk is typically bulged and histologically is the site of increased proteoglycan deposition. If pain and dysfunction persist despite treatment of a coexistent parafunctional habit, surgery should be considered. These patients are best managed with open surgery and reduction of the obstructing portions of the articular disk. Diskoplasty, partial discectomy, or full discectomy may be performed, depending on the degree of disk atrophy and deformation. Disk repositioning should be considered only when the disk is minimally deformed and of near-normal length. Clinical indicators for surgical intervention of this condition are rare. Some clinicians prefer to perform arthroscopic disk-stabilizing procedures using suturing or sclerosing techniques.

The second clinical setting in which internal derangements are identified is the condition of closed lock. *Closed lock* refers to an acute or chronic limitation of movement of the condyle owing to an intra-articular disturbance. Patients experiencing closed lock often complain of muscle dysfunction secondary to efforts to reach a baseline mouth opening.

The coexistence of muscle dysfunction and an internal derangement does not imply a relationship. A large segment of the general population have minimal signs and symptoms associated with internal derangements. Careful recording of the chief and

ancillary complaints is imperative, with attention being paid to the details of onset and duration of facial pain and joint noise, timing of symptoms of facial tightness, inability to open or close the mouth, and distribution of headaches. Concomitant sources of pain need to be identified and consultations with neurology, otolaryngology, psychology, or general dentistry, as required, obtained. The history of previous treatment is equally important.

There are usually a number of factors that are considered in the etiology of closed lock, including intracapsular and extracapsular inflammation and adhesions, muscle tension or spasm, disk displacement, synovial fluid viscosity, and reduction in synovial lubrication.

The closed lock phenomenon may resolve spontaneously or gradually over a period of weeks to months. Hence, it is important to evaluate the patient on several visits to effectively note a response to non-steroidal anti-inflammatory agents and muscle relaxants. In the absence of pain, many patients are able to tolerate the restriction in mouth opening, which gradually improves over several months to years.

MRI of the closed lock condition usually demonstrates a displaced disk, with various degrees of deformation. In some patients the disk appears in a normal position but is unable to be displaced down the slope of the eminence. Although not the subject of this chapter, it suffices to say that T1 and T2 (or gradient echo imaging) in sagittal planes is required to delineate intra-articular fluid, interstitial inflammation, and disk morphology. Magnetic resonance images demonstrate that the condyle is unable to displace the disk anterior enough to reach the apex of the eminence or beyond. On fast magnetic resonance or T2 images, inflammatory fluid or increased vascularity appears as a high signal intensity (Figure 50-1).

Adhesions associated with closed lock cannot be definitively identified on an MRI scan. They are suspected when there

FIGURE 50-1 A, T1-weighted sagittal magnetic resonance image demonstrating a dislocated disk. Note the low signal intensity, which represents a portion of the deformed disk (arrow). B, Fast imaging (GRASS [gradient recalled acquisition in steady state]) of the same section demonstrates the presence of extra-articular and intra-articular fluid or an increase in vascularity in the anterior regions of the joint. These changes may be partly responsible for the closed lock phenomenon.

is a confluence of the low signal intensities of the condyle and glenoid fossa without intervening intermediate signal intensity. Arthrocentesis followed by arthroscopic lysis of superior joint space adhesions, lavage, and manipulation are the treatments of choice for this condition. Open surgical procedures are indicated when arthroscopy has failed to resolve the restriction in opening. The choice of open procedure largely depends on disk anatomy and position.

The third clinical setting is the internal derangement condition of disk displacement that reduces on opening and is associated with persistent preauricular pain refractory to nonsurgical therapy. This is the most difficult of the three conditions to treat and requires long-term therapy with control of parafunctional habits. The clinician must ask whether the pain is occurring from hypermobility caused by contralateral hypomobility, acute or chronic separation of disk surfaces during displacement and reduction, noncompliance with diet restrictions, or persistent parafunctional or work-related habits. There are indications for surgical intervention; however, it is this condition that

carries the greatest peril of being rendered into the painful operated ankylosed joint after several fruitless surgeries.

Arthrocentesis has supplanted arthroscopic surgery as the most successful treatment modality. It should be attempted before performing any open surgical procedure. The type of open procedure is governed by the degree of disk morphology. The key to arthroscopy is to remove the source of the persistent inflammation including the vascular retrodiskal tissue and hyperplastic inflamed synovium.

Goals of Surgery

The general goals of any surgical intervention are to return the patient to a regular diet, with some limitations, and to establish an adequate functional range of motion. Each patient's complaints must be individually analyzed, and specific outcomes set for the operation. Postoperatively the surgeon should evaluate the patient's response to therapy according to whether the patient feels there has been a total eradication, significant reduction, or minimal reduction of his or her complaints, or no change or worsening of the condition. It is unreasonable for the surgeon to evaluate the results

of an operation on the basis of attainment of a finite mouth opening. Many patients are quite satisfied with reductions in their mouth opening as long as their facial pain is relieved. The goals for all surgical procedures should include preservation of articular tissue to permit normalization and regeneration of synovium, and a restoration of the articular relations to permit the joint structures to adapt and function through an adequate range of motion. The remodeled disk is only one element of the degenerative process. Joint function may be asymptomatic and satisfactory in the presence of various types of internal derangement. Thus, surgically returning a displaced disk to the ideal position found in a healthy joint may not be appropriate for an individual patient. To illustrate this point, one would not reposition a disk in a joint in which the articular tissue is so severely damaged that it is incapable of healing. In this situation removing the disk is recommended. Repositioning the disk is recommended in the patient with minimal changes in the joint structures, in whom symptoms have persisted despite nonsurgical and arthroscopic intervention. As indicated above, this condition is indeed rare.

Additional magnetic resonance and arthroscopic information about the structure and function of the joint in health and disease is needed to establish reliable indicators and predictors of surgical outcome.

Surgical Approaches

The classic surgical approaches to the TMJ may be classified as preauricular, endaural, and postauricular. The choice of approach is usually a matter of surgeon's preference and is based on his or her ability and experience. Cosmetic considerations may also influence the choice of approach.

Surgical Anatomic Considerations

Anterior to the auricle, the auricularis anterior and superior muscles overlie the

superficial temporalis fascia and the temporalis fascia. These muscles are incised in the classic preauricular and endaural approaches. The fascia superficial to the muscles is thin and a dull white. This layer is confluent with the galea aponeurotica above and the parotideomasseteric fascia below. The temporalis fascia is a tough fibrous connective tissue structure, substantially thicker than the overlying superficial fascia. It is stark white and extends from the superior temporal line of the temporal bone to the zygomatic arch. The deep surface furnishes one of the origins of the temporalis muscle. Inferiorly, at a variable distance, the fascia splits into two well-defined layers (Figure 50-2). The outer layer attaches to the

FIGURE 50-2 Coronal section at the level of the zygomatic arch. Two well-defined layers of temporalis fascia are noted (arrows).

lateral margin of the superior border of the zygomatic arch, and the inner layer to the medial margin. A small quantity of fat, the zygomatico-orbital branch of the temporal artery, and zygomaticotemporal branch of the maxillary nerve are located between the fascial layers. The splitting of the fascial layers is most noticeable at the level of the zygomatic arch. Posteriorly, superior to the glenoid fossa, the separation is not as well-defined (Figure 50-3).

The superficial temporal vessels are typically located in the superficial fascia below the auricularis anterior muscle. The vessels are often visible, invested in the superficial fascia without incising the muscle. The superficial temporal vein lies posterior to the artery and the auriculotemporal nerve immediately behind the vessels. The superficial temporal vessels and auriculotemporal nerve appear to take on a horizontal course once the flap is fully developed and reflected anteroinferiorly.²

Numerous authors have studied the facial nerve's anatomic relations to determine clinically applicable landmarks for its main trunk, temporofacial division, and temporal branches. Al-Kayat and Bramley noted that the facial nerve bifurcated into temporofacial and cervicofacial components within 2.3 cm (range 1.5–2.8 cm) inferior to the lowest concavity of the bony external auditory canal and within 3.0 cm (range 2.4–3.5 cm) in an inferoposterior direction from the postglenoid tubercle.³ The temporal nerve branches lie closest to the joint and are the most commonly injured branches during surgery. These nerves are located in a condensation of superficial fascia, temporalis fascia, and periosteum as they cross the zygomatic arch. The most posterior temporal branches lie anteriorly to the postglenoid tubercle. Their location was measured by Al-Kayat and Bramley as 3.5 ± 0.8 cm from the anterior margin of the bony external auditory canal (Figure 50-4).³

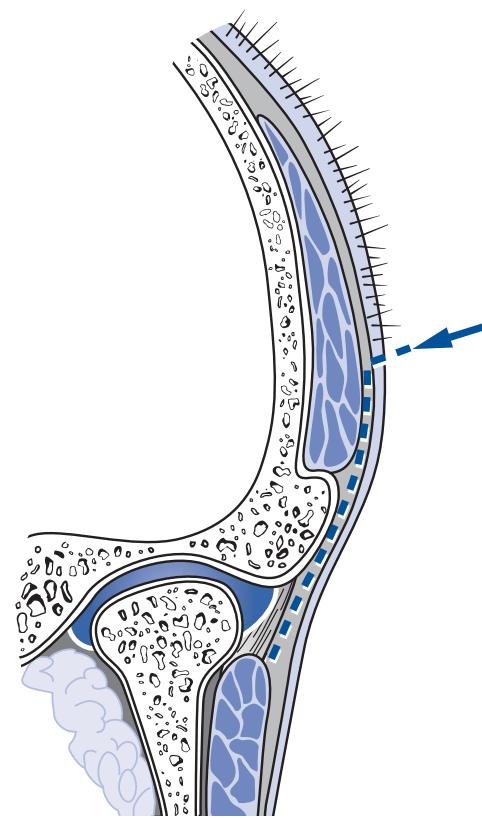

FIGURE 50-3 Coronal section at the level of the glenoid fossa. The splitting of the temporalis fascia is not as well-defined (broken line).

Thus, the two potential sources of facial nerve injury are dissection anterior to the posterior glenoid tubercle where the temporal branches cross the arch, and aggressive retraction at the inferior margin of the flap where the main trunk and temporofacial division are located.

Preauricular Approach

Historically, a myriad of preauricular incisions have been proposed. Many of the earlier designs afforded good access but increased the risk of facial nerve injury and compromised esthetics. The preauricular incisions used today are essentially modifications of the Blair curvilinear or inverted-L incision.⁴ This approach has become the favorite chosen by oral and maxillofacial surgeons. The technique is an incision commencing from within the temporal hairline and extending inferiorly
